NPDES: "National Pollutant Discharge Elimination System" the name of the surface water quality program authorized by Congress as part of the 1987 Clean Water Act. This is EPA's program to control the discharge of pollutants to waters of the United States (see 40 CFR 122.2).

O&M Expenditures: The operating and maintenance costs associated with the continual workings of a project.

Outfall: The point where wastewater or drainage discharges from a sewer pipe, ditch, or other conveyance to a receiving body of water.

Permitting Authority (PA): The NPDES-authorized state agency or EPA regional office that administers the NPDES Storm Water Program. PAs issue permits, provide compliance assistance, and inspect and enforce the program.

Physically interconnected MS4: This means that one MS4 is connected to a second MS4 in such a way that it allows for direct discharges into the second system.

Point Source Pollutant: Pollutants from a single, identifiable source such as a factory or refinery.

Pollutant Loading: The total quantity of pollutants in storm water runoff.

Qualifying local program: A local, State or Tribal municipal storm water management program that imposes, at a minimum, the relevant requirements of one or more of the minimum control measures includes in 122.34(b).

Regulated MS4: Any MS4 covered by the NPDES Storm Water Program (regulated small, medium, or large MS4s).

Retrofit: The modification of storm water management systems through the construction and/or enhancement of wet ponds, wetland plantings, or other BMPs designed to improve water quality

Runoff: Drainage or flood discharge that leaves an area as surface flow or as pipeline flow. Has reached a channel or pipeline by either surface or sub-surface routes.

Sanitary Sewer: A system of underground pipes that carries sanitary waste or process wastewater to a treatment plant.

Sediment: Soil, sand, and minerals washed from land into water, usually after rain. Sediment can destroy fish-nesting areas, clog animal habitats, and cloud waters so that sunlight does not reach aquatic plants.

Sheet flow: The portion of precipitation that moves initially as overland flow in very shallow depths before eventually reaching a stream channel.

Site Plan: A graphical representation of a layout of buildings and facilities on a parcel of land.

Site Runoff: Any drainage or flood discharge that is released from a specified area.

Small Municipal Separate Storm Sewer System (MS4): Any MS4 that is not regulated under Phase I of the NPDES Storm Water Program and Federally-owned MS4s.

Stakeholder: An entity that holds a special interest in an issue or program -- such as the storm water program -- since it is or may be affected by it.

Standard Industrial Classification (SIC) Code: A four digit number which is used to identify various types of industries.

Storm Drain: A slotted opening leading to an underground pipe or an open ditch for carrying surface runoff.

Storm Water: Precipitation that accumulates in natural and/or constructed storage and storm water systems during and immediately following a storm event.

Storm Water Management: Functions associated with planning, designing, constructing, maintaining, financing, and regulating the facilities (both constructed and natural) that collect, store, control, and/or convey storm water.

Storm Water Pollution Prevention Plan (SWPPP): A plan to describe a process whereby a facility thoroughly evaluates potential pollutant sources at a site and selects and implements appropriate measures designed to prevent or control the discharge of pollutants in storm water runoff.

Surface Water: Water that remains on the surface of the ground, including rivers, lakes, reservoirs, streams, wetlands, impoundments, seas, estuaries, etc.

Total Maximum Daily Load (TMDL): The maximum amount of pollutants which can released into a water body without adversely affecting the water quality.

Tool Box: A term to describe the activities and materials that EPA plans to perform/produce to facilitate implementation of the storm water program in an effective and cost-efficient manner. The eight components include: 1)fact sheets; 2) guidance documents; 3) menu of BMPs; 4) compliance assistance; 5) information clearing house; 6) training and outreach efforts; 7) technical research; and 8) support for demonstration projects.

Urbanized Area (UA): A Bureau of the Census determination of a central place (or places) and the adjacent densely settled surrounding territory that together have a minimum residential population of 50,000 people and a minimum average density of 1,000 people/square mile. This is a simplified definition of a UA, the full definition is very complex.

Urban Runoff: Storm water from urban areas, which tends to contain heavy concentrations of pollutants from urban activities.

Watershed: That geographical area which drains to a specified point on a water course, usually a confluence of streams or rivers (also known as drainage area, catchment, or river basin).

Wet Weather Flows: Water entering storm drains during rainstorms/wet weather events.

Building a Balance: Housing Affordability and Environmental Protection in the USA

Gregory L. Potter
Independent Scholar

Abstract

Current trends in household formation and housing development in the United States are creating pressures on communities to provide adequate infrastructure services for a growing population. Homeownership rates are the highest in history. All indications suggest this rate will continue to increase over the next few years. Builders and developers respond to this need by constructing housing units in suburban fringe and rural areas because of the availability of cheaper land and the lack of attractive sites in more urban areas. Environmental regulations are frequently cited as barriers to development and impediments to affordability. This paper reviews the literature of potential linkages between housing affordability and environmental protection and reports on a project in which focus groups were conducted with developers, environmental regulators, and others. Content analysis of focus group transcripts showed much agreement from various sides of the complicated and interconnected issues that are related to sustainable development.

Introduction

Since enactment of the first major environmental legislation in the United States in 1972, an increasing number of laws have been passed for the purpose of improving air and water quality and protecting biodiversity. Although Americans agree environmental protection is essential (Dunlap, 1992), there is considerable controversy over what constitutes an acceptable level of regulation and how the economic burden of environmental regulation should be distributed (Branconi, 1996).

With escalating levels of environmental regulation has come an increasing estrangement between environmental protection and business interests. An uneasy coexistence has evolved into a heated battle pitting the federal government, state governments, business, and the environmental community against each other in a contest over control and use of the nation's natural resources. The eventual outcome of this conflict will have a substantial affect on generations of future Americans as well as on the global community at large.

Perhaps nowhere has this controversy been more visible than in the building industry. Land use restrictions, impact fees, mitigation and other compliance costs, and delays precipitated by permitting procedures are given as the means by which environmental protection has stymied builders and adversely affected their livelihoods (Branconi, 1996). Housing researchers, as well, maintain that financial burdens imposed by environmental regulations have played a large part in driving the cost of new homes beyond what can be borne by most first-time buyers, thereby helping to create an affordability crisis (Olenik and Cheng, 1994; Meeks, 1992).

This paper reviews some perceptions about housing affordability, environmental protection, and the public's attitude toward the environment in hopes of contributing to the development of a new, more realistic perspective on what has become an increasingly muddled situation.

Homeownership Rates, Prices, and Affordability

A decline in homeownership during the 1980's, viewed against a backdrop of housing prices that had been steadily increasing since the early 1960's, has been interpreted by many housing analysts as an indication of a housing affordability "crisis." Due to the amount of attention given to this issue, a widespread perception has developed that a serious, generalized affordability problem was beleaguering the nation's housing markets. To many, the cause of this alleged affordability problem seemed clear: housing prices had finally risen to the point that many American households simply could not afford to purchase.

A review of the literature, however, indicates a division of opinion as to the merits of this conclusion. Some see the existence of a crisis in affordability as hinging on differing interpretations of home ownership trends. While many believe the decline in homeownership is an indication of an affordability problem, others view it as being more the result of changing demographics (Koebel and Zappettini, 1993).

While earlier generations tended to marry and begin families in their twenties, recent years have seen these events postponed or forsaken altogether. The number of single-parent families has risen sharply. Other less traditional types of households, such as those composed of non-relatives and individuals who simply choose to live alone, have also increased. These fundamental societal changes are seen as having had a profound effect on home ownership rates (Koebel and Zappettini, 1993).

This demographic view of lower home ownership rates is countered by other theories such as that of Linneman and Megbolugbe (1992) which seek to explain the phenomenon in economic terms. In defining the scope and causation of the so-called affordability crisis, these authors present three points that offer a very useful lens for examining this issue.

First, Linneman and Megbolugbe (1992) reject the notion that an affordability crisis has ever existed for affluent young households. The decline in home ownership within this segment of housing markets is attributed to demographic changes. Secondly, they admit that low-income households have experienced affordability problems, but these are seen as being due to income inadequacy, incomes too low to keep up with concurrent increases in housing prices (which are seen as having been caused mainly by a substantial increase in the quality of housing stock). Affordability for low-income families is a long-term problem, one which, although undoubtedly exacerbated by rising home prices and economic upheavals in the 1970's and 80's, was not caused by them.

Thirdly, Linneman and Megbolugbe (1992) identify the real focus of affordability concerns as being on the middle class, which in the 1970's began to confront decreasing housing affordability for the first time. Indeed, it seems to have only been when this group began experiencing problems that the notion of a crisis surfaced and the issue of affordability moved to the forefront in housing policy circles. This phenomenon attracted the attention of housing researchers (and the housing industry) because the middle class, unlike low-income households, was a group that had not previously experienced such problems (Linneman and Megbolugbe, 1992). This is seen as the crux of the affordability crisis.

Linneman and Megbolugbe's (1992) interpretation of the problem therefore, is that middle-class households in some parts of the country, those households having low levels of job skills and education, began to experience affordability problems not because of the mere fact that housing prices had risen, but because their incomes became stagnant or in many cases declined.

The degree of financial security such households had previously enjoyed was based largely on income from relatively well paying manufacturing jobs. This changed when the global economy took hold and manufacturing jobs in the United States went to developing countries, being largely replaced by lower-paying jobs in the service industry. Wage earners in affected households were not able to find jobs in the service industry paying wages comparable to those offered by the lost manufacturing jobs. The resulting income disparity precipitated the decline in home ownership (Linneman and Megbolugbe, 1992).

Yet another economic interpretation of falling home ownership rates is posited by Mayer and Englehardt (1996). While they admit the role of such factors as increasing real house prices, changing demographics, declining incomes, and rising interest rates result in the decline of home ownership, these authors contend that these factors alone cannot explain the phenomenon. Statistics showing an increased reliance by first-time homebuyers on financial gifts to make down payments, along with longer periods of time needed to accumulate down payments, are presented to show that, even when income may be adequate to make mortgage payments, down payments may present a substantial obstacle for many potential home buyers (Mayer and Englehardt, 1996).

Mayer and Englehardt (1996) do not emphasize the relationship between declining home ownership rates and the simple fact that homes were more expensive relative to the past. The focus here is on a specific demand-side problem: the difficulty in providing a down payment. This in turn is seen as due to the well-known propensity of Americans not to save money, as well as to restraints on saving represented by increasing credit card and other consumer debt.

As evidenced by even this truncated review of the literature, there is little agreement that the decline in home ownership experienced in the 1980's constituted a "crisis" or that is was due simply to house prices that had risen so sharply as to preclude purchase. The varying interpretations present in the literature, if merged, produce a more likely view in which changing lifestyles and tastes, along with income and related demand-side variables such as higher levels of consumer debt and low personal savings rates, controlled homeownership rates more than house price increases.

The widespread, lopsided perception that buyers were simply priced out of the market still exists in spite of evidence supporting a more complete and plausible explanation for decreased home ownership. Given this, solutions for bolstering ownership rates tended to focus on specific factors seen as contributing to escalating house prices, one of these factors being the cost of environmental protection.

House Price Increases and Environmental Protection

To the extent that house prices have increased, what role might environmental protection have played? Downs (1992) states outright that federal environmental regulations, specifically the Endangered Species Act and wetlands regulations, are not significant contributors to the increase in housing costs.

Branconi (1996) examines the escalation of house prices between 1963 and 1993 and determines that environmental regulations may have played a role in the increase. He feels that factors which should have positively affected housing affordability by moderating further price increases were offset, at least partially, by an increase in costs associated with environmental protection.

In rebuttal to Branconi (1996) Evans (1996) argues that there is no direct connection between increased environmental regulation and house price increases. In support of this thesis, he points out that during the first one-third of the period studied, environmental regulations affecting housing were all but nonexistent and yet house prices rose. Given this, the author concludes that the observed rise in prices cannot be explained by environmental protection costs. This argument is bolstered by the fact that the home ownership rate in the U.S. is currently at a record high of 66.8 percent (Seiders, 1998), and that this has occurred without a significant rollback in environmental regulations.

Evans (1996) also sees as significant the disparity between regional house price activity and environmental progressivity. This too, is believed to indicate that increasing environmental regulation and escalating house prices are largely unrelated. As an example, real house prices in the environmentally progressive Northeastern part of the United States dropped substantially between 1973 and 1983 in spite of the fact that a wide range of new environmental regulations were being implemented during the period. Conversely, in the South and West (excluding the West Coast), which are less environmentally progressive, real house prices rose during the same period. Evans (1996) believes the opposite result would be expected if the cost of environmental protection did exert substantial upward pressure on house prices.

While not denying the possibility that environmental regulations have contributed to house price increases over the last thirty years, Evans (1996) believes that the connection between implementation of environmental regulations and price increases, when compared to other forces at work, is minuscule at best.

Meyer (1998) makes the environmental protection/development controversy more specific by examining one of the most controversial federal environmental programs, the Endangered Species Act (ESA) and its affect on the building industry. Meyer (1998) analyzed economic impacts of (ESA) from two perspectives. First, he examined potential relationships between listings of the spotted owl in the Pacific Northwest of the United States and prices for lumber and single family homes. He then observed rates of growth in state real estate markets, after controlling for a number of variables, and compared this growth with increases in listings of protected species.

In the first part of his analysis, Meyer (1998) plotted Douglas Fir production against housing starts. The latter variable historically follows a cyclical pattern (REF), as was illustrated in this study for the period 1970-1995, when Douglas Fir production cycles matched those of housing starts. The author correctly concluded that while there may have been some impact of the spotted owl listing on Douglas Fir production, that impact is minuscule by comparison with the long-standing relationship between that production and housing starts. He went further in this stage of analysis and compared median prices of new homes with Douglas Fir prices. Again he presented convincing evidence that no relationship exists, and that home price increases are more likely related to size and amenity increases in new homes.

In the second stage of his analysis, Meyer (1998) regressed each state's growth in its real estate industry against appropriate industry indicators. After regressing numbers of listed endangered species against those same variables, he plotted the residuals from both sets of equations to demonstrate increased real estate activity with increases in endangered species listing. While this result may initially appear confusing, Meyer's (1998) conclusion is that in robust real estate markets, increased encroachment on wildlife habitats is expected but markets adjust and are not adversely affected. This is a key finding from this study--markets adjust.

Linneman and Megbolugbe (1992) consider that housing price increases have been due mainly to significant increases in the quality of housing stock. These authors also point to inflation in the 1970's and 1980's and the increasingly speculative nature of homeownership in response to inflation, as contributing factors. Koebel and Zappattini (1993) too, identify the increasing quality of houses and their amenity levels as a factor in price increases. Evans (1996) identifies a number of factors as being responsible for increased house prices including demand and demographics. Other contributing factors he cites are increases in house size and quality, rising interest rates, and general price inflation.

Seiders (1998), citing the results of a survey of builders, points to subdivision controls as being most responsible for unnecessarily increasing housing costs. Echoing this,

Downs (1992) identifies local zoning regulations as the greatest regulatory barrier to the development of less expensive housing.

An important factor which must underscore any debate on this issue is that systematic studies of relationships between environmental protection efforts and house prices are scant, and that it is extremely difficult to accurately quantify the effect of a given regulation or regulatory program on a specific housing development (Suchman, 1996a; Branconi, 1996; Engel, Stromberg, and Turner, 1996). In light of this uncertainty, it is puzzling how many individuals and organizations have been able to so confidently make the sweeping generalization that environmental regulations have had profoundly negative effects on housing affordability (Suchman, 1996b; Olenik, 1994). Clear, specific, and reliable scientific data supporting this conclusion simply do not exist.

Public Support for Environmental Protection

Substantial increases in the membership of environmental organizations over the last twenty years indicate a widespread concern for the environment. Results from a number of surveys show that the American public is overwhelmingly in favor of environmental protection (Dunlap, 1992). Such surveys indicate that many in fact, feel the government should be spending more on protecting the environment, and substantial numbers of survey respondents indicated a willingness to pay more for products and services that are produced and provided in more environmentally sensitive ways (Dunlap, 1992). Surprisingly large numbers of those surveyed voiced the opinion that they would be willing to see economic growth sacrificed to protect the environment, and that environmental improvements must be pursued regardless of the cost (Dunlap, 1992).

Dunlap (1992) interprets these data and others as strongly suggesting that public concern for the environment is more solid today than in 1970, that environmental protection has become a consensual issue with overwhelming public support, and that its only opposition comes from a small but vocal minority.

Analysis

To investigate issues related to housing development and environmental protection and to better understand perspectives of those directly involved with these issues, the focus group technique was chosen as a means of data collection. This is an appropriate method for obtaining qualitative and quantitative information about a complex topic and is useful for identifying specific areas for further research.

The use of focus groups has been defined as a style of interviewing small groups whose participants provide information about complex topics from a variety of perspectives (Berg, 1998). Moderators solicit opinions through a series of open-ended questions that encourage the expression of individual opinions and interaction among participants. Sessions are typically tape recorded, transcribed, and analyzed through research methods such as content analysis (Tesch, 1995). Findings can be useful for observing and identifying trends, patterns, themes and commonalities.

As a data-collection technique, the focus group has been utilized since the beginning of World War II, when the effectiveness of radio programs on troop morale was studied by military psychologists (Berg, 1998). While marketing researchers have long relied on the methodology since that time, widespread use of the technique by social scientists did not occur until the 1980s. In conjunction with qualitative analytical tools, focus groups have been used extensively over the past decade to investigate human perceptions of numerous issues (Shelton and Atiles, 1995).

Shelton and Atiles (1995) discussed issues related to findings from qualitative research and noted that these are significant to the extent that they are valid. Such validity is attained when there is agreement between a study's intentions and its outcomes. This is best achieved through unobtrusive data collection techniques and precautions against the introduction of a researcher's biases or preexisting theories.

To investigate various points of view on the numerous issues that affect housing affordability and environmental protection, two, two-hour focus groups were conducted in the Fall of 1997—one in Seattle, Washington to represent the West Coast, and one in Gainesville, Florida to represent the Southern half of the Eastern Seaboard. The focus group participants included developers, environmental regulators, affordable housing advocates, environmental advocates, Congressional staffers, students of construction management, and faculty in academic programs of construction management. The

R0010696

specific composition of each group is listed in Table 1.

Questions posed to each focus group elicited comments about the loss of species, housing affordability, equity, property rights, regulatory burdens, and other issues. In both groups conversations covered issues many participants had direct experiences with. For example, in Gainesville the university researcher discussed recent findings about the rate at which endangered species are predicted to be lost; the developer shared his experiences with environmental regulators and endangered species; and the environmental regulator talked about his frustrations with the process through which species become listed as endangered. A consensus that emerged in both sessions, however, was that this type of discussion, with various interests represented, was useful for gaining an understanding of alternative views on these issues.

TABLE 1. Composition of the Focus Groups

Seattle	Gainesville
Moderators (2)	Moderators (2)
Student	Student
Congressional Staffer	University Researcher
Builder/Developer	Community College Faculty
National Audubon Society Director	U.S. Fish & Wildlife Service Regulator
College Professor	Affordable Housing Center Director
	Developer
	Home Builders Association Director

Transcripts of the discussions were examined through content analysis software (Ethnograph). Key categories were coded which allowed for identification of passages in which common themes emerged. The key categories, frequencies of their being mentioned during the discussions, and rankings are presented in Table 2.

R0010697

Table 2. Frequencies and Rankings of Key Categories

Categories	Seattle	Gainesville
Affordability	10 (6)	18 (2)
Balance	29 (2)	8 (6)
Confusing Regulations	8 (7)	8 (6)
Education	6 (9)	11 (5)
Environmental	32 (1)	18 (2)
Equity	12 (4)	12 (4)
Excessive Regulations	6 (9)	20 (1)
Low Income	6 (9)	4 (8)
Needs	12 (4)	2 (10)
Property	7 (8)	5 (7)
Public	11 (5)	5 (7)
Research	0 (10)	5 (7)
Species	11 (5)	5 (7)
Sustainability	11 (5)	16 (3)
Wetlands	14 (3)	3 (9)

The frequencies in Table 2 refer to occurrence rates of concepts that can be categorized by the listed terms, whether the terms were explicitly stated or not. Numbers in parentheses indicate how many times the issue was mentioned during the focus group. Note that in the Seattle group, Environmental issues ranked first as the most frequently mentioned issue, while Excessive Regulations ranked first in the Gainesville group. Affordability tied for second place in the Gainesville group and ranked sixth in the Seattle group.

Following are selected quotes from the discussions that provide a sampling of perspectives on the issues covered. The first quote is from the Seattle group and was coded in the Balance Category:

> "... You have to build what the market wants. You have to be careful that you can do it under the government's rules and regulations. But ... the developer who resists the government tends to have more problems than the developer who does not. And the developer who resists and has more problems with the government increases his costs a fair amount because he is going to spend his time in court. ... I think you can make a living and still follow regulations. The important thing is to understand up-front what they are and plan accordingly."
>
> Managing partner of a large building firm.

An important point in the preceding quote is "understanding up-front." This theme emerged later in this session under the Equity Category:

> "...As a developer you ... analyze that piece of ground and make a decision and purchase based on the rules and regulations in place at the time. Wetlands rules came into play in the mid-80s, roughly. ... The rules and regulations on wetlands changed substantially, even from the time the wetlands rules went into place. Should those landowners be held accountable for a major change in rules and regulations to benefit the public in general--not benefit the developer?... The landowner is stuck with a social cost."
>
> Managing partner of a large building firm.

At several points in both sessions, equitable distribution of the social cost of species or wetlands protection was discussed. During the Gainesville discussion, an unintended consequence of the Endangered Species Act was mentioned:

> "Unfortunately, what I see happening is people using the federal endangered species act as a growth management issue, as a local land use issue. Instead of going to the local governments, going to the state government, going to the local communities, and saying, ... 'Do we care about this issue? And how can we plan with it? How can we get the quality of life issues or the sustainability issues or the economic issues integrated into land use for city use?' As opposed to what we see as the old model, or what people see as the old model--which is whatever goes. And there are some people who say , 'I can't really do anything I ... want to do to my property...' I think that is where planning comes into play."
>
> Federal environmental regulator.

Issues related to planning were brought up at many points in both focus groups and were coded in categories that included Environment, Need, Affordability, and others. Sprawl, transportation problems, and inner city decay, are mentioned in the following quote from the Gainesville group:

> "There is a limit to how far cities can grow out before the whole idea collapses. It is starting to reach a point where people are miserable. They drive an hour back and forth to work because they are pushed so far out that (the) inner circle starts collapsing. People start forming the second circle. Of course, the second circles have already started forming, so now they are forming this third circle. ... It can only go so far. I think it would be really great to start concentrating on and invigorating the interior of the cities. Because we have already established ourselves there. ... You would not be going on pristine land or virgin land."
>
> Student of construction management.

R0010699

The fact that affordability was not the most frequent category in either discussion suggests that focus group participants were more concerned with other aspects of environmental regulations, including Excessive and Confusing Regulations, Balance, Environmental issues, and Wetlands, among others. A surprising amount of agreement was seen in points made by the developers, environmental advocates, environmental regulators, and academics. Property rights were seen as essential, with the main problems viewed as lost property rights without compensation when laws change or species-related restrictions are placed on land after a purchase has been made. A point made in both focus groups was that confusing layers of regulations should be made easier to understand through more coordination among federal, state, and local agencies. The faculty and students of construction management expressed much interest in the issues discussed as well as concern that they are not currently integrated into programs of construction management.

Conclusions and Implications

Several important points emerge from the literature review and analysis. There are a variety of perspectives as to the extent and reality of a housing affordability crisis. Strong evidence points to a conclusion that what has been perceived as a crisis in affordability was more likely a reflection of demographic trends. The decline in home ownership rates was more accurately explained by changes in tastes and lifestyles and not necessarily economic hardship. Stagnant incomes due to economic restructuring, difficulties in amassing down payments because of neglected savings, and higher consumer debt loads led to the inability of many to purchase homes, the prices of which had indeed risen, but mainly because of substantial increases in size, quality, and amenities.

Examining the literature also makes it quite clear that sufficient data do not exists to draw definitive conclusions regarding the negative impacts of environmental regulations on housing affordability. Arguments that such regulations result in higher housing costs and that they play a significant role in preventing the development of affordable housing lack credibility. And the analysis demonstrated that when the topic of environmental regulations is discussed in focused interviews, housing affordability is not a primary concern. Finally, the state of public opinion on environmental issues indicates strong support among the American public for environmental protection efforts.

This paper has not sought to give an authoritative answer to the question of environmental regulation and affordable housing, but to show that no such answer exists because of insufficient research. The only clear conclusion that can be reached regarding this is that claims of environmental regulation having been a substantial contributor to a housing affordability crisis can be legitimately questioned from a number of perspectives.

Study Nails Building Costs

By Janice Billingsley
HealthSCOUT Reporter

MONDAY, Sept. 4 (HealthSCOUT) -- It's square feet, not soil erosion, that is adding to the increase in new home prices, a Cornell University study says.

A review of more than 100 studies on housing affordability found no evidence to support the popular belief that the cost of complying with environmental regulations is largely responsible for the increase in housing prices.

The median price of a new home in this country has tripled since 1977, according to study author Joseph Laquatra, associate professor of design and environmental analysis at Cornell, but you can't blame environmental regulations.

The study showed "those costs are miniscule," he says. "In a development of 100 houses, a builder will have to pay $50,000 for permits. What really is causing the increase in housing prices is the increase in the size of houses and amenities."

The size of the average new home has increased by about one-third over the last two decades, from 1,645 square feet in 1975 to 2,190 square feet in 1999, Laquatra says, and along with bigger houses have come higher price tags. The average house price increased from $62,500 in 1978 to $195,000 in 1999.

Builders and developers must comply with federal regulations that include the Clean Water Act, the Federal Water Pollution Control Act and the Endangered Species Act. Most have long assumed that these environmental regulations have thwarted development and driven the costs of new homes beyond what first-time buyers can afford.

That is partly true, says Susan Asmus, assistant staff vice president for environmental policy at the National Association of Home Builders (NAHB) in Washington, D.C.

A 1998 NAHB survey found the cost of environmental compliance added, on average, 10 percent to the cost of building a new house, which, she says, can be a big burden for smaller builders working on affordable new housing.

"The high-end builder is able to put in amenities and pass along" regulatory costs, she says. "But the guy who is trying to build affordable housing has a narrower window. Every time you add $1,000 to the price of a home, less people can afford your product. Although you try to pass costs along to the buyers, you can't always do it, and if you can't do it often enough, you don't have a business."

Another problem with the environmental regulations, Asmus says, is the cost of overlapping permits from different government agencies.

"No one [government agency] wants to give up the ability to decide what's going up. So, for instance, there are local, state and federal laws regarding sediment and erosion, which mean increasing costs [for filing duplicate permits] but no real, positive results," she says.

But Laquatra and fellow researcher Gregory Potter found in their review that environmental compliance costs have little impact on new-home prices. "The numbers are very difficult to compile," says Laquatra, "But while the regulations may have some impact [on housing prices], it is negligible at best."

The study appeared in the recent Earth Day 2000 issue of the *Electronic Green Journal*.

In the studies and in two focus groups researchers held with a cross-section of housing professionals from builders to environmental advocates, they found widespread support for environmental protections in home building.

"The public is overwhelmingly in favor of environmental protection and thinks the government should be spending even more on protecting the environment," Laquatra says.

"We are not anti-environment," Asmus counters, "but let's make regulations" that are "workable and meaningful, that make sense."

What To Do

Go to the Electronic Green Journal to read the study.

A rundown of the federal government's regulatory laws regarding the environment can be found at The Environmental Protection Agency.

And if you have Adobe Acrobat Reader(available through downloading), you can access the National Association of Homebuilders' 1998 report detailing the costs of building a new house by going to NAHB.

Economic Issues in Water Quality Regulation

by

Adrian Griffin, Ph.D., Senior Economist, State Water Resources Control Board

The views presented in this paper are those of the author and may not represent the policy of the State Water Resources Control Board or the views of Board management

In recent years, there has been growing public concern over the effect of regulation on the economy. While most people are agreed that environmental quality is important, there is often reluctance to support regulatory actions because of the belief that they increase the cost of products and reduce job opportunities. This trend is not surprising considering the difficult times Californians have gone through in the last several years. Real wages—that is, wages adjusted for inflation—have remained stagnant over the past two decades, and by some measures, have actually fallen. This situation is in stark contrast to experience in the 1950s and 1960s when real wages advanced steadily. In the past few years, California has done particularly badly. We used to be significantly better off than the rest of the U.S. Per capita income was 15-20 percent higher in California than in the U.S. as a whole during the 1960s and 1970s. In 1993, this gap was 5 percent.

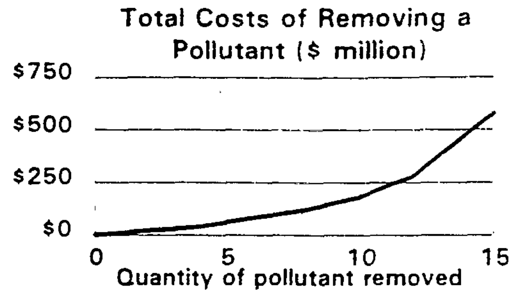
Because of these developments, it is important that we demonstrate to the public that we are giving them good value for money from water quality regulation. It is impractical to make a detailed economic analysis of every board action. However, common sense suggests that we should try to improve water quality up to the point where costs begin to exceed benefits. Finding this point is much more easily said than done because the economic value of protecting and improving water quality is not known with certainty. For example, an action which protects groundwater quality may allow a local water utility the option of using the groundwater as a water source in dry years. We cannot put a dollar value on this option without doing a comprehensive study of the utility's operations. Protecting water quality in a river will result in a variety of aesthetic and recreational benefits. These benefits have a significant value. However, because scenic quality and access for recreational use are not bought and sold in a marketplace like other goods and services, it is difficult to assess the value that the public puts on these benefits as compared with other goods and services. Assessing the costs of regulatory action also presents difficulties. The cost of the process used for treatment of discharges may be known, but all too often, there are concerns that reduction in discharges may result in indirect costs on other industries, job losses, and impacts on the local economy.

Nevertheless, considering these questions gives some framework for decision-making. The following pages contains a discussion of a few issues which may be helpful in bringing economic factors into the decision-making process.

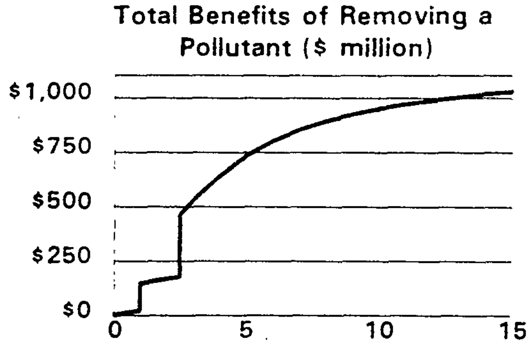
Optimal Pollution Levels

Determining the desired level of protection often presents difficulties. Treatment costs typically increase at higher levels of removal as dischargers must turn to more advanced treatment methods. Typically, the benefits of removing the pollutant decrease after a certain level of water quality has been achieved.

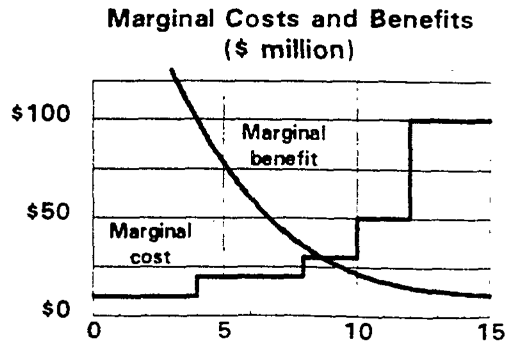
The graphs show the cost and benefits of removing a hypothetical pollutant from a water body. The uppermost graph shows that costs are modest at low amounts of removal from current levels, but climb rapidly as dischargers must switch to more advanced treatment. The bottom graph shows the incremental, or marginal, cost of removing an additional unit of pollutant. This cost increases in steps as the limits of each type of treatment are reached. Removing up to 4 units can be achieved at a cost of $10 million/unit. The cost of removal then climbs to $20 million/unit, eventually reaching $100/unit.



The middle graph shows the benefits of removing the pollutant. At first, benefits climb rapidly as the water body becomes capable of supporting a wider variety of uses and as its aesthetics improve. However, as removal levels increase, there are diminishing returns from further increases in removal amounts. At high levels of removal, benefits increase slowly with further removal of the pollutant. The incremental, or marginal, benefits of removing an additional unit of pollutant are shown in the lower graph. The line shows that the benefits of removing an additional unit of pollutant are high at low levels of removal, but fall rapidly as removal levels increase.



From an economic point of view, the most desirable level of pollution is that where the cost of further increases in removal begins to exceed the benefits of further removal. Provided that the marginal cost and benefit curves capture all of the costs and benefits of removing the pollutants, this point is where the two lines cross on the lowest graph. There is no reason to expect this point to correspond to the best available technology (which corresponds to the top step on the benefits curve in this example), or what a discharger may feel is affordable.



R0010707

This example [illegible] simple benefit-cost ratios can lead us astray. For example, a removal level of 15 [illegible] would cost $600 million, yield benefits of just over $1 billion, and have a benefit-cost ratio of 1.7. However, this level of removal would not be desirable economically. If we were to drop back to the optimum level of 9 units, we would save over $400 million in costs but lose only $100 million in benefits. This kind of analysis can be useful in the board's role in balancing economic and environmental impacts.

Should Intangible Benefits be Compared with Costs?

Often it is argued that, because of the intangible nature of environmental benefits, it is inappropriate to compare costs and benefits in the way outlined in the preceding section. However, we make similar comparisons implicitly in a wide variety of everyday decisions. For example, when a consumer decides how much to donate to a charity, he is weighing the intangible satisfaction of giving against the goods and services that he could otherwise buy with his donation. This type of decision is no different in principle from a comparison of the intangible benefits of improved water quality with the costs of pollution control. In both cases, a comparison is made between an intangible benefit and other goods and services forgone as a result of spending to achieve this benefit.

Environmental decision-making is always easier if accurate estimates of benefits are available. However, it may be impractical to quantify intangible benefits to the extent that they can be confidently compared with costs. Nevertheless, it is usually wise to make some comparison of costs and benefits and to assess whether the same goals can be achieved by less costly means.

The absence of this kind of scrutiny may lead to wasteful regulation. Recently, a northern California county passed an ordinance requiring a the installation of outlets for charging electric cars in all new residential garages. The cost of these additional outlets is only about $50. However, only a small proportion of these outlets will be used. Assuming a market penetration of 2 percent for electric cars, $2,500 will be spent for each outlet actually used.

This ordinance may be have been motivated by the feelings that the costs per household are small and that clean air is important for aesthetic and health reasons, so economic analysis is unnecessary. However the requirement to install outlets, most of which will never be used, results in a consumption of resources that are now no longer available for other purposes, including other environmental programs.

Economic Impacts: Some Traps for the Unwary

The effect of board action on the economy in general is always a concern. Often, it is feared that the costs imposed on a discharger will affect other industries and spread throughout the economy, resulting in widespread economic impacts. In some cases, these fears are exaggerated and arise from misinterpreting economic analyses. Some of the more common sources of error are as follows:

Double Counting. Care must be taken to avoid adding together impacts which are not additive. In many cases, the cost of a regulation will be split in an unknown manner between an industry directly affected by the action, industries purchasing from this industry, and consumers. Studies commissioned by interest groups may assume that all of the costs fall on one particular group. Consider for example, a regulation requiring operators of truck stops to treat runoff from paved areas. If the market for truck stop services is highly competitive, truck stops will not be able to raise their prices and the cost of the treatment will be borne entirely by truck stop operators. However, there will be no impacts on the trucking industry. If market conditions are not competitive, truck stops will be free to pass on increased costs to their customers. In this case, there will no impacts on truck stop operators and the entire cost will be borne by the trucking industry. The full impacts cannot fall on both industries at the same time. When reviewing studies by affected groups, it is essential to determine whether the impacts presented are a part of the total impact or a worst case for a particular group.

Misinterpretation of Job Losses. Job impacts are an important concern in water quality regulation. All too often, estimates of job losses resulting from regulatory action are presented without any discussion of the duration of these job losses. This may gives the impression that a lost job represents one person-year of unemployment, or even a permanent job loss in the region. However, if a business cuts back its operations as a result of regulatory action, any workers laid off will not be unemployed indefinitely. The length of time that these displaced workers are without work will depend on the local labor market. If the demand for their skills is poor, they may be unemployed for many months. However, we should not assume that this is always the case. In a strong labor market, displaced workers will find new jobs without delay and job losses will merely be a temporary job displacement.

Use of Gross Output as a Measure of Impacts. Economic impact studies often present estimates of the effect of regulatory action on the gross output or sales revenues. However, these can be misleading figures. The true measure of the economic impact of regulatory action is its effect on income. The value of an industry's gross output reflects the cost of materials and components and other production expenses, as well as the income of employees and proprietors. If an industry curtails its output, many of these expenses will be reduced. Thus, impacts on gross output are always greater than actual income losses.

In some cases, multipliers are applied to impacts on the affected industry to give an estimate of impacts on gross regional output. The resulting figure should not be interpreted as the total cost of the regulation to the region since it is significantly larger than overall impact on income in the region.

Misuse of Multipliers. Job multipliers are often used to estimate the indirect economic impacts. A job multiplier for an industry shows the total number of jobs that are supported by each job in the industry. These multipliers are often used without an understanding of their limitations. In some cases, state or even national multipliers are used to estimate local economic impacts. This is a serious misuse of multipliers, since state and national multipliers are nearly always larger than county multipliers.

Multipliers are often smaller than generally imagined. There seem to be the widespread belief that job multipliers are generally around 3.0. This is true for industries such as automobile and computer manufacturing operating in established industrial centers where they buy parts and components from other industries in the area. But for most industries, multipliers are much smaller. For example, the job multiplier for apparel manufacturing in Los Angeles County is 1.8. Multipliers are still smaller in rural counties where a higher proportion of spending by businesses and consumers is on goods and services produced outside the area.

Multipliers usually overestimate indirect economic effects because the methods used to develop them assume fixed trading patterns between industries. That is to say, each industry in an area buys from local and outside industries in fixed proportions and production by suppliers automatically rises and falls with production in the purchasing industry. In reality, there is more flexibility in the economy, so economic impacts are softened.

Businesses are always adapting to changing conditions. For example, if a plant closes or cuts back its output, suppliers will generally make up some of their losses in business by finding new markets in other areas. Growth in other parts of the economy will often provide opportunities for these firms. Consequently, there is rarely a fixed proportional relationship between jobs lost at a plant affected by a regulation and jobs lost at suppliers. Job multipliers give an upper limit on the jobs lost due to a plant closure or cutback, rather than the most reasonable estimate of this figure.

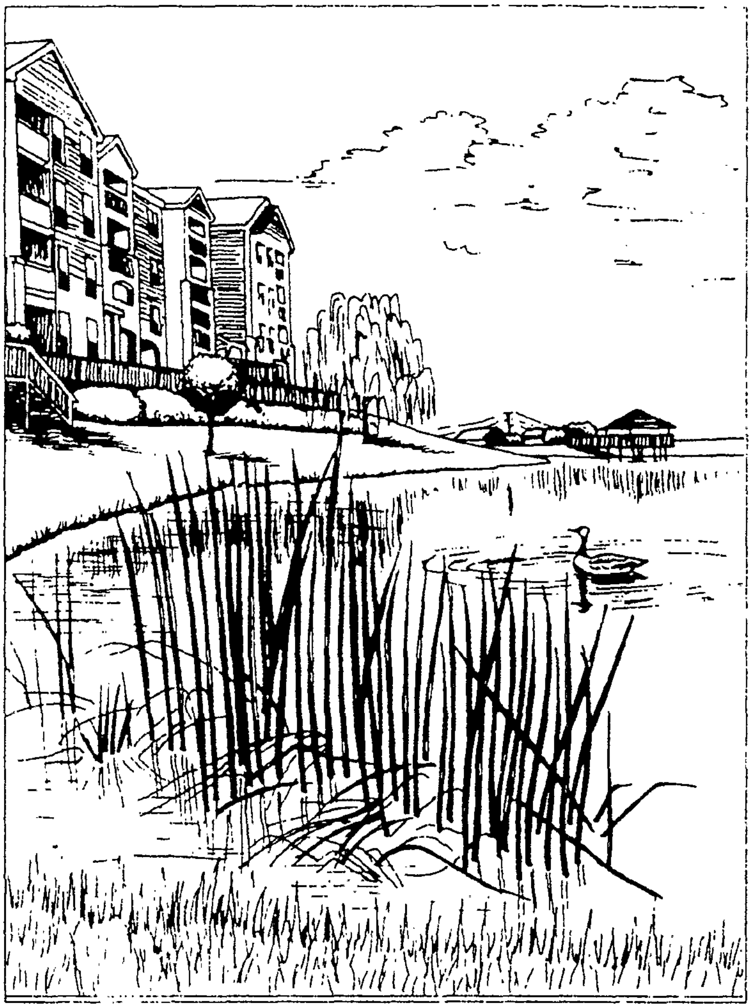
Lack of Comparisons. Estimates of economic impacts sometimes show hundreds of lost jobs and millions of dollars in lost output. These impacts may sound severe, but they should always be compared with regional totals and, more importantly, normal fluctuations in these numbers. California had nearly 12 million jobs in 1995. This number varies by several thousand from month to month. California's gross state product is nearly $950 billion. Labor markets are also affected by migration. Los Angeles County has lost people in recent years, but in the 1980s, net in-migration ranged up to 80,000 annually. Even in smaller counties, 100 lost jobs may be equivalent to only a few months' net in-migration. Impacts should always be put in context by comparing them with economic statistics for the area affected.

EPA

Economic Benefits of Runoff Controls

Even though urban runoff management costs money, properly designed runoff systems can provide economic benefits that counterbalance or even outweigh those costs.

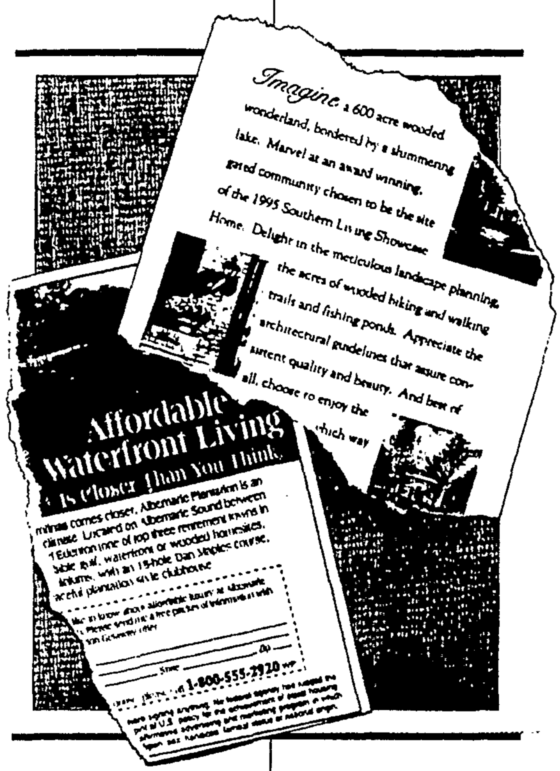
This report describes the economic impacts of various types of urban runoff controls and presents case studies of developments where the implementation of runoff control requirements has provided economic benefits to developers and property owners.



R0010711

Overview

PEOPLE HAVE a strong emotional attachment to water, arising from its aesthetic qualities—tranquility, coolness, and beauty. As a result, most waterbodies within developments can be used as marketing tools to set the tone for entire projects *(Tourbier and Westmacott, 1992)*. A recent study conducted by the National Association of Home Builders indicates that "whether a beach, pond, or stream, the proximity to water raises the value of a home by up to 28 percent." A 1991 American Housing Survey conducted by the Department of Housing and Urban Development and the Department of Commerce also concurs that "when all else is equal, the price of a home located within 300 feet from a body of water increases by up to 27.8 percent" *(NAHB, 1993)*. Dick Dillingham, President of the National Association of Realtors' Residential Sales Council, declares, "Water makes a difference . . . there is such a very small supply of properties that can claim a water location and it is something you cannot add" *(Lehman, 1994)*.



Although there are a limited number of natural waterfront sites adjacent to lakes, rivers, streams, estuaries, or open ocean, many opportunities exist to create waterfront property. Homes and businesses can be sited along hydroelectric or water supply impoundments or near the banks of artificial lakes created for wildlife, recreational, or aesthetic reasons. A practice becoming more prevalent is to site developments around man-made ponds, lakes, or wetlands created to control flooding and reduce the impacts of urban runoff on neighboring natural streams, lakes, or coastal areas. When designed and sited correctly, artificial lakes or wetlands can help developers reduce negative environmental impacts caused by the development process and increase the value of the property.

The purpose of this report is to show that certain urban runoff management controls can be incorporated into a development in a way that provides aesthetic and economic benefits. Table 1 summarizes the findings of this report. Urban runoff controls that are pleasing to the eye and safe for children can lead to increased property values. Because the beauty of natural surroundings can increase real property values and enhance the quality of life, location of land areas adjacent to waterways and detention ponds should be considered an integral part of planning by developers. For existing runoff controls that are unsightly, corrective renovations can be made to increase the property value and quality of life.

People have a strong emotional attachment to water, arising from its aesthetic qualities—tranquility, coolness, and beauty.

Table 1: Examples of real estate premiums charged for property fronting urban runoff controls

Location	*Base Costs of Lots/Homes*	*Estimated Water Premium*
Chancery on the Lake, Alexandria, Virginia	*Condominium: $129,990 - $139,990*	*Up to $7,500*
Centex Homes at Barkley, Fairfax, Virginia	*Home with lot: $330,000 - $368,000*	*Up to $10,000*
Townhomes at Lake Barton, Burke, Virginia	*Townhome with lot: $130,000 - $160,000*	*Up to $10,000*
Lake of the Woods, Orange County, Virginia	*Varies*	*Up to $49,000*
Dodson Homes, Layton, Faquier County, Virginia	*Home with lot: $289,000 - $305,000*	*Up to $10,000*
Ashburn Village, Loudon County, Virginia	*Varies*	*$7,500 - $10,000*
Weston Development, Broward County, Florida	*Home with lot: $110,000 - $1,000,000*	*$6,000 - $60,000 depending on lake size, location, and the percent of lakefront property in the neighborhood*
Silver Lakes Development, Broward County, Florida	*Varies*	*$200 - $400 per linear foot of waterfront, depending on lake size and view*
Highland Parks, Hybernia, Illinois	*Waterfront lot: $299,900 - $374,900*	*$30,000 - $37,500*
Waterside Apartments, Reston, Virginia	*Apartment Rental*	*Up to $10/month*
Village Lake Apartments, Waldorf, Maryland	*Apartment Rental*	*$5 - $10/month depending on apartment floor plan*
Lake Arbors Towers, Mitchellville, Maryland	*Apartment Rental*	*$10/month*
Marymount at Laurel Lakes Apartments, Laurel Lakes, Maryland	*Apartment Rental*	*$10/month*
Lynne Lake Arms, St. Petersburg, Florida	*Apartment Rental: $336 - $566/month*	*$5 - $35/month depending on lake size*
Sale Lake, Boulder, Colorado	*Waterfront lot $[illegible]4,000*	*Up to $35,000*
The Landing, Wichita, Kansas	*Waterfront lot $[illegible],000 - $40,000*	*Up to $20,000*
Fairfax County, Virginia	*Commercial Office Space Rental*	*Up to $1/square foot*
Laurel Lakes Executive Park, Laurel, Maryland	*Commercial Office Space Rental*	*$1 - $1.50/square foot*

Impacts and Controls

Urbanization causes changes and impacts to the environment and our communities. Many effects of urbanization are positive, such as new places for people to live and work, increased recreational opportunities, and economic growth. However, some of the impacts might be negative if they are not handled with foresight.

Most local governments require some form of urban runoff management for new development.

Development leads to an increase in the amount of pollutants in an area. Sediment from construction sites can end up in streams and rivers, choking plant and animal life. Oil and gas from vehicles can leak onto roads and parking lots. Fertilizers and pesticides, if not applied properly, can wash off lawns. Pesticides are often found in higher concentrations in urban areas than in agricultural areas *(USGS, 1995)*. Pet waste, if not properly disposed of, can enter storm drains that lead to wetlands, streams, or rivers. Household chemicals, such as paints and cleaning products, can leak if not stored or disposed of properly. All of these pollutants can wash away when it rains and end up in streams, rivers, lakes, estuaries, or ground water. Many pollutants also bind to the sediment, so when sediment washes away it takes the pollutants with it.

Urbanization also leads to loss of pervious areas (porous surfaces) that allow rainwater to soak into the ground. This can increase the amount and velocity of rainwater flowing to streams and rivers, as illustrated in Figures 1 and 2. This increased speed and volume of water can have many impacts, including eroded stream banks, increased turbidity and pollution, increased stream water temperature, and increased water flow. All of these can have an adverse effect on the fish and other organisms living in the stream and the receiving waters. When rainwater cannot soak into the ground, the result can be a loss of drinking water because many areas of the country rely on rainwater soaking into the ground to replenish underground drinking water supplies.

Loss of trees due to urbanization can have negative impacts. Trees are important for controlling the water temperature along the shorelines of waterbodies. Since many aquatic plant and animal species are sensitive to changes in water temperature (trout, for example), it is important to keep stream temperatures as close to natural levels as possible. When the shade of trees is lost, the water temperature can increase.

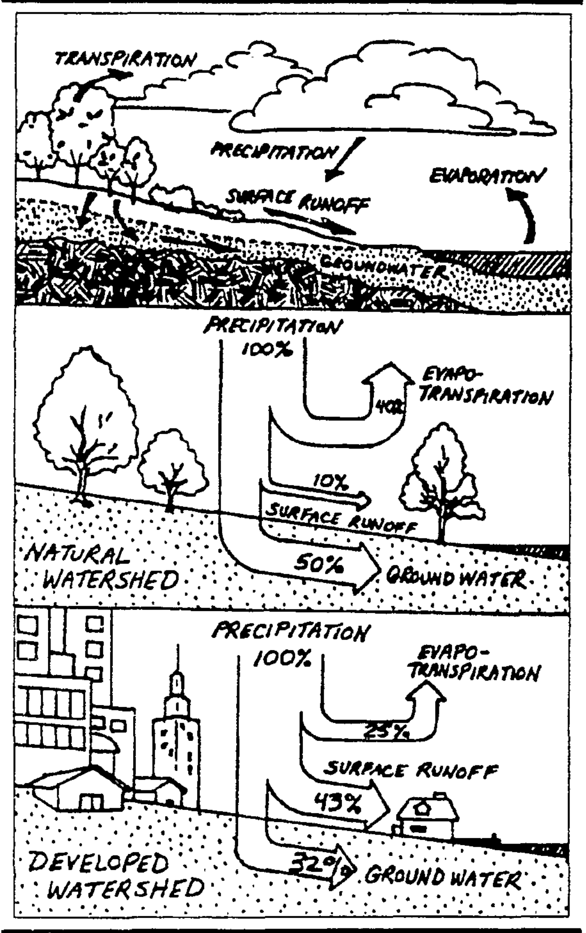


Figure 1. Development decreases the amount of rainwater that can soak into the ground. (L.B. Leopold, USGS Circular 554, 1968, cited in NYSDEC, 1992)

"Best management practices," or BMPs, help address these impacts. BMPs are designed to help reduce the amount of pollution in urban runoff. Some help to control the volume and speed of runoff before it enters receiving waters. Many help to increase the amount of rainwater that soaks into the ground to restore groundwater. There are two general types of BMPs: structural and nonstructural. Structural controls involve building a "facility" for controlling urban runoff. There are a variety of structural controls and most require some level of routine maintenance. This report discusses two types of structural controls that have been documented as providing economic benefits: urban runoff ponds and constructed wetlands. Nonstructural BMPs do not require construction of a facility. For example, planning a development so that there are buffers along stream banks and minimizing the amount of impervious area are types of nonstructural controls. Structural and nonstructural controls can be used in combination to manage runoff.

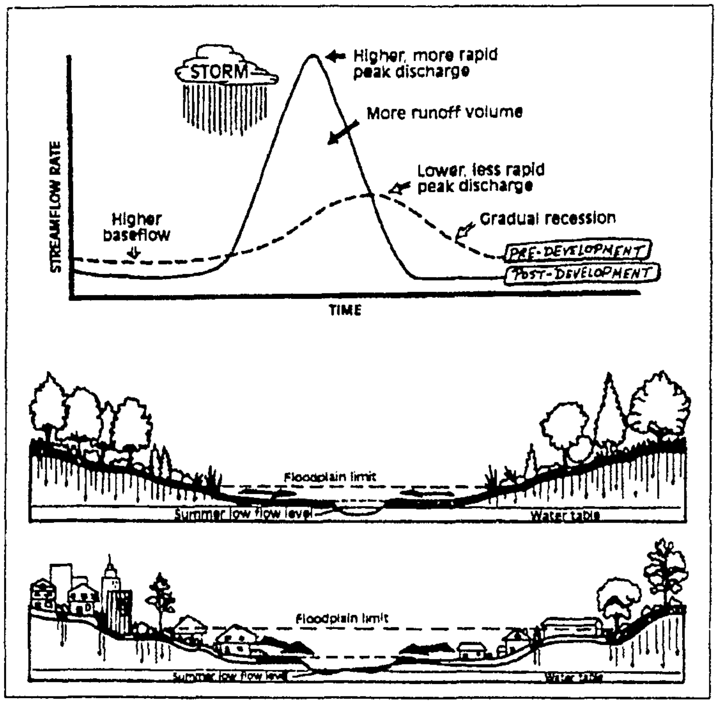

Figure 2: Development can alter an area's hydrology by increasing the amount of impervious surface. (adapted from Schueler, 1987).

Urban runoff management controls are now widely accepted due to lessons learned from not planning properly for the impacts associated with increased urbanization. Most local governments require some form of urban runoff management for new development. They require such controls for two reasons: to prevent pollution and to prevent flooding caused by increased runoff, mostly from impervious areas. Usually they require structural controls although some local governments give credit for nonstructural controls.

Methodology

A LITERATURE REVIEW was conducted to examine the impacts of urban runoff management ponds on property values. Many experts in the real estate field and experts involved in management of urban BMPs/runoff controls were contacted. Discussions with organizations including the Urban Land Institute, the American Planning Association, and the National Association of Home Builders proved valuable in identifying developments that have incorporated urban runoff management requirements into site development and have realized an economic benefit. Regional personnel of the U.S. Environmental Protection Agency (EPA) were contacted and provided information on their region of the country as well as potential case study examples. Developers and realtors provided comparative values and information on premiums charged for various properties nationwide.

"Why not take an environmental negative and turn it into a positive, into a visual asset?"

(Don Basile in Tourbier and Westmacott, 1992)

Information regarding case studies was compiled through literature reviews, site visits, and discussions with developers and realtors. After the information-gathering process was completed, case studies were selected. The case studies are

R0010715

[illegible] impacts on new development, existing development, and commercial property. Conclusions were made based on information gathered and discussions with experts in the fields of real estate and urban runoff controls.

Ponds and Wetlands for Urban Runoff Control

MOST STRUCTURAL urban runoff BMPs function on the principle that it is best to hold runoff for a period of time. This approach serves two functions. It controls the peak flow rates of water released from a site, thereby controlling downstream flooding, and it allows pollutants to be removed from the water column. There are many different types of urban BMPs, many of which add value to adjacent property. This report focuses on two types of BMPs that are often used: urban runoff "wet ponds" and constructed wetlands, as illustrated in Figure 3.

"Preservation is not a problem for developers; it's a golden opportunity."

(David Hoffman in Tourbier and Westmacott, 1992)

Wet Ponds

Wet ponds, as their name implies, are runoff holding facilities that have water in them all the time. Storm flows are held in the pond temporarily and then released to maintain healthy downstream habitats. Sediment and other pollutants settle out of the water and are not discharged to the receiving waters. Wet ponds are usually vegetated, and the plants' roots hold sediment and use the nutrients that are often contained in urban runoff. The ponds are designed to be big enough to control onsite and offsite flooding in the event of a major storm. This helps to control impacts on downstream habitats.

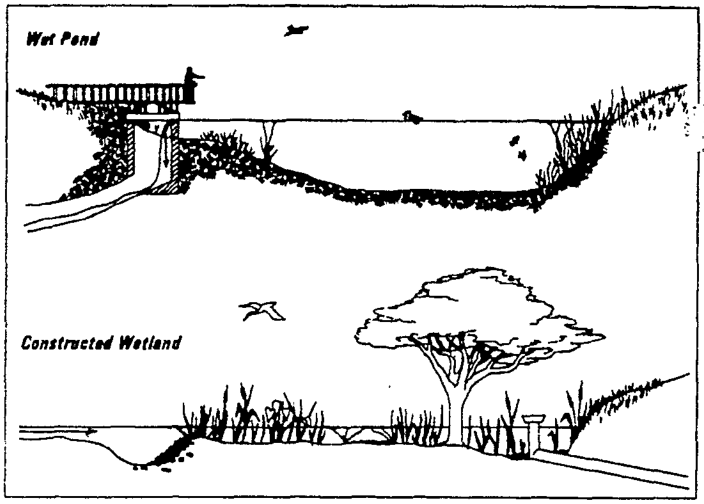

Figure 3: Wet ponds and constructed wetlands are two types of runoff controls.

Many of the "lakes" in developments are actually detention or retention wet ponds. Developers can design the wet ponds to look like natural lakes. Wet ponds can be highly effective in removing sediment and in reducing nutrients if they are properly constructed and maintained. They can usually be used for large drainage areas. Wet ponds can be incorporated into new development site plans and can enhance the value of surrounding property. Old wet ponds can also add value to the surrounding property once they have been aesthetically improved.

Constructed Wetlands

Wetlands serve an important function in controlling the impacts of urban runoff. Because wetlands are heavily vegetated, they serve as a natural filter for urban runoff. They also help to slow the flow of water to the receiving waters and replenish groundwater. When properly designed, constructed wetlands have many advantages as an urban BMP, including reliable pollutant removal, longevity, adaptability to many development sites, ability to be combined with other BMPs, and excellent wildlife habitat potential (MWCOG, 1992).

Making Urban Runoff Management Work for You

IN MANY CASES, developers are able to realize additional profits (and quicker sales) from units that are adjacent to a wet pond (Harden 1995; MWCOG, 1983). If the urban runoff management control is also developed to allow passive recreation (e.g., a walking path around a lake or pond), the recreational area and the wet pond/constructed wetland can become the feature attraction when advertising the property (Figure 4). Adding walking trails, fitness equipment, gazebos, bird houses, and other facilities to enhance a detention area can be costly, but eventually additional profits are realized (Sala, 1995).

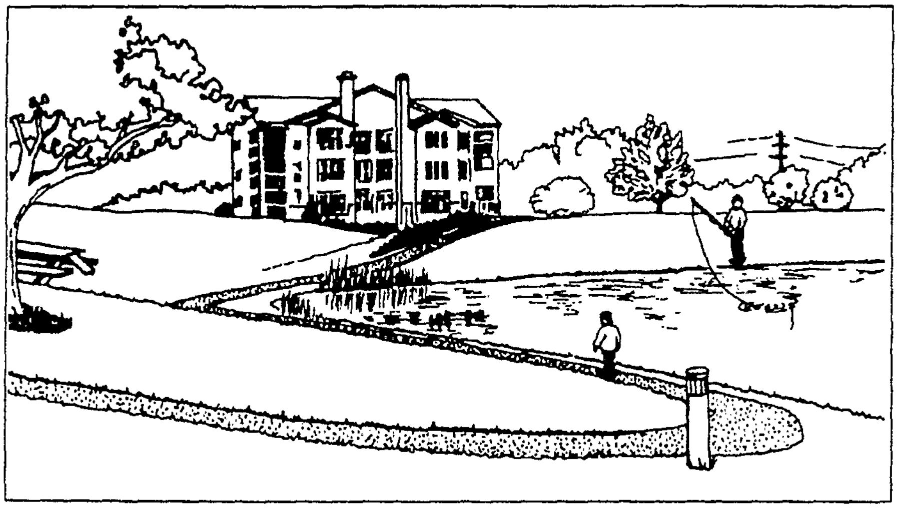

Figure 4: Urban runoff controls can be assets to a development.

The impacts of urban runoff management controls on property values are site-specific (CDM, 1982). Controls can affect property values in one of three ways: increase the value, decrease the value, or have no impact. "Urban runoff controls are greeted with varying degrees of skepticism and acceptance by residential versus commercial property owners," according to Judith Costello Pearson, Manager, Market Research, Fairfax County (Virginia) Economic Development Authority. One must consider the appeal of an attractive urban runoff management control along with the liability of open water. A childless adult might perceive a wet pond as an amenity, but a family might view it as a potential hazard to children.

"Whether a beach, pond, or stream, the proximity to water raises the value of a home by up to 28 percent."

(Lehman, 1994)

Factors That Lead to Increases in Property Value

Urban runoff systems with standing water often appear to be natural systems. A clean lake or pond offers benefits to developers by creating an ideal setting for model units and for the sales office. If located close to the entrance and visible from the road, it will have considerable curb appeal and can repay installation costs through faster sales, in addition to raising the value of adjacent lots (Tourbier and Westmacott, 1992). Developers can charge premiums (extra charges) for property with water views, views of wooded land, or other amenities.

Many ponds planned for urban runoff control are also designed to provide recreational facilities. They are often surrounded by walking trails and picnic areas complete with gazebos and outdoor grills. The ponds also can be used by nonmotorized boats like canoes and are excellent areas for bird-watching. This natural setting creates a home for a variety of birds and animals that homeowners find appealing (Figure 5). Fountains, often included in plans, also add to the aesthetic qualities of the pond.

"Higher sales prices for properties with views of the water have been consistent for 23 years."
(Wade, 1995)

Many developers have capitalized on urban runoff regulations by designing aesthetic wet ponds and marketing them as if they were natural lakes or ponds. A Pennsylvania developer has said, "We are required to build urban runoff management basins. Why not take an environmental negative and turn it into a positive, into a visual asset?" (Tourbier and Westmacott, 1992). In an effort to incorporate landscape design into stormwater management planning to enhance the value and quality of development, General Telephone of Marion, Ohio, created an attractive wet pond ornamented with plantings, stones, and pedestrian paths. Runoff from the Hyatt Regency Ravina hotel complex in Atlanta, Georgia, flows into a series of beautifully designed wet ponds linked together by streams and waterfalls that are kept flowing by recirculating pumps. A carefully designed wet pond at the Woods in Rhinebeck, New York, provides flood control and water quality benefits, and the waterfront created by the impoundment enhances the value of surrounding townhouses (NYSDEC, 1992).

Figure 5: Constructed wetlands provide wildlife habitat and are aesthetically pleasing.

Factors That Lead to Decreases in Property Value

Residential lots located near an urban runoff pond are often a concern to home buyers with young children. Parents fear their children will be attracted by the water or wildlife and drown. Incidents of drowning in urban runoff management areas have occurred in residential as well as commercial areas. Children who fall through frozen ponds or fall into the water without knowing how to swim are usually the victims (Suit filed, 1990; Woellert, 1993). Adults have also drowned in detention ponds. A Chicago man fell into an 18-foot-deep retention pond located on the property of a junkyard and drowned (OSHA probing, 1994). According to one real estate appraiser, safety is the only issue regarding urban runoff management controls that adversely affects property value (Jablonski, 1995).

One solution is to construct a fence surrounding the pond to deter entry and reduce accident potential. Chain-link fencing is often used. Rusting, poorly maintained chain-link fencing reduces any aesthetic qualities of the area, but fencing that has a black or green protective coating is more attractive and can improve the appearance of the runoff control. Prince William County, Virginia, has a fencing ordinance for constructed ponds aimed at preventing entry of children under 4 years of age (Guzman, 1995; MWCOG, 1983). A "protective device" of the developer's choice must be placed around ponds near residential areas with over 2 feet of standing water or more than 2 hours of drainage time. The protective device may be fencing or plantings of bushes and trees (Figure 6); in some cases, flat slopes or shallow beaches extending at least 20 feet from the perimeter of the pond are acceptable. These flat slopes or beaches provide protection for children who could roll down steep slopes directly into the pond.

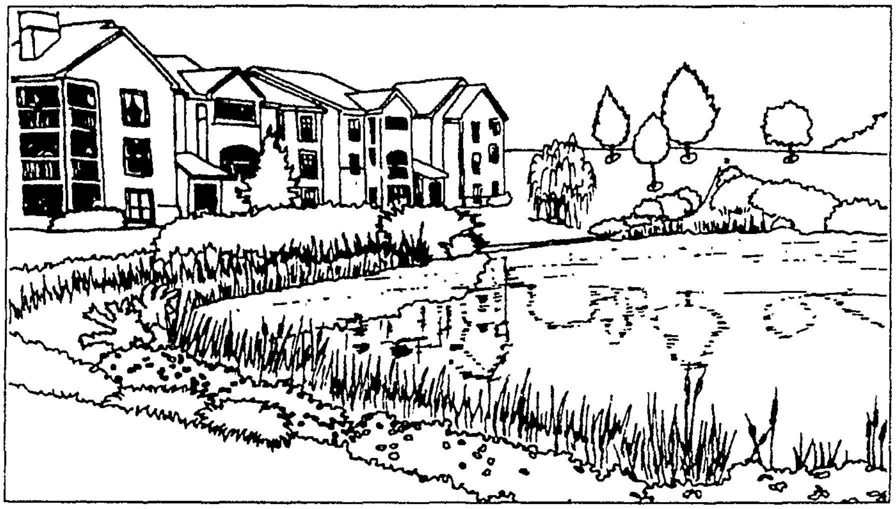

Figure 6: Natural "fencing" can be used as a protective device.

Using flat slopes reduces the amount of land available for development, however, and is the least used option. Fencing is the most inexpensive solution and is used frequently. It has been reported to be an "attractive nuisance," however, because some older children feel challenged to climb fences and enter restricted areas (MWCOG, 1983).

Requirements to construct wet ponds for urban runoff management are a concern for developers, who lose the potential profit from this otherwise buildable land. This unrealized profit, or foregone value, can be substantial if, for example, a builder is no longer able to construct several planned townhomes (Rolband, 1995). Developers often increase the number of homes built in the area available for development and reduce the size of individual homes to recoup the foregone value of the property.

Urban runoff management controls are now widely accepted due to lessons learned from not planning properly for the impacts associated with increased urbanization.

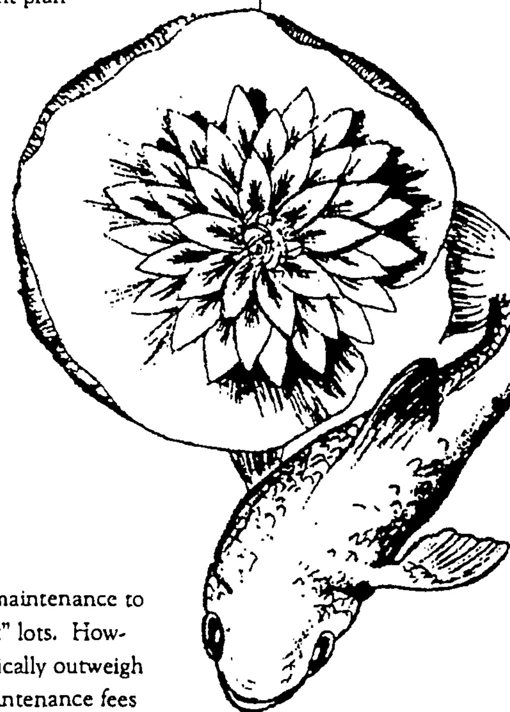
Poorly maintained wet ponds or constructed wetlands are often unsightly due to excessive algal growth or garbage build-up. These conditions are considered detriments by area residents and people passing through the areas. Wet ponds and constructed wetlands can also become mosquito breeding grounds. Mosquito problems usually can be reduced or eliminated by designing the wet pond so that all portions of the basin are connected to open water to allow natural predators to control the mosquito larvae (Tourner and Westmacott, 1992). Generally mosquitoes are not a problem in the presence of a good biological community. Organic controls such as mosquito-eating fish or insecticidal bacteria like *Bacillus thuringiensis israelensis* (Bti), however, are also options where mosquitoes need to be controlled.

When designed and sited correctly, artificial lakes or wetlands can help developers reduce negative environmental impacts caused by the development process and increase the value of the property.

Improving the Acceptance of Urban Runoff Facilities

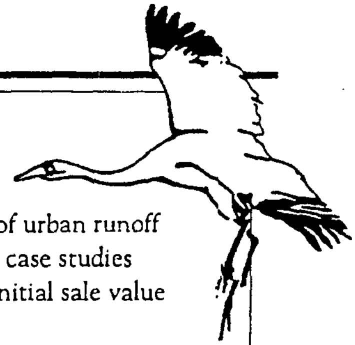
Effective landscaping can do much to overcome the disadvantages of urban runoff systems and improve the appearance of facilities. Banks of urban runoff storage areas and drainage ditches should be graded smoothly into adjacent areas where feasible. Steep slopes should be protected against erosion by stabilization techniques, such as gabions, rip-rap, or other practices that detract as little as possible from the natural setting. Planting and preservation of trees, shrubs, and other vegetation should also be a part of the improvement plan (Poertner, 1974).

Sediment accumulation and waterlogging of otherwise usable land areas can be avoided by the use of proper design, construction, and operation techniques. Ponds used for urban runoff control can be spared from excessive sediment accumulation by the use of forebays for silt collection. The amount of silt transported can be reduced by directing runoff through vegetated areas or specially designed runoff filters. Waterlogging of land surrounding urban runoff storage areas can be minimized by sloping the ground toward storage areas, eliminating water pockets, and minimizing the frequency and duration of ponding on areas otherwise suitable for multipurpose use (Poertner, 1974).



Operation and Maintenance

Wet ponds and constructed wetlands require periodic maintenance to preserve environmental and monetary benefits of "waterfront" lots. However, the benefits of higher resale value and quality of life typically outweigh the combined costs of the initial lot premium and annual maintenance fees charged by homeowners' associations. In fact, operation and maintenance costs of urban runoff retention ponds can be as low as $62 per year for homeowners (MWCOG, 1983).



Case Studies

THE FOLLOWING CASE studies highlight developments where the incorporation of urban runoff controls resulted in economic benefits to the local homeowners or developers. The case studies detail how the presence of aesthetically designed runoff controls affected both the initial sale value of new developments and the resale values for existing developments.

New Development

Columbia, Maryland *A landmark survey by the National Institute for Urban Wildlife indicated that 75 percent of the residents of Columbia, Maryland, a community planned for a population of 100,000, prefer urban runoff ponds that contain permanent pools of water, wetlands, and wildlife over the dry ponds many municipalities prescribe for their subdivisions. Residents (94 percent) overwhelmingly believed that managing future runoff basins for fish and wildlife as well as for flood and sediment control would be desirable. Residents (92 percent) considered the view of birds and other wildlife to be particularly important and felt that the sight of them outweighed any nuisances they created. Perhaps most importantly, 75 percent of Columbia homeowners felt that permanent bodies of water added to real estate values and* ***73 percent said they would pay more for property located in a neighborhood with stormwater control basins designed to enhance fish or wildlife use.*** *The study in Columbia covered an area that contained 3 lakes, 22 runoff ponds with a permanent pool of water, and 9 dry detention basins (Adams et al., 1984; Tourbier and Westmacott, 1992).*

For further information contact Charles Rhodehamel, Columbia Association, Land Management Division, 9450 Gerwig Lane, Columbia, Maryland 21046; phone (410) 381-0288.

Champaign-Urbana, Illinois *Residents of seven Champaign-Urbana, Illinois, subdivisions with urban runoff detention ponds were questioned about the role the pond played in their decision to purchase their home. Sixty-three percent of the respondents living adjacent to a wet pond identified the pond as what they liked most about their neighborhood. Seventy-four percent of homeowners surveyed believed that wet ponds contributed positively to the image of a subdivision as a desirable place to live. Only 3.5 percent felt a wet pond had a negative influence on the image of their neighborhood. Overall, respondents believed that* ***lots adjacent to a wet pond were worth an average of 21.9 percent more than comparable nonadjacent lots in the same subdivision.*** *Eighty-two percent of all respondents said they would, in the future, be willing to pay a premium for a lot adjacent to a wet pond (Emmerling-DiNovo, 1995).*

Boulder, Colorado *Built in 1993, the Sale Lake subdivision of single-family homes surrounds a 4-acre constructed wetland. Sale Lake demonstrates environmental sensitivity in suburban development.* ***Lots located alongside the wetland sold for as much as $134,000, up to a 30 percent premium over lots with no water view*** *(St. Germain, 1995).*

For further information contact Will St. Germain, St. Germain Construction, Inc., 2709 Pine Street, Boulder, Colorado 80302; phone (303) 449-1379.

Highland Parks, Illinois

"Preservation is not a problem for developers; it's a golden opportunity," insists the president of the development company for **Hybernia**, *a community of 122 single-family houses on a 133.5-acre site in Highland Parks, Illinois. The site, zoned for 40,000-square-foot lots, was laid out around a constructed pond/stream system and 27 acres of land approved as a state nature preserve. The site includes 16.5 acres of ponds. Forebays at urban runoff inlets catch sediments (Tourbier and Westmacott, 1992).*

Hybernia is a an example of ecological landscape planning. ***Waterfront lots, which now sell for $299,900 to $374,900, draw a 10 percent premium above those with no water view*** *(Margolin, 1995).*

For further information contact Peter Margolin, Hybernia Homeowners Association, c/o Red Seal Development Corporation, 425 Huehl Road, Building 18, Northbrook, Illinois 60062; phone (708) 272-5600.

Alexandria, Virginia

Chancery on the Lake, *a condominium development in Alexandria, Virginia, is a residential project with an attractive 14-acre urban runoff detention area. Realtors are currently promoting the wet pond as the development's feature selling point. The wet pond will be surrounded by a walking trail, and a gazebo and fishing pier will also be built. According to Ginger Harden, Sales Associate of Chancery Associates LP, condominiums are priced between $129,990 and $139,990.* ***Condominiums that front the lake are selling at a $7,500 premium.*** *For the first four buildings on the market, a $5,000 premium was charged for units fronting the lake. The lakefront units were the only units selling, and now the premium has been raised to $7,500 (Harden, 1995).*

For further information contact Eric Yakuchev, sales manager, 6540 S. Van Dorn Street, Alexandria, Virginia 22315; phone (703) 922-7171

St. Petersburg, Florida

A development consisting of apartments and townhouses in St. Petersburg, Florida, **Lynne Lake Arms**, *has four urban runoff detention ponds on site. Three of the ponds are 3 to 5 acres in size, and the fourth is a 25-acre pond with a large fountain in the center. Apartments or townhouses rent for between $336 and $566 a month.* ***Units facing the three smaller ponds have a $15 per month waterfront premium; units facing the large pond are rented at a $35 per month premium*** *(McInturf, 1995). A small channel connects the large detention pond and one of the smaller ponds. Even apartments fronting this channel have a $5 per month waterfront premium.*

For further information contact Mark Mahaffey, leasing agent, 5800 Lynn Lake Drive South, St. Petersburg, Florida 33712; phone (813) 823-3399.

Wichita, Kansas

The owner of a 72.3-acre parcel of land had plans to fill deteriorating wetlands before building a subdivision. He was persuaded to enhance them instead and now promotes enhanced and constructed wetlands as the feature selling point of **The Landing**. *A lake with 3,750 feet of shoreline provides aesthetic and recreational value, as well as [illegible] detention of urban runoff.* ***Waterfront lots currently sell for $18,000 to $40,000, a premium of up to $21,000 (150 percent) above comparable lots with no water view*** *(Baird, 1995).*

For further information contact Sally Baird, sales agent, 520 S [illegible] Suite 401, Wichita, Kansas 67209, phone (316) 722-0777.

R0010722

Existing Development

Fairfax County, Virginia *Since their construction in 1971, units facing the constructed pond in the townhouse community of* ***Pinewood Lakes*** *have sold at a premium. Of the 497 units, all with exactly the same square footage according to tax records, only 20 have direct water views in either the front or the rear. Figures show the average 1994 sales price of townhouses lacking the water amenity to be $93,833. The average waterfront sales price is $100,000, a premium of $6,117.* ***Higher sales prices for properties with views of the water have been consistent for 23 years*** *(Wade, 1995).*

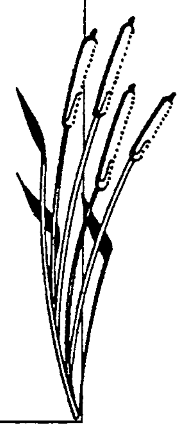
Evans Mills *is an upscale community of 41 townhouses in the Tysons Corner area built around an existing pond. Fairfax County tax records show Evans Mills waterfront townhouses sell at higher prices.* ***In 1994, waterfront homes sold for an average $17,467 premium above the average*** *$419,200 price of homes not facing the pond (Wade, 1995).*

Single-family homes can have higher initial sale values as well as higher resale values when they face urban runoff detention areas. County tax records reveal that land values in ***Franklin Farms****, an established residential neighborhood in northern Virginia, are highest when located in view of its 5-acre urban runoff detention area, which is surrounded by a walking path furnished by the developer.* ***"Waterfront" homes in this neighborhood sold for 10 to 20 percent more initially and again at resale than land with no water view*** *(Downham, 1995). (These percentages might be slightly higher than actual premiums due to possible additional amenities in the waterfront homes.)*

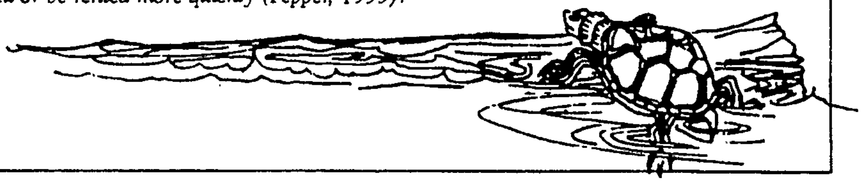
Commercial Property

Prince George's County, Maryland ***Laurel Lakes Executive Park****, commercial property in Laurel, Maryland, also has created an attractive wet pond system.* ***Office space fronting the water rents at a premium of $100 to $200 per month*** *depending on the size and layout of the office space (Kalish, 1995). On average, first-class office space located in Prince George's County with a lakefront view rents for between $17.50 and $20.00 per square foot, whereas properties without a view rent for between $16.50 and $18.50 per square foot (Duncan, 1995).*

Fairfax County, Virginia *Commercial office space also can be valued higher when it fronts aesthetically designed runoff retention ponds. The lakefront* ***Lakeside at Avion*** *and* ***Tysons Pond****, both located in Fairfax County, Virginia, are examples of commercial projects that took advantage of the requirement to implement urban runoff management controls by enhancing a retention pond and then capitalizing on the presence of the pond when naming the project.* ***In Fairfax, Virginia, the average cost of commercial office space without water as an amenity is approximately $15 per square foot. The average leasing rate for commercial waterfront office space is $16 per square foot*** *(Consum. 1995 Goeller, 1995).*



In a soft commercial real estate market, where office space is overabundant, it can be difficult to ask for a premium of any kind. However, ***real estate brokers agree that, when all else is equal, commercial waterfront property rents considerably faster than space that does not front water*** *(Berman, 1995; Constam, 1995; Goeller, 1995; Pepper, 1995). Although a tenant might not be charged for a water amenity, it can provide a steadier flow of income and fewer vacancies for the realtor (Berman, 1995). Mike Pepper, Vice President of CB Commercial Real Estate Group, Inc., declares that "There is absolutely a premium associated with commercial lakefront property. Anything adding to the aesthetic value is going to raise a property's value." Mr. Pepper concedes that in the saturated market of northern Virginia, property with a water view might or might not rent for a $1-$3 per square foot premium, but will always sell or be rented more quickly (Pepper, 1995).*



Conclusion

ENVIRONMENTAL BENEFITS are not the only valid reason for encouraging developers to incorporate urban runoff controls into new residential and commercial developments. Increased property values can result from aesthetically landscaped controls. Both homeowners and developers have realized benefits from beautification of areas adjacent to waterways and detention ponds. Residents find the beauty and tranquility of water, as well as fish, birds, and other wildlife, highly desirable. The beauty of natural surroundings increases real residential property values by up to 28 percent while also enhancing the quality of life. Commercial property owners, too, can benefit when their property is adjacent to an aesthetically designed urban runoff control. They can realize lower vacancies, lower tenant turnover, and high rental prices. Real estate professionals agree that the more amenities a property has, the faster it will sell or rent. Of course, to maintain higher property values, aesthetics must be considered during the operation and maintenance of wet ponds and constructed wetlands over the years. Moreover, for runoff controls to be successful, they must have the support of people in the community as well as developers (Adams et al., 1984). Then, everyone can benefit.

(2) For any group application submitted in accordance with paragraph (c)(2) of this section:

(i) Part 1 of the application shall be submitted to the Director, Office of Water Enforcement and Permits by March 18, 1991;

(ii) Based on information in the part 1 application, the Director will approve or deny the members in the group application within 60 days after receiving part 1 of the group application.

(iii) Part 2 of the application shall be submitted to the Director, Office of Water Enforcement and Permits no later than 12 months after the date of approval of the part 1 application.

(iv) Facilities that are rejected as members of a group by the permitting authority shall have 12 months to file an individual permit application from the date they receive notification of their rejection.

(v) A facility listed under paragraph (b)(14) (i)-(xi) of this section may add on to a group application submitted in accordance with paragraph (e)(2)(i) of this section at the discretion of the Office of Water Enforcement and Permits, and only upon a showing of good cause by the facility and the group applicant; the request for the addition of the facility shall be made no later than February 18,1992; the addition of the facility shall not cause the percentage of the facilities that are required to submit quantitative data to be less than 10%, unless there are over 100 facilities in the group that are submitting quantitative data; approval to become part of group application must be obtained from the group or the trade association representing the individual facilities.

(3) For any discharge from a large municipal separate storm sewer system;

(i) Part 1 of the application shall be submitted to the Director by November 18, 1991;

(ii) Based on information received in the part 1 application the Director will approve or deny a sampling plan under paragraph (d)(1)(iv)(E) of this section within 90 days after receiving the part 1 application;

(iii) Part 2 of the application shall be submitted to the Director by November 16, 1992.

(4) For any discharge from a medium municipal separate storm sewer system;

(i) Part 1 of the application shall be submitted to the Director by May 18, 1992.

(ii) Based on information received in the part 1 application the Director will approve or deny a sampling plan under paragraph (d)(1)(iv)(E) of this section within 90 days after receiving the part 1 application.

(iii) Part 2 of the application shall be submitted to the Director by May 17, 1993.

(5) A permit application shall be submitted to the Director within 60 days of notice, unless permission for a later date is granted by the Director (*see* 40 CFR 124.52(c)), for:

(i) A storm water discharge which the Director, or in States with approved NPDES programs, either the Director or the EPA Regional Administrator, determines that the discharge contributes to a violation of a water quality standard or is a significant contributor of pollutants to waters of the United States (see paragraph (a)(1)(v) of this section);

(ii) A storm water discharge subject to paragraph (c)(1)(v) of this section.

(6) Facilities with existing NPDES permits for storm water discharges associated with industrial activity shall maintain existing permits. New applications shall be submitted in accordance with the requirements of 40 CFR 122.21 and 40 CFR 122.26(c) 180 days before the expiration of such permits. Facilities with expired permits or permits due to expire before May 18, 1992, shall submit applications in accordance with the deadline set forth under paragraph (e)(1) of this section.

(f) *Petitions.* (1) Any operator of a municipal separate storm sewer system may petition the Director to require a separate NPDES permit (or a permit issued under an approved NPDES State program) for any discharge into the municipal separate storm sewer system.

(2) Any person may petition the Director to require a NPDES permit for a discharge which is composed entirely of storm water which contributes to a violation of a water quality standard or is a significant contributor of pollutants to waters of the United States.

(3) The owner or operator of a municipal separate storm sewer system may petition the Director to reduce the Census estimates of the population served by such separate system to account for storm water discharged to combined sewers as defined by 40 CFR 35.2005(b)(11) that is treated in a publicly owned treatment works. In municipalities in which combined sewers are operated, the Census estimates of population may be reduced proportional to the fraction, based on estimated lengths, of the length of combined sewers over the sum of the length of combined sewers and municipal separate storm sewers where an applicant has submitted the NPDES permit number associated with each discharge point and a map indicating areas served by combined sewers and the location of any combined sewer overflow discharge point.

(4) Any person may petition the Director for the designation of a large or medium municipal separate storm sewer system as defined by paragraphs (b)(4)(iv) or (b)(7)(iv) of this section.

(5) The Director shall make a final determination on any petition received under this section within 90 days after receiving the petition.

6. Section 122.28(b)(2)(i) is revised to read as follows:

§ 122.28 General permits (applicable to State NPDES programs, see § 123.25).

* * * * *

(b) * * *

(2) *Requiring an individual permit.* (i) The Director may require any discharger authorized by a general permit to apply for and obtain an individual NPDES permit. Any interested person may petition the Director to take action under this paragraph. Cases where an individual NPDES permit may be required include the following:

(A) The discharger or "treatment works treating domestic sewage" is not in compliance with the conditions of the general NPDES permit;

(B) A change has occurred in the availability of demonstrated technology or practices for the control or abatement of pollutants applicable to the point source or treatment works treating domestic sewage;

(C) Effluent limitation guidelines are promulgated for point sources covered by the general NPDES permit;

(D) A Water Quality Management plan containing requirements applicable to such point sources is approved;

(E) Circumstances have changed since the time of the request to be covered so that the discharger is no longer appropriately controlled under the general permit, or either a temporary or permanent reduction or elimination of the authorized discharge is necessary;

(F) Standards for sewage sludge use or disposal have been promulgated for the sludge use and disposal practice covered by the general NPDES permit; or

(G) The discharge(s) is a significant contributor of pollutants. In making this determination, the Director may consider the following factors:

(*1*) The location of the discharge with respect to waters of the United States;

(*2*) The size of the discharge;

(*3*) The quantity and nature of the pollutants discharged to waters of the United States; and

(*4*) Other relevant factors;

* * * * *

B-11

R0010725

7. Section 122.42 is amended by adding paragraph (c) to read as follows:

§ 122.42 Additional conditions applicable to specified categories of NPDES permits (applicable to State NPDES programs, see § 123.25).

* * * * *

(c) *Municipal separate storm sewer systems.* The operator of a large or medium municipal separate storm sewer system or a municipal separate storm sewer that has been designated by the Director under § 122.26(a)(1)(v) of this part must submit an annual report by the anniversary of the date of the issuance of the permit for such system. The report shall include:

(1) The status of implementing the components of the storm water management program that are established as permit conditions;

(2) Proposed changes to the storm water management programs that are established as permit condition. Such proposed changes shall be consistent with § 122.26(d)(2)(iii) of this part; and

(3) Revisions, if necessary, to the assessment of controls and the fiscal analysis reported in the permit application under § 122.26(d)(2)(iv) and (d)(2)(v) of this part;

(4) A summary of data, including monitoring data, that is accumulated throughout the reporting year;

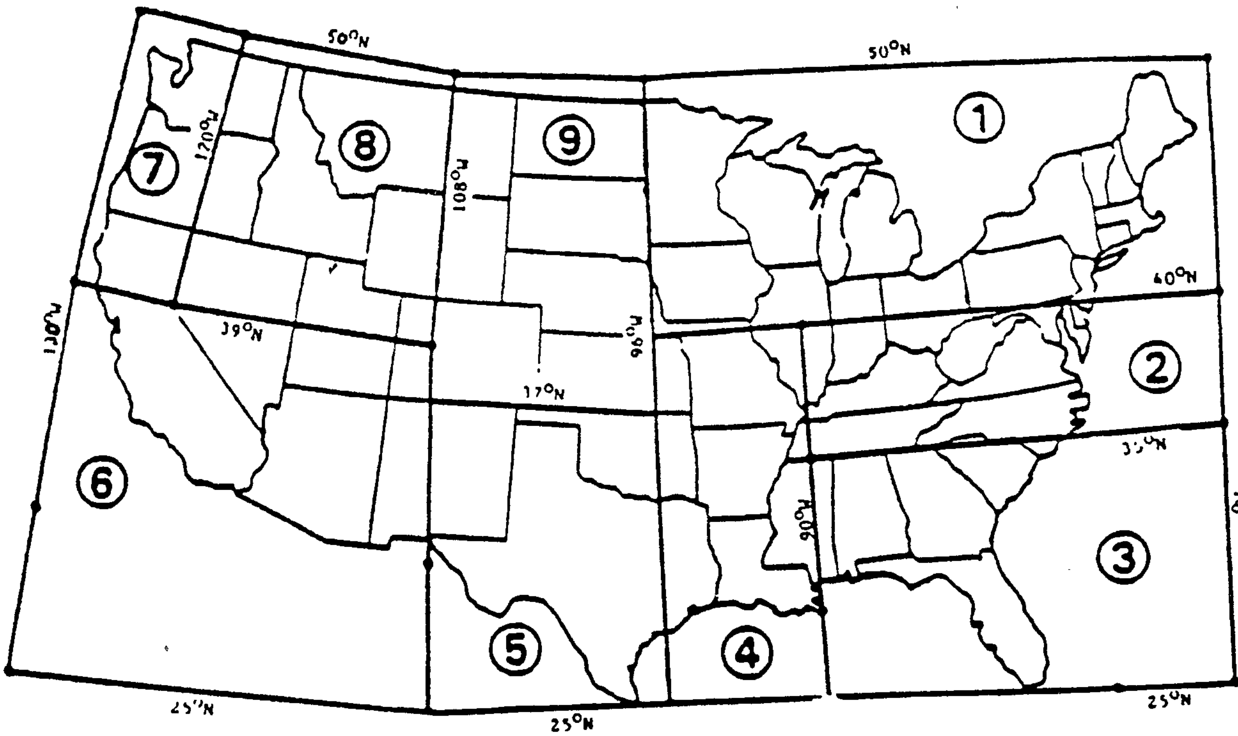
(5) Annual expenditures and budget for year following each annual report;

(6) A summary describing the number and nature of enforcement actions, inspections, and public education programs;

(7) Identification of water quality improvements or degradation;

7a. Part 122 is amended by adding appendices E through I as follows:

Appendix E to Part 122—Rainfall Zones of the United States



Not Shown: Alaska (Zone 7); Hawaii (Zone 7); Northern Mariana Islands (Zone 7); Guam (Zone 7); American Samoa (Zone 7); Trust Territory of the Pacific Islands (Zone 7); Puerto Rico (Zone 3) Virgin Islands (Zone 3).

PART 123—STATE PROGRAM REQUIREMENTS

8. The authority citation for part 123 continues to read as follows:

Authority: Clean Water Act, 33 U.S.C. 1251 *et seq.*

9. Section 123.25 is amended by revising paragraph (a)(9) to read as follows:

§ 123.25 Requirements for permitting.

(a) * * *

(9) § 122.26—(Storm water discharges);

* * * * *

PART 124—PROCEDURES FOR DECISIONMAKING

10. The authority citation for part 124 continues to read as follows:

Authority: Resource Conservation and Recovery Act, 42 U.S.C. 6901 *et seq.*; Safe Drinking Water Act, 42 U.S.C. 300f *et seq.*; Clean Water Act, 33 U.S.C. 1251 *et seq.*; and Clean Air Act, 42 U.S.C. 1857 *et seq.*

11. Section 124.52 is revised to read as follows:

§ 124.52 Permits required on a case-by-case basis.

(a) Various sections of part 122, subpart B allow the Director to determine, on a case-by-case basis, that certain concentrated animal feeding operations (§ 122.23), concentrated aquatic animal production facilities (§ 122.24), storm water discharges (§ 122.26), and certain other facilities covered by general permits (§ 122.28) that do not generally require an individual permit may be required to obtain an individual permit because of their contributions to water pollution.

(b) Whenever the Regional Administrator decides that an individual permit is required under this section, except as provided in paragraph (c) of this section, the Regional Administrator shall notify the discharger in writing of that decision and the reasons for it, and shall send an application form with the notice. The discharger must apply for a permit under § 122.21 within 60 days of notice, unless permission for a later date is granted by the Regional Administrator. The question whether the designation was proper will remain open for consideration during the public comment period under § 124.11 or § 124.118 and in any subsequent hearing.

(c) Prior to a case-by-case determination that an individual permi is required for a storm water discharge under this section (*see* 40 CFR 122.26 (a)(1)(v) and (c)(1)(v)), the Regional Administrator may require the discharger to submit a permit application or other information regarding the discharge under section 308 of the CWA. In requiring such information, the Regional Administrator shall notify the discharger in writing and shall send an application form with the notice. The discharger must apply for a permit under § 122.26 within 60 days of notice, unless permission for a later date is granted by the Regional Administrator. The question whether the initial designation was proper will remain open for consideration during the public comment period under § 124.11 or § 124.118 and in any subsequent hearing.

Note: The following form will not appear in the Code of Federal Regulations.

BILLING CODE 6560-50-M

R0010728

APPENDIX C:
ADEQUATE LEGAL AUTHORITY

contrivance for the elimination or destruction of human waste, within those portions of the watershed of the city contiguous to the intake of the city's water supply, as hereinafter described, or by placing any foul or putrescible substance, whether solid or liquid, and whether the same be buried or not, within the limits of the portion of the watershed so described.

Sec. 49-6. Application for permit.

(a) Any person who desires to use or develop any vegetated wetland and on and after January 1, 1983, any nonvegetated wetland, within this city, other than for those activities specified in section 49-3 above, shall first file an application for a permit with the wetlands board.

Sec. 49-22. Application for permit.

(a) Any person who desires to use or alter any coastal primary sand dune within this city, other than for those activities specified in section 49-20 above, shall first file an application for a permit with the wetlands board.

1.6 Authority to Meet Part 2 Permit Requirements

The NPDES stormwater permit application regulations require an assessment of whether existing legal authority is sufficient to meet the criteria for Part 2 of the permit application provided in *40 CFR 122.26(d)(2)(i)* as follows:

40 CFR 122.26(d)(2)(i)

A demonstration that the applicant can operate pursuant to legal authority established by statute, ordinance or series of contracts which authorizes or enables the applicant at a minimum to:

(A) Control through ordinance, permit, contract, order or similar means, the contribution of pollutants to the municipal storm sewer system by storm water discharges associated with industrial activity and the quality of storm water discharged from sites of industrial activity;

(B) Prohibit through ordinance, order or similar means, illicit discharges to the municipal separate storm sewer;

(C) Control through ordinance, order or similar means the discharge to a municipal separate storm sewer of spills, dumping or disposal of materials other than storm water;

(D) Control through interagency agreements among coapplicants the contribution of pollutants from one portion of the municipal system to another portion of the municipal system;

(E) Require compliance with conditions in ordinances, permits, contracts or order; and

(F) Carry out all inspection, surveillance and monitoring procedures necessary to determine compliance and noncompliance with permit conditions including the prohibition on illicit discharges to the municipal separate storm sewer.

The City Code sections identified above are referenced in an assessment of the individual Part 2 legal authority criteria.

(A) Control through ordinance, permit, contract, order or similar means, the contribution of pollutants to the municipal storm sewer system by storm water discharges associated with industrial activity and the quality of storm water discharged from sites of industrial activity. Section 39.1-19 of the City Code prohibits the discharge of sanitary sewer flow to the storm sewer system. Section 39.2-5 of the City Code prohibits the discharge of any sewage from a private sewage disposal facility on any public or private property in the City. Section 41.1-4 of the City Code prohibits pollutants to be discharged to the storm sewer system including the discharge of industrial process water, wash water, or other unpermitted industrial discharges in Section 41.1-4(c). Section 41.1-5 of the City Code provides the City with authority to order the correction of drainage problems on any site in the City. Sections 9-10, 30-69, 41-16, and 41-17 of the City Code prohibit pollution of waters of the City and littering. Sections 42-20.1 and 42-20.2 of the City Code prohibit the obstruction of drains or drainage areas. Sections 42-24, 42-25, and 42-46 of the City Code establish regulations for protecting the City from spills or deposits of liquid wastes. Section 46-28 of the City Code prohibits pollution of the City's water supply.

For development or redevelopment of industrial sites, the City's Zoning Ordinance establishes lot size, yard size, and maximum lot coverage requirements for industrial activity. Chapter 15 of the City Code establishes erosion and sedimentation control regulations. If development or redevelopment of industrial sites occurs within a Chesapeake Bay Preservation Area, Section 494 of the City's Zoning Ordinance and Chapter 32.2 of the City Code establish stringent criteria for stormwater management, protection of water quality, and use of Best Management Practices. Chapter 49 of the City Code protects development within wetlands or coastal primary sand dunes by requiring a permit application with the wetlands board.

Enforcement provisions and penalties for violations of the referenced sections of City Code are also provided in specific chapters. Chapter 27 of the City Code provides additional authority for the abatement of nuisances.

(B) Prohibit through ordinance, order or similar means, illicit discharges to the municipal separate storm sewer. Section 39.1-19 of the City Code prohibits the discharge of sanitary sewer flow to the storm sewer system. Section 39.2-5 of the City Code prohibits the discharge of any sewage from a private sewage disposal facility on any public or private property in the City. Section 41.1-4 of the City Code prohibits pollutants to be discharged to the storm sewer system. Section 41.1-5 of the City Code provides the City with authority to order the correction of drainage problems on any site in the City. Sections 9-10, 30-69, 41-16, and 41-17 of the City Code prohibit pollution of waters of the City and littering. Sections 42-20.1 and 42-20.2 of the City Code prohibit the obstruction of drains or drainage areas. Sections 42-24, 42-25, and 42-46 of the City Code establish regulations for protecting the City from spills or deposits of liquid wastes. Section 46-28 of the City Code prohibits pollution of the City's water supply.

Enforcement provisions and penalties for violations of the referenced sections of City Code are also provided in specific chapters. Chapter 27 of the City Code provides additional authority for the abatement of nuisances.

(C) Control through ordinance, order or similar means the discharge to a municipal separate storm sewer of spills, dumping or disposal of materials other than storm water. Section 39.1-19 of the City Code prohibits the discharge of sanitary sewer flow to the storm sewer system. Section 39.2-5 of the City Code prohibits the discharge of any sewage from a private sewage disposal facility on any public or private property in the City. Section 41.1-4 of the City Code prohibits pollutants to be discharged to the storm sewer system. Sections 9-10, 30-69, 41-16, and 41-17 of the City Code prohibit pollution of waters of the City and littering. Sections 42-24, 42-25, and 42-46 of the City Code establish regulations for protecting the City from spills or deposits of liquid wastes. Section 46-28 of the City Code prohibits pollution of the City's water supply.

Enforcement provisions and penalties for violations of the referenced sections of City Code are also provided in specific chapters. Chapter 27 of the City Code provides additional authority for the abatement of nuisances.

(D) Control through interagency agreements among coapplicants the contribution of pollutants from one portion of the municipal system to another portion of the municipal system. The City of Norfolk owns the entire separate storm water system and is an individual NPDES permit applicant.

The City of Norfolk relies on its In-Town Reservoir System as a vital part of the water supply system. To protect water quality within the In-Town Reservoir System, the City of Norfolk will seek an intermunicipal agreement with the City of Virginia Beach to control nonpoint source pollution for the areas of the In-Town Reservoir System bordering and located within the jurisdiction of the City of Virginia Beach. After approval of Part 1 of the application by the EPA, the City of Norfolk will meet with the City of Virginia Beach to discuss the development of an agreement before submittal of Part 2 of the application on November 16, 1992.

(E) Require compliance with conditions in ordinances, permits, contracts or order. Enforcement provisions and penalties for violations of the referenced sections of City Code are provided in specific chapters. Chapter 27 of the City Codes provides additional authority for the abatement of nuisances.

(F) Carry out all inspection, surveillance and monitoring procedures necessary to determine compliance and noncompliance with permit conditions including the prohibition on illicit discharges to the municipal separate storm sewer. Chapter 41.1, entitled "Storm Water Management", provides authority for the City's Director of Public Works to establish procedures and enforce regulations pertaining to the storm water system in Section 41.1-3. Authority to prohibit and inspect for illicit connections to the storm sewer system is provided to the Department of City Planning and Codes Administration in Section 39.1-19. Authority to enforce violations of private sewage disposal regulations is provided to the Department of Health in Section 39.2-1 of the City Code. For development and redevelopment, the Department of City Planning and Codes Administration has authority over erosion and sediment control plans, the site review process, and stormwater management regulations required for activity within the Chesapeake Bay Preservation Area. Additional authority for enforcement of erosion and sediment control regulations and stormwater management is being established for the Department of Public Works in an ordinance currently under review by the state. Authority to enforce regulations and permits of the City's Tree Ordinance is provided in Section 30-23 of the City Code.

1.7 Legal Authority Overview

Overall, the City of Norfolk has the existing legal authority, or is in the process of modifying existing City Code with ordinances, to control discharges to the municipal storm sewer system and meet the legal authority requirements of *40 CFR 122.26(d)(2)(i)*.

☆U.S. GOVERNMENT PRINTING OFFICE 1993-717-408/60980

EPA

Preliminary Data Summary of Urban Storm Water Best Management Practices

R0010735

6.0 Costs and Benefits of Storm Water BMPs

Storm water best management practices (BMPs) are the primary tool to improve the quality of urban streams and meet the requirements of NPDES permits. They include both the structural and non-structural options reviewed in Section 5.2 of this report. Some BMPs can represent a significant cost to communities, but these costs should be weighed against the various benefits they provide. This chapter will focus on reviewing available data on the costs and potential benefits of both structural and non-structural BMPs designed to improve the quality of urban and urbanizing streams, and the larger water bodies to which they drain.

As described in previous chapters, storm water runoff can contribute loadings of nutrients, metals, oil and grease, and litter that result in impairment of local water bodies. The extent to which these impairments are eliminated by BMPs will depend on a number of factors, including the number, intensity, and duration of wet weather events; BMP construction and maintenance activities; and the site-specific water quality and physical conditions. Because these factors will vary substantially from site to site, data and information are not available with which to develop dollar estimates of costs and benefits for individual types of BMPs. However, EPA's national estimates of costs and benefits associated with implementation of the NPDES Phase II rule are discussed in Section 6.4.

6.1 Structural BMP Costs

The term structural BMPs, often referred to as "Treatment BMPs," refers to physical structures designed to remove pollutants from storm water runoff, reduce downstream erosion, provide flood control and promote groundwater recharge. In contrast with non-structural BMPs, structural measures include some engineering design and construction.

Structural BMPs evaluated in this report include:

- Retention Basins
- Detention Basins
- Constructed Wetlands
- Infiltration Practices
- Filters
- Bioretention
- Biofilters (swales and filter strips).

The two infiltration systems focused on in this report are infiltration trenches and infiltration basins. Although bioretention can serve as a filtering system or infiltration practice, it is discussed separately because it has separate cost data and design criteria. In this report, wet swales are assumed to have the same cost as biofilters, because there are little cost data available on this practice. Additional information about these structural BMPs, including descriptions, applicability and performance data can be found in Chapter 5 of this report. Other BMPs include experimental and proprietary products, as well as some conventional structures such as water quality inlets. They are not included in this analysis because sufficient data are not available to support either the performance or the cost of these practices.

6.1.1 Base Capital Costs

The base capital costs refer primarily to the cost of constructing the BMP. This may include the cost of erosion and sediment control during construction. The costs of design, geotechnical testing, legal fees, land costs, and other unexpected or additional costs are not included in this estimate. The cost of constructing any BMP is variable and depends largely on site conditions and drainage area. For example, if a BMP is constructed in very rocky soils, the increased excavation costs may substantially increase the cost of construction. Also, land acquisition costs vary greatly from site to site.[4] In addition, designs vary slightly among BMP types. A wet pond may be designed with or without various levels of landscaping, for example. The data in Table 6-1 represent typical unit costs (dollars per cubic foot of treated water volume) from various studies, and should be considered planning level. In the case of retention and detention basins, ranges are used to reflect the economies of scale involved in designing these BMPs.

[4] Land cost is the largest variable influencing overall BMP cost.

Table 6-1. Typical Base Capital Construction Costs for BMPs

BMP Type	Typical Cost* ($/cf)	Notes	Source
Retention and Detention Basins	0.50-1.00	Cost range reflects economies of scale in designing this BMP. The lowest unit cost represents approx. 150,000 cubic feet of storage, while the highest is approx. 15,000 cubic feet. Typically, dry detention basins are the least expensive design options among retention and detention practices.	Adapted from Brown and Schueler (1997b)
Constructed Wetland	0.60-1.25	Although little data are available to assess the cost of wetlands, it is assumed that they are approx. 25% more expensive (because of plant selection and sediment forebay requirements) than retention basins..	Adapted from Brown and Schueler (1997b)
Infiltration Trench	4.00	Represents typical costs for a 100-foot long trench.	Adapted from SWRPC (1991)
Infiltration Basin	1.30	Represents typical costs for a 0.25-acre infiltration basin.	Adapted from SWRPC (1991)
Sand Filter	3.00-6.00	The range in costs for sand filter construction is largely due to the different sand filter designs. Of the three most common options available, perimeter sand filters are moderate cost whereas surface sand filters and underground sand filters are the most expensive.	Adapted from Brown and Schueler (1997b)
Bioretention	5.30	Bioretention is relatively constant in cost, because it is usually designed as a constant fraction of the total drainage area.	Adapted from Brown and Schueler (1997b)
Grass Swale	0.50	Based on cost per square foot, and assuming 6 inches of storage in the filter.	Adapted from SWRPC (1991)
Filter Strip	0.00-1.30	Based on cost per square foot, and assuming 6 inches of storage in the filter strip. The lowest cost assumes that the buffer uses existing vegetation, and the highest cost assumes that sod was used to establish the filter strip.	Adapted from SWRPC (1991)

* Base year for all cost data: 1997

In some ways there is no such value as the "average" construction cost for some BMPs, because many BMPs can be designed for widely varying drainage areas. However, there is some value in assessing the cost of a typical application of each BMP. The data in Table 6-2 reflect base capital costs for typical applications of each category of BMP. It is important to note that, since many BMPs have economies of scale, it is not practical to extrapolate these values to larger or smaller drainage areas in many cases.

Table 6-2. Base Costs of Typical Applications of Storm Water BMPs[1]

BMP Type	Typical Cost ($/BMP)	Application	Data Source
Retention Basin	$100,000	50-Acre Residential Site (Impervious Cover = 35%)	Adapted from Brown and Schueler (1997b)
Wetland	$125,000	50-Acre Residential Site (Impervious Cover = 35%)	Adapted from Brown and Schueler (1997b)
Infiltration Trench	$45,000	5-Acre Commercial Site (Impervious Cover = 65%)	Adapted from SWRPC (1991)
Infiltration Basin	$15,000	5-Acre Commercial Site (Impervious Cover = 65%)	Adapted from SWRPC (1991)
Sand Filter	$35,000-$70,000[2,3]	5-Acre Commercial Site (Impervious Cover = 65%)	Adapted from Brown and Schueler (1997b)
Bioretention	$60,000	5-Acre Commercial Site (Impervious Cover = 65%)	Adapted from Brown and Schueler (1997b)
Grass Swale	$3,500	5-Acre Residential Site (Impervious Cover = 35%)	Adapted from SWRPC (1991)
Filter Strip	$0-$9,000[3]	5-Acre Residential Site (Impervious Cover = 35%)	Adapted from SWRPC (1991)

1. Base costs do not include land costs.
2. Total capital costs can typically be determined [illegible] these costs by approximately 30%.
3. A range is given to account for design variations

Although various manuals report construction cost estimates for storm water ponds, EPA has identified only three studies that have systematically evaluated the construction costs associated with structural BMPs since 1985. The three studies used slightly different estimation procedures. Two of these studies were conducted in the Washington, DC region and used a similar methodology (Wiegand et al, 1986; Brown and Schueler, 1997b). In both studies, the costs were determined based on engineering estimates of construction costs from actual BMPs throughout the region. In the third study, conducted in Southeastern Wisconsin, costs were determined using standardized cost data for different elements of the BMP, and assumptions of BMP design (SWRPC, 1991).

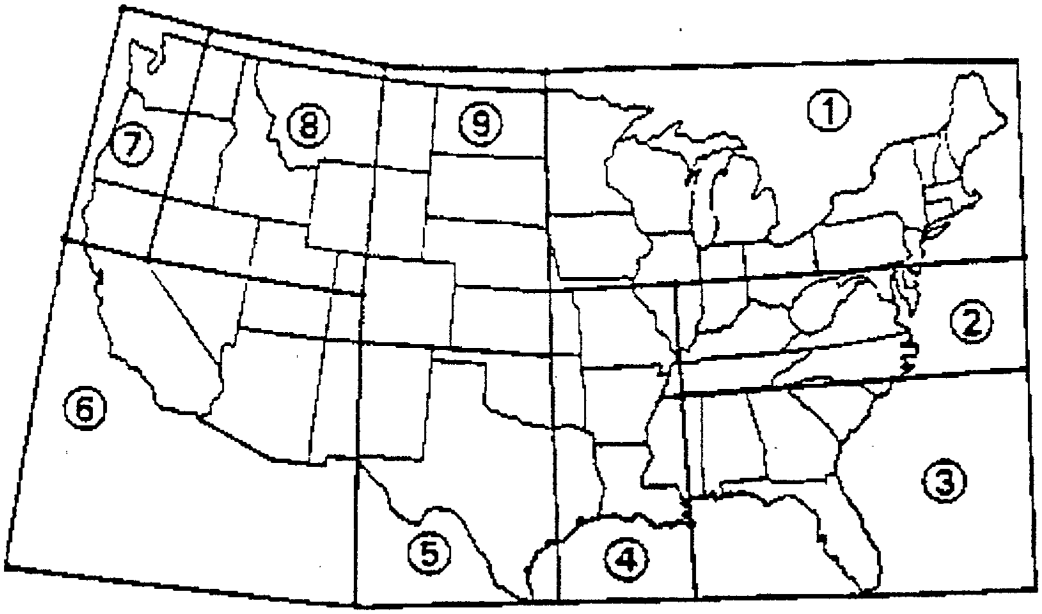
Any costs reported in the literature need to be adjusted for inflation and regional differences. All costs reported in this report assume a 3 percent annual inflation rate. In addition, studies are adjusted to the "twenty cities average" construction cost index, to adjust for regional biases, based on a methodology followed by the American Public Works Association (APWA, 1992). Using EPA's rainfall zones (see Figure 6-1), a cost adjustment factor is assigned to each zone (Table 6-3). For example, rainfall region 1 has a factor of 1.12. Thus, all studies in the Northeastern United States are divided by 1.12 in order to adjust for this bias.

Table 6-3. Regional Cost Adjustment Factors

Rainfall Zone	1	2	3	4	5	6	7	8	9
Adjustment Factor	1.12	0.90	0.67	0.92	0.67	1.24	1.04	1.04	0.76

Source: Modified from APWA, 1992

Figure 6-1. Rainfall Zones of the United States



Not shown: Alaska (Zone 7); Hawaii (Zone 7); Northern Mariana Islands (Zone 7); Guam (Zone 7); American Samoa (Zone 7); Trust Territory of the Pacific Islands (Zone 7); Puerto Rico (Zone 3) Virgin Islands (Zone 3).
Source: NPDES Phase I regulations, 40 CFR Part 122, Appendix E (US EPA, 1990)

6.1.1.1 Retention/Detention Basins and Constructed Wetlands

The total volume of the basin is generally a strong predictor of cost (Table 6-4). There are some economies of scale associated with constructing these systems, as evidenced by the slope of the volume equations derived. This is largely because of the costs of inlet and outlet design, and mobilization of heavy equipment that are relatively similar regardless of basin size.

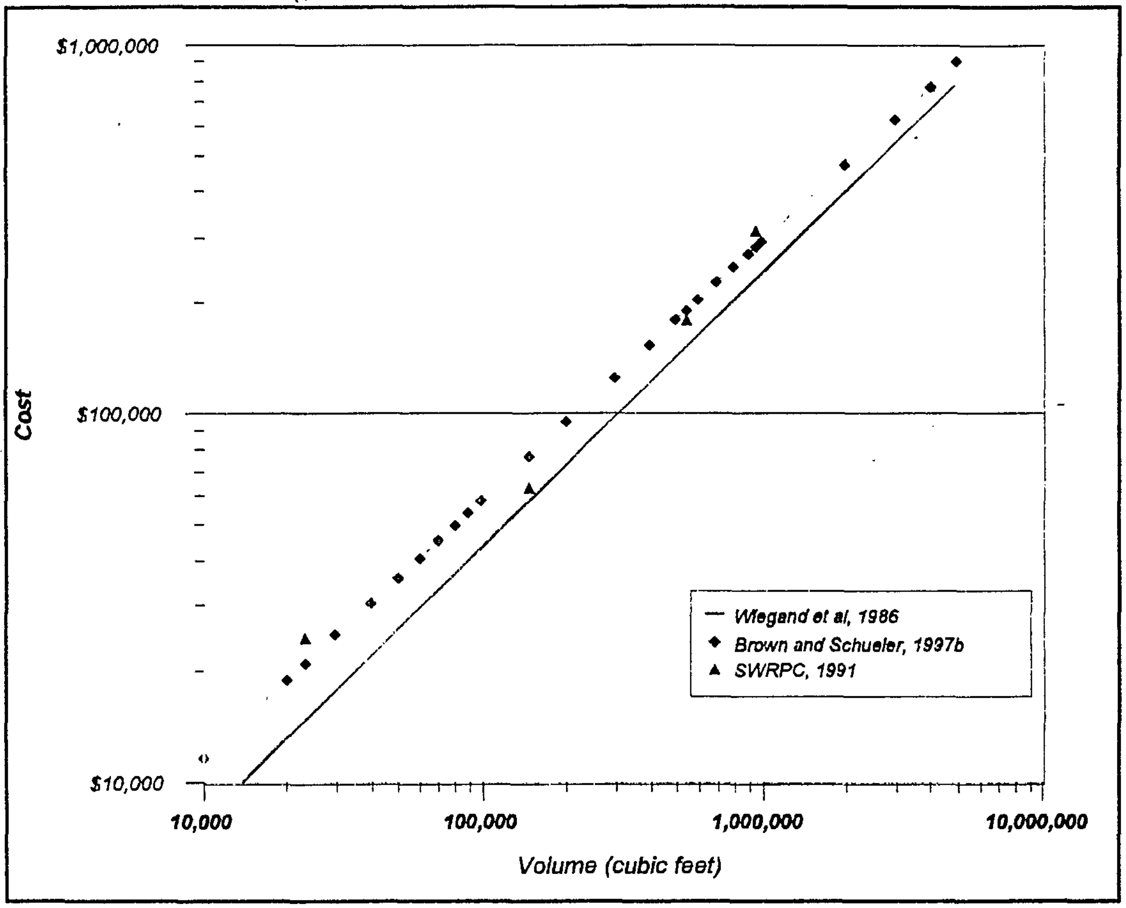
Erosion and sediment control represents only about 5 percent of the construction cost of basins and wetlands (Brown and Schueler, 1997b). Thus, the construction cost estimates presented in Table 6-2 are comparable. The cost of building storm water retention and detention systems has increased since 1986 (Figure 6-2), even after adjusting for inflation. Part of the reason for this increase is thought to be attributable to the improved design of these systems to enhance water quality driven by a more complex regulatory and review environment (Brown and Schueler, 1997b). The cost estimations made by SWRPC (1991) were generally a mid-range between the earlier and more recent studies.

Table 6-4. Base Capital Costs for Storm Water Ponds and Wetlands

BMP Type	Cost Equation or Estimate	Costs Included		Source
		Construction	E&S Control	
Retention Basins and Wetlands	$7.75V^{0.75}$	✔	✔	Wiegand et al, 1986
	$18.5V^{0.70}$	✔		Brown and Schueler, 1997b
Detention Basins	$7.47V^{0.78}$	✔	✔	Brown and Schueler, 1997b
Retention Basins	1.06V: 0.25 acre retention basin (23,300 cubic feet)	✔		SWRPC, 1991
	0.43V: 1.0 acre retention basin (148,000 cubic feet)			
	0.33V: 3.0 acre retention basin (547,000 cubic feet)			
	0.31V: 5.0 acre retention basin (952,000 cubic feet)			

Notes
V refers to the total basin volume in cubic feet
Costs presented from SWRPC (1991) are "moderate" costs reported in that study.

Figure 6-2. Retention Basin Construction Cost



6.1.1.2 Infiltration Practices

Costs for infiltration BMPs are highly variable from site to site, depending on soils and other geotechnical information. Perhaps because of this variability, cost estimates for infiltration trenches have been widely different (Table 6-5; Figure 6-3). Brown and Schueler (1997b) concluded that the Wiegand (1986) equation underestimated cost, partially because of the lack of pretreatment in earlier designs, although they were unable to develop a consistent equation due to a small sample size.

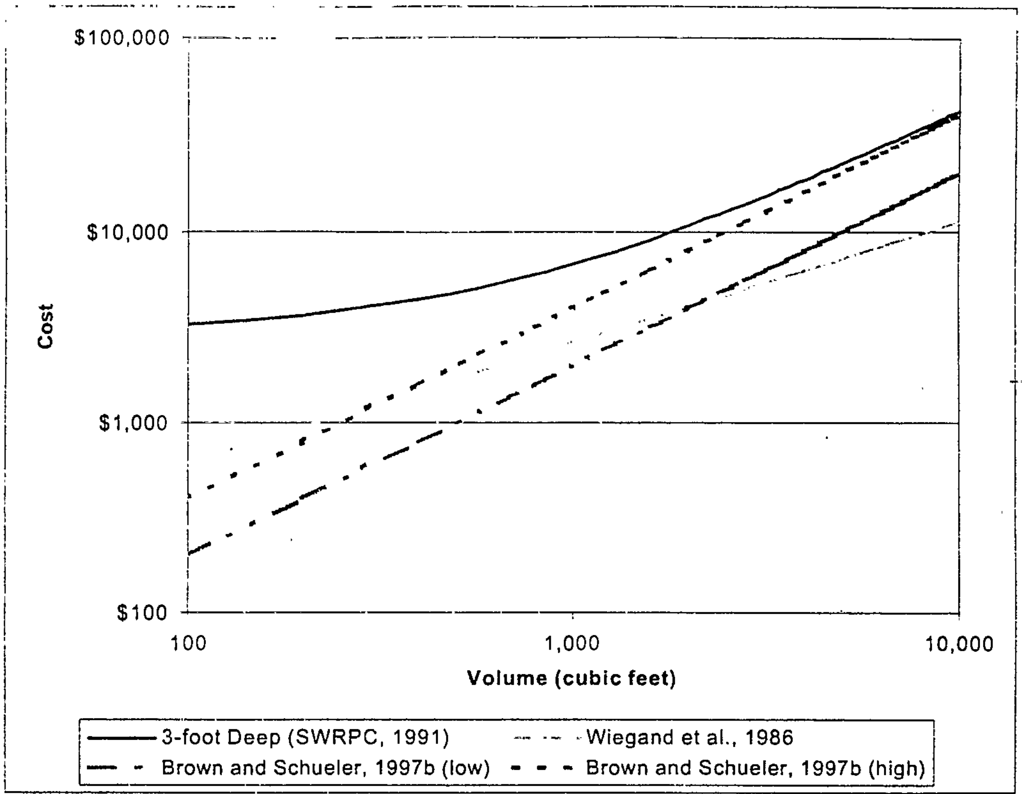
It is difficult to estimate the cost of infiltration basins, mainly due to a lack of recent cost data. The costs estimates for SWRPC are dramatically higher than those estimated by Schueler, 1987 (Figure 6-4). This is largely because the SWRPC document assumes that 50 percent additional volume is excavated for the spillway, while Schueler uses a retention basin cost equation.

Table 6-5. Base Capital Costs for Infiltration Practices

BMP Type	Cost Equation or Estimate[4]	Costs Included		Source
		Construction	E&S Control	
Infiltration Trenches[1]	$33.7V^{0.63}$	✔		Wiegand et al, 1986
	2V to 4V; average of 2.5V	✔		Brown and Schueler, 1997b
	$4,400: 3-foot deep, 4-foot wide, 100-foot long trench	✔		SWRPC, 1991
	$10,400: 6-foot deep, 10-foot wide, 100-foot long trench			
	3.9V+2,900: 3-foot deep, 100-foot long trench	✔		Modified from SWRPC, 1991
Infiltration Basins[2]	$13.2V^{0.69}$	✔	✔	Schueler, 1987; Modified from Wiegand et al, 1986
	1.3V: 0.25-acre infiltration basin (15,000 cubic feet)	✔		SWRPC, 1991
	0.8V: 1.0-acre infiltration basin (76,300 cubic feet)			
Porous Pavement[3]	50,000A	✔		SWRPC, 1991
	80,000A	✔		Schueler, 1987

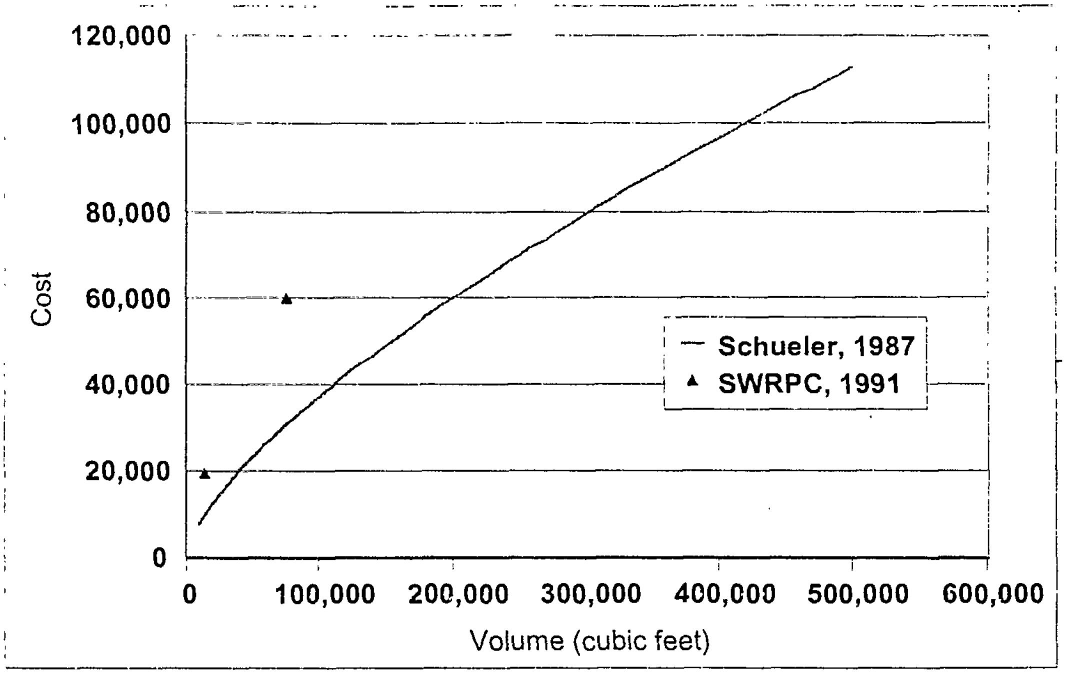
1. V for infiltration trenches refers to the treatment volume (cubic feet) within the trench, assuming a porosity of 32%.
2. V for infiltration basins refers to the total basin volume (cubic feet).
3. A is the surface area in acres of porous pavement.
4. Costs presented from SWRPC (1991) are "moderate" costs reported in that study.

Figure 6-3. Infiltration Trench Cost



R0010745

Figure 6-4. Infiltration Basin Construction Cost



6.1.1.3 Sand Filters

Since sand filters have not been used as long as other BMPs, less information is available on their cost than on most BMPs. In addition, the costs of sand filters vary significantly due to the wide range of design criteria for sand filters (Table 6-6). Brown and Schueler (1997b) were unable to derive a valid relationship between sand filter cost and water quality volume, with costs ranging between $2 and $6 per cubic foot of water quality volume, with a mean cost of $2.50 per cubic foot. The water quality volume includes the pore space in the sand filter, plus additional storage in the pretreatment basin.

Because of the lack of cost data, no equation referencing the economies of scale has been developed. However, it appears that economies of scale do exist. For example, data from Austin indicates that the cost per acre decreased by over 80 percent for a design of a 20-acre drainage area, when compared with a 1-acre drainage area. (Schueler, 1994a).

R0010746

Table 6-6. **Construction Costs for Various Sand Filters**

Region (Design)	Cost/Impervious Acre
Delaware	$10,000
Alexandria, VA (Delaware)	$23,500
Austin, TX (< 2 acres)	$16,000
Austin, TX (> 5 acres)	$3,400
Washington, DC (underground)	$14,000
Denver, CO	$30,000-$50,000

Source: Schueler, 1994a

6.1.1.4 Bioretention

Little information is available on the costs of bioretention because it is a relatively new practice. Brown and Schueler (1997b) found consistent construction costs of approximately $5.30 per cubic foot of water quality volume for the construction cost. The water quality volume includes 9 inches above the surface area of the bioretention structure.

6.1.1.5 Vegetative BMPs

The two major types of vegetative BMPs include filter strips and grassed swales (also called "biofilters"). The costs for these BMPs vary, and largely depend on the method used to establish vegetation (Table 6-7).

Table 6-7. Base Capital Costs of Vegetative BMPs

BMP Type	Cost Equation or Estimate[1]	Costs Included		Source
		Construction	E&S Control	
Filter Strips	Existing Vegetation: 0	✔		SWRPC, 1991
	Seed: $13,800/acre			
	Sod: $29,000/acre			
Grassed Channels	25¢ per square foot	✔		SWRPC, 1991

1. Costs presented from SWRPC (1991) are "moderate" costs reported in that study.

6.1.2 Design, Contingency and Permitting Costs

Most BMP cost studies assess only part of the cost of constructing a BMP, usually excluding permitting fees, engineering design and contingency or unexpected costs. In general, these costs are expressed as a fraction of the construction cost (Table 6-8). These costs are generally only estimates, based on the experience of designers.

Table 6-8. Design, Contingency and Permitting Costs

Additional Costs Estimate (Fraction of base construction costs)	Source	Comments
25%	Wiegand et al, 1986	Includes design, contingencies and permitting fees
32%	Brown and Schueler, 1997b	Includes design, contingencies, permitting process and erosion and sediment control

6.1.3 Land Costs

The cost of land is extremely variable both regionally and by surrounding land use. For example, many suburban jurisdictions require open space allocations within the developed site, reducing the effective cost of land for BMPs to zero (Schueler, 1987). On the other hand, the cost of land may far outweigh construction and design costs in ultra-urban settings. For this reason, some underground BMPs that are relatively expensive to construct may be attractive in this "ultra-urban" setting if sub-surface conditions are suitable (Lundgren, 1996). The land consumed per treatment volume depends largely on how much of the BMP's treatment is underground, and varies considerably (Table 6-9).

Table 6-9. Relative Land Consumption of Storm Water BMPs

BMP Type	Land consumption (% of Impervious Area)
Retention Basin	2-3%
Constructed Wetland	3-5%
Infiltration Trench	2-3%
Infiltration Basin	2-3%
Porous Pavement	0%
Sand Filters	0%-3%
Bioretention	5%
Swales	10%-20%
Filter Strips	100%

Note: Represents the amount of land needed as a percent of the impervious area that drains to the practice to achieve effective treatment.
Source: Claytor and Schueler, 1996

6.1.4 Operation and Maintenance Costs

Maintenance can be broken down into two primary categories: aesthetic/nuisance maintenance and functional maintenance. Functional maintenance is important for performance and safety reasons, while aesthetic maintenance is important primarily for public acceptance of BMPs, and because it may also reduce needed functional maintenance. Aesthetic maintenance is obviously more important for BMPs that are [illegible]sible, such as ponds and biofiltration facilities.

In most studies, operation and maintenance (O&M) costs have been estimated as a percentage of base construction costs (Table [illegible]). While some BMPs require infrequent, costly maintenance, others need more frequent but less costly maintenance.[5] Accordingly, selection of appropriate structural BMPs must factor in maintenance cost (and a responsible party to carry out maintenance) to ensure the necessary long-term performance. Typical maintenance activities are included in Table 5-3.

Table 6-10. Annual Maintenance Costs

BMP	Annual Maintenance Cost (% of Construction Cost)	Source(s)
Retention Basins and Constructed Wetlands	3%-6%	Wiegand et al, 1986 Schueler, 1987 SWRPC, 1991
Detention Basins[1]	<1%	Livingston et al, 1997; Brown and Schueler, 1997b
Constructed Wetlands[1]	2%	Livingston et al, 1997; Brown and Schueler, 1997b
Infiltration Trench	5%-20%	Schueler, 1987 SWRPC, 1991
Infiltration Basin[1]	1%-3%	Livingston et al, 1997; SWRPC, 1991
	5%-10%	Wiegand et al, 1986; Schueler, 1987; SWRPC, 1991
Sand Filters[1]	11%-13%	Livingston et al, 1997; Brown and Schueler, 1997b
Swales	5%-7%	SWRPC, 1991
Bioretention	5%-7%	(Assumes the same as swales)
Filter strips	$320/acre (maintained)	SWRPC, 1991

1. Livingston et al (1997) reported maintenance costs from the maintenance budgets of several cities, and percentages were derived from costs in other studies

[5] Maintenance costs can also vary significantly based on a variety of site- and region-specific parameters, therefore the maintenance costs presented in Table 6-10 should be considered only as general guidelines.

6.1.5 Long-Term BMP Costs: Two Scenarios

In order to compare various BMP options, costs were calculated for a 5-acre commercial site and a 38-acre residential site.[6] Construction costs were evaluated using the following steps:

1. *Calculate the water quality volume* (WQ_v).[7]
Using a water quality volume based on a 1-inch storm, the volume is equal to:

$$WQ_v = (.05 + .9I)\, A/12$$

where:
WQ_v = Water Quality Volume (Acre-Feet)
I = Impervious Fraction in the Watershed
A = Watershed Area (Acres)

2. *Calculate the detention storage volume.*
Total detention storage was determined using standard peak flow methods (USDA/NRCS, 1986). Detention storage was calculated for a 5-inch storm.

3. *Calculate total volume.*
Many BMPs do not require any detention storage, but for BMPs that do provide flood storage, the total volume is the sum of the water quality and detention volumes calculated in steps 1 and 2.

4. *Determine the construction cost.*
The construction cost for each BMP is determined based on equations described in Section 6.1.1.

---

[6] Although these evaluations are useful for comparing potential costs of various structural BMPs, they should not be applied for use in all areas of the country. In addition, the BMPs, selected in these examples and the sizing criteria that the costs were based on should not be considered as recommendations for actual BMP selection and design. They are presented solely for illustrative purposes.

[7] "Water quality volume" refers to the volume of water that the BMP is designed to treat. For example, a BMP may be designed to capture the first inch of runoff from the drainage area. Any volume of rainfall over the first inch would bypass the BMP. Therefore water quality volume for this BMP would be one watershed inch.

6.1.5.1 5-Acre Commercial Development

The following data were used as the basis for the 5-acre commercial development.

Table 6-11. Data for the Commercial Site Scenario

Area (A)	5 acres
Impervious Cover (I)	65%
Water Quality Volume P · Rv · A/12 P = 1" of rainfall Rv = 0.5 + 0.9 (I) A = Drainage Area	0.26 ac-ft
Total Detention Storage (using TR-55 model)	0.74 ac-ft
Total Storage	1.00 ac-ft

These data were then used to compare various BMP options (Table 6-12). Grassed swales and filter strips were not included in this analysis because, although they do improve water quality, they are typically used only in combination with other BMPs in a new development area. Again, it is important to note that the cost of land is not included in this calculation. Although retention basins are the least expensive option on an annual basis, the cost of land may drive designs to less space-consumptive BMPs, such as sand filters or bioretention systems.

Table 6-12. BMP Costs for a Five Acre Commercial Development

BMP Type	Construction Cost Equation	Construction Cost	Typical Design, Contingency & Other Capital Costs (30% of Construction Costs)	Annual Maintenance Costs (% of Construction, $)	Notes	Sources
Retention Basin	$18.5V_t^{0.70}$	$32,700	$9,810	5%; $1,640	Much of the cost associated with this BMP is the extra storage to provide flood control and channel protection. Ponds are very reliable.	a, b, c, d, e
Infiltration Trench	$3.9WQ_v$ +2,900	$47,100	$14,100	12%; $5,650	Although infiltration trenches are designed to last a long time, they need to be inspected and rebuilt if they become clogged.	c, d, e
Infiltration Basin	$1.3WQ_v$	$14,700	$4,410	8%; $1,180	Infiltration basins require careful siting and design to perform effectively..	b, c d, e
Sand Filter	$4WQ_v$	$45,200	$13,600	12%; $5,420	Sand filters require frequent maintenance in order to function long-term.	a, e, f
Bioretention	$5.30WQ_v$	$60,000	$18,000	6%; $3,600	Bioretention is a relatively new BMP. Little is known about its long-term performance.	a, d

1. WQv = Water Quality Volume, cu. ft. 2. V_t = Total Volume, cu. ft.
3. Sand filter volume was estimated at 4WQv, which is slightly high, to account for the relatively small drainage area.

a. Brown and Schueler, 1997b b. Wiegand et al, 1986 c. Schueler, 1987 d. SWRPC, 1991 e. US EPA, 1993a f. Livingston et al, 1997

6.1.5.2 38-Acre Residential Development

The following data were used as the basis for the 38-acre residential development.

Table 6-13. Data for the Residential Site Scenario

Area (A)	38 acres
Impervious Cover (I)	36%
Water Quality Volume	1.1 ac-ft
Total Detention Storage (using TR-55 model)	2.8 ac-ft
Total Storage	3.9 ac-ft

The same analysis conducted for the commercial site was repeated for the larger site (Table 6-14). Bioretention and infiltration systems were not included in this analysis, because these BMPs are best applied on smaller sites. The costs of swales and filter strips were also not included, although they could be effectively used in combination with retention systems to provide pretreatment.

6.1.6 Adjusting Costs Regionally

The cost data in these examples can be adjusted to specific zones of the country using the regional cost adjustment factors in Table 6-3. For example, if costs for Rainfall Zone 1 were needed, the data in Tables 6-12 or 6-14 would be multiplied by 1.12.

In addition, design variations in different regions of the country may cause prices to be changed. For example, wetland and wet ponds may be restricted in arid regions of the country. Furthermore, while retention basins are used in semi-arid regions, they usually incorporate design variations to improve their performance (Saunders and Gilroy, 1997). In cold regions, BMPs may need to be adapted to account for snowmelt treatment, deep freezes and road salt application (Oberts, 1994; Caraco and Claytor, 1997), which will cause additional changes in BMP costs.

Table 6-14. BMP Costs for a Thirty-Eight Acre Residential Development

BMP Type	Construction Cost Equation	Construction Cost	Design, Contingency and other Capital Costs (30% of Construction)	Annual Maintenance Costs (% of Construction; $)	Notes	Sources
Retention Basin	$18.5V_t^{0.70}$	$84,800	$25,400	5%; $4,240	Pond systems are relatively easy to apply to large sites.	a, b, c, d, e
Sand Filter	$2WQ_v$	$95,800	$28,700	12%; $11,500	Although the sand filter is used in this example, some evidence suggests that sand filters may be subject to clogging if used on a site that drains a relatively pervious drainage area such as this one.	a, e, f

1. WQv = Water Quality Volume, cu. ft. 2. Vt = Total Volume, cu. ft.
3. Sand filter volume was estimated at 2V, which is slightly low, to account for the relatively large drainage area

a. Brown and Schueler, 1997b b. Wiegand et al, 1986 c. Schueler, 1987 d. SWRPC, 1991 e. US EPA, 1993a f. Livingston et al, 1997

6.2 Non-Structural BMP Costs

Non-structural BMPs are management measures that prevent degradation of water resources by preventing pollution at the source, rather than treating polluted runoff. Non-structural practices include a variety of site-specific and regional practices, including: street sweeping, illicit connection identification and elimination, public education and outreach, land use modifications to minimize the amount of impervious surface area, waste collection and proper materials storage. While non-structural practices play an invaluable role in protecting surface waters, their costs are generally not as easily quantified as for structural BMPs. This is primarily because there are no "design standards" for these practices. For example, the cost of a public education program may vary due to staff size. However, it is possible to identify costs associated with specific components of these programs based on past experience.

6.2.1 Street Sweeping

The costs of street sweeping include the capital costs of purchasing the equipment, plus the maintenance and operational costs to operate the sweepers. as well as costs of disposing the materials that are removed. Both equipment and operating costs vary depending on the type of sweeper selected. There are several different options for sweepers, but the two basic choices are mechanical sweepers versus vacuum-assisted sweepers. Mechanical sweepers use brushes to remove particles from streets. Vacuum-assisted dry sweepers, on the other hand, use a specialized brush and vacuum system in order to remove finer particles. While the equipment costs of mechanical sweepers are significantly higher, the total operation and maintenance costs of vacuum sweepers can be lower (Table 6-15).

Table 6-15. Street Sweeper Cost Data

Sweeper Type	Life (Years)	Purchase Price ($)	Operation and Maintenance Costs ($/curb mile)	Sources
Mechanical	5	75,000	30	Finley, 1996; SWRPC, 1991
Vacuum-assisted	8	150,000	15	Satterfield, 1996; SWRPC, 1991

Using these data, the cost of operating street sweepers per curb mile were developed, assuming various sweeping frequencies (Table 6-16). The following assumptions were made to conduct this analysis:

- One sweeper serves 8,160 curb miles during a year (SWRPC, 1991).

- The annual interest rate is 8 percent.

Table 6-16. Annualized Sweeper Costs ($/curb mile/year)

Sweeper Type	Sweeping Frequency					
	Weekly	Bi-weekly	Monthly	Four times per year	Twice per year	Annual
Mechanical	1,680	840	388	129	65	32
Vacuum-Assisted	946	473	218	73	36	18

Modified from Finley, 1996; SWRPC, 1991; and Satterfield, 1996

6.2.2 Illicit Connection Identification and Elimination

One source of pollutants is direct connections or infiltration to the storm drain system of wastewaters other than storm water, such as industrial wastes. These pollutants are then discharged through the storm drain system directly to streams without receiving treatment. These illicit connections can be identified using visual inspection during dry weather or through the use of smoke or dye tests. Using visual inspection techniques, illicit connections can be identified for between $1,250 and $1,750 per square mile (Center for Watershed Protection, 1996).

6.2.3 Public Education and Outreach

Public education programs encompass many other more specific programs, such as fertilizer and pesticide management, public involvement in stream restoration and monitoring projects, storm drain stenciling, and overall awareness of aquatic resources. All public education programs seek to reduce pollutant loads by changing people's behavior. They also make the public aware of and gain support for programs in place to protect water resources. Most municipalities have at least some educational component as a part of their program. A recent survey found that 30 of the 32 municipal storm water programs surveyed (94 percent) incorporate an education element and 11 programs (34 percent) mandated this element in law or regulation (Livingston et al, 1997).

The City of Seattle, with a population of approximately 535,000, has a relatively aggressive education program, including classroom and field involvement programs. The 1997 budget for some aspects of the program is included in Table 6-17. Although this does not necessarily reflect typical effort or expenditures, it does provide information on some educational expenditures. These data represent only a portion of the entire annual budget.

Table 6-17. Public Education Costs in Seattle, Washington

Item	Description	1997 Budget
Supplies for Volunteers	Covers supplies for the Stewardship Through Environmental Partnership Program	$17,500
Communications	Communications strategy highlighting a newly formed program within the city	$18,000
Environmental Education	Transportation costs from schools to field visits (105 schools with four trips each)	$46,500
Education Services / Field Trips	Fees for student visits to various sites	$55,000
Teacher Training	Covers the cost of training classroom teachers for the environmental education program	$3,400
Equipment	Equipment for classroom education, including displays, handouts, etc.	$38,800
Water Interpretive Specialist: Staff	Staff to provide public information at two creeks	$79,300
Water Interpretive Specialist: Equipment	Materials and equipment to support interpretive specialist program	$12,100
Youth Conservation Corps	Supports clean-up activities in creeks	$210,900

Source: Washington DOE, 1997

Some unit costs for educational program components (based on two different programs) are included in Table 6-18.

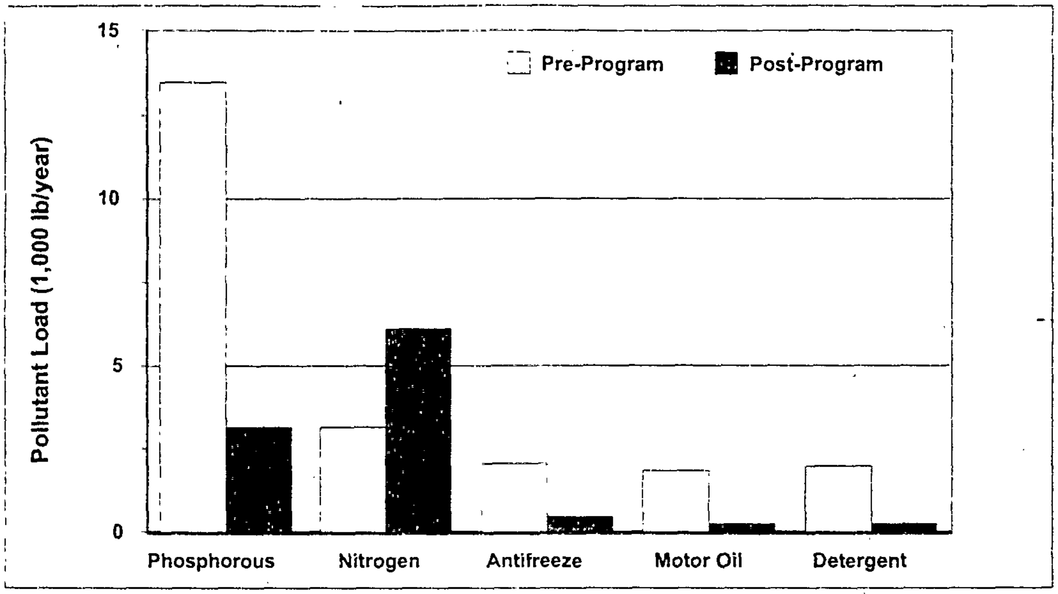
Table 6-18. Unit Program Costs for Public Education Programs

Item	Cost	Source
Public Attitude Survey	$1,250-$1,750 per 1,000 households	Center for Watershed Protection, 1996
Flyers	10-25¢/ flyer	Ferguson et al, 1997
Soil Test Kit*	$10	Ferguson et al, 1997
Paint	25-30¢/SD Stencil	Ferguson et al, 1997
Safety Vests for Volunteers	$2	Ferguson et al, 1997

* Includes cost of testing, but not sampling.

Although public education has the intended benefit of raising public awareness, and therefore creating support of environmental programs, it is difficult to quantify actual pollutant reductions associated with education efforts. Public attitudes can be used as a gauge of how these programs perform, however. In Prince George's County, Maryland a public survey was used in combination with modeling to estimate pollutant load reductions associated with public education (Smith et al, 1994; Claytor, 1996; Figure 6-5). An initial study was conducted to estimate pollution from field application of fertilizers, and use of detergents, oil and antifreeze. Pollutant reductions were then completed assuming that 70 percent of the population complied with recommendations of the public education program. A follow-up survey was used to assess the effectiveness of the program. Although insufficient data were available to support a second model run, a follow-up survey indicated that educational programs influenced many citizen behaviors, such as recycling. They were unsuccessful, however, at changing the rate at which citizens apply lawn fertilizers.

Figure 6-5. Changes in Pollutant Load Associated with a Public Education Program Based on a Public Survey



Source: Claytor, 1996

6.2.4 Land Use Modifications

One of the most effective tools to reduce the impacts of urbanization on water resources is to modify the way growth and development occurs across the landscape. At the jurisdictional or regional level, growth can be managed to minimize the outward extension of development. Jurisdictions can direct growth away from environmentally sensitive areas using such techniques as open space preservation, re-zoning or the transfer of development rights. At the site level, the nature of development can be modified to reduce the impacts of impervious cover at individual development projects through techniques such as reduced street widths, clustered housing, smaller parking lots, and incorporation of vegetative BMPs into site design. While there are legal fees associated with changing both local and regional zoning codes, data suggest that concentrating development and minimizing impervious cover at the site level can actually reduce construction costs to both developers and local governments.

By concentrating development near urban areas, the capital costs of development can be lowered substantially due to existing infrastructure and other public services. With conventional development patterns, the cost of servicing residential developments exceeds the tax revenues from these developments by approximately [illegible] percent (Pelley, 1997). By encouraging growth to occur in a compact region, rather than over a large area, these capital costs can be reduced substantially (Table 6-19).

R0010760

Table 6-19. Comparison of Capital Costs of Municipal Infrastructure for a Single Dwelling Unit

Development Pattern	Capital Costs[1] (1987 Dollars)
Compact Growth[2]	$18,000
Low-Density Growth (3 units/acre)	$35,000
Low-Density Growth, 10 Miles from Existing Development[3]	$48,000

Notes
1. Costs include streets (full curb and gutter), central sewers and water supply, storm drainage and school construction.
2. Assumes housing mix of 30% single family units and townhouses; 70% apartments.
3. Assumes housing is located 10 miles from major concentration of employment, drinking water plant and sewage treatment plant.

Source: Frank, 1989

Savings can also be realized at the site level by reducing the costs of clearing and grading, paving and drainage infrastructure. A recent study compared conventional development plans with alternative options designed to reduce the impacts of development on the quality of water resources. The cost savings realized through these alternative options are summarized in Table 6-20. In all site designs, the road width was reduced from 28 feet to 20 feet, lot sizes were reduced or reconfigured to consume less open space, and on-site storm water treatment was provided.

Table 6-20. Impervious Cover Reduction and Cost Savings of Conservation Development

Location	Techniques Used	Impervious Cover Reduction	Cost Savings
Sussex County, DE	1. Reduced street widths 2. Smaller lots 3. Cluster development	38%	52%
New Castle County, DE	4.Houses clustered into attached units around courtyards	6%	63%
Kent County, DE	5. Reduced road and driveway widths 6. Minimum disturbance boundary	24%	39%

Source: Delaware DNREC, 1997

6.2.5 Oil and Hazardous Waste Collection

Providing a central location for the disposal of oil or hazardous wastes protects water quality by offering citizens an alternative to disposing of these materials in the storm drain. Disposal costs vary considerably depending on the size of the program, and what types of wastes are collected. One study estimated the capital costs at approximately $30,000, with about $12,000 maintenance for a used oil collection recycling program in a typical MS4 (US EPA, 1998b). This estimate was based on data from the Galveston Bay National Estuary Program. Data from the City of Livonia, Michigan indicates that the cost of hazardous waste disposal averages about $12 per gallon (Ferguson et al, 1997).

6.2.6 Proper Storage of Materials

Proper storage of materials can prevent accidental spills or runoff into the storm drain. The design of storage structures varies depending on the needs of the facility. There are also training costs associated with the proper storage of materials. Typical cost estimates, based on standard construction data, are $6 to $11 per square foot for pre-engineered buildings and $3.40 to $5 per square foot for a 6-inch thick concrete slab (Ferguson et al, 1997).

6.3 Benefits of Storm Water BMPs

Although it is possible to estimate the economic benefits of water quality improvement (US EPA, 1983a), it is difficult to create a "balance sheet" of economic costs and benefits for individual BMPs. Ideally, benefits analysis would specify and quantify a chain of events: pollutant loading reductions achieved by the BMP; the physical-chemical properties of receiving streams and consequent linkages to biologic/ecologic responses in the aquatic environment; and human responses and values associated with these changes. However, the necessary data to conduct such an analysis does not currently exist. Instead, the benefits can be outlined in terms of: 1) effectiveness at reducing pollutant loads; 2) direct water quality impacts; and 3) economic benefits or costs.

6.3.1 Storm Water Pollutant Reduction

A primary function of storm water BMPs is to prevent pollutants from reaching streams and rivers. While all BMPs achieve this function to some extent, there is considerable variability between different types of BMPs. The extent of benefits from non-structural BMPs may be more speculative, partly because their ability to influence human behavior is difficult to predict.

A detailed discussion of pollution removal efficiencies for individual structural BMPs is provided in Section 5.5 of this report, so only non-structural BMPs will be reviewed in this section. Unlike structural BMPs, it is generally not possible to associate specific pollutant removal rates with non-structural BMPs, with the exception of street sweeping (Satterfield, 1996). However, some non-structural BMPs are targeted at specific pollutants. Table 6-21 outlines non-structural BMPs believed by designers to be the most effective for removing specific types of pollutants.

Table 6-21. Non-Structural BMPs Suited to Controlling Various Pollutants

Pollutant	Appropriate BMPs	
Solids	Street Sweeping	Land Use Modifications
Oxygen-Demanding Substances	Street Sweeping Education: Storm Drain Stenciling Land Use Modifications	Education: Pet Scoop Ordinance Illicit Connections Eliminated
Nitrogen and Phosphorus	Street Sweeping Education: Pet Scoop Ordinance Land Use Modifications Proper Materials Handling	Illicit Connections Eliminated Education: Lawn Care Materials Storage and Recycling
Pathogens	Illicit Connections Eliminated Land Use Modifications	Education: Pet Scoop Ordinance
Petroleum Hydrocarbons	Street Sweeping Education: Storm Drain Stenciling Proper Materials Handling	Illicit Connections Eliminated Materials Storage and Recycling Land Use Modifications
Metals	Street Sweeping Education: Storm Drain Stenciling Proper Materials Handling	Illicit Connections Eliminated Materials Storage and Recycling Land Use Modifications
Synthetic Organics	Illicit Connections Eliminated Education: Storm Drain Stenciling Proper Materials Handling	Education: Lawn Care Materials Storage and Recycling Land Use Modifications
Temperature	Land Use Modifications	
pH	Illicit Connections Eliminated Proper Materials Handling	Materials Storage and Recycling Land Use Modifications

6.3.1.1 Solids

Both highway runoff and soil erosion can be sources of solids in urban runoff. Street sweeping can reduce solids in urban runoff by removing solids from roadways and parking lots before they can be detached and transported by runoff. The benefits associated with street sweeping depend largely on the climate. In arid regions, airborne pollutants are a serious concern, and there is a long time between storms for pollutants to accumulate[8]. In humid regions, on the other hand, frequent rainfall makes the use of sweepers between storms less practical. In colder

[8] Therefore, regular sweeping programs in these areas can potentially remove large amounts of solids from roadways.

regions, sweeping is recommended twice per year: once in the fall after leaves fall and once in the spring in anticipation of the spring snowmelt (MPCA, 1989).

Modifying land use to preserve open space and to limit the impervious cover can also reduce solids loads. By preserving open space and maintaining vegetative cover, the amount of land cleared is limited, thus reducing the erosion potential during construction. Natural vegetated cover has less than one percent of the erosion potential of bare soil (Wischmeier and Smith, 1978).

6.3.1.2 Oxygen-Demanding Substances

Since the primary oxygen-demanding substances are organic materials (such as leaves and yard waste), BMPs that target these substances are best suited to reducing the oxygen demand in storm water. BMPs that reduce sediment loads often also reduce the loads of the organic material associated with that sediment. Pet waste is also a significant source of organic pollutants, and its control can reduce the loads of oxygen demanding substances in urban runoff. Finally, programs geared at reducing illegal dumping and eliminating illicit connections and accidental spills of materials can reduce the oxygen demand associated with these sources.

6.3.1.3 Nitrogen and Phosphorus

Nitrogen and phosphorus are prevalent in urban and suburban storm water. Nitrogen and phosphorus are natural components of soil, and can enter runoff from storm-induced erosion. Additional sources include the use of fertilizer on urban lawns and airborne deposition. Street sweeping can reduce nutrient loads by removing deposited nutrients from the street surface. Programs that focus on lawn chemical handling or replacing turf with natural vegetation also act to reduce nutrient loading. Finally, programs that educate the public or industry about illegal dumping to storm drains can result in reducing the nutrient loads associated with dumping chemicals that have high nutrient content. Energy conservation and reduced automobile use can reduce airborne nitrogen deposition.

6.3.1.4 Pathogens

Pathogens, including protozoa, viruses and bacteria, are prevalent in urban runoff. Bacteria can be found naturally in soil, and the urban landscape can produce large loads of bacteria that can be carried by runoff. Dogs in particular can be a significant source of pathogens. Thus, pet scoop ordinances and associated education are effective tools at reducing bacteria in urban runoff. Illicit connections of sewage may also be a source of pathogens, therefore eliminating these sources can effectively reduce pathogens in runoff.

6.3.1.5 Petroleum Hydrocarbons

Petroleum hydrocarbons are present in many chemicals used in the urban environment, from gasoline to cleaning solvents. Since roadways are a major source of petroleum pollution, scheduled street sweeping can be used to remove hydrocarbon build-up prior to storm water runoff. Programs geared at preventing spills of chemicals to the storm drain, either through deliberate or accidental dumping, are effective at reducing hydrocarbon loads. Modifying the way land is developed can reduce hydrocarbon loads on both a site and a regional level by reducing the use of the automobile and replacing impervious surfaces with natural vegetation.

6.3.1.6 Metals

Metals sources in urban runoff include automobiles and household chemicals, which can contain trace metals. Street sweeping can reduce metals loads deposited on the road surface. In addition, programs that focus on reducing dumping and proper material storage can reduce accidental or purposeful spills of chemicals with trace metals to the storm drain system. Finally, modifying land use can reduce metals loads by reducing impervious cover, thus reducing total runoff containing metals, and reducing the roadway length, which is often a source of runoff containing metals.

6.3.1.7 Synthetic Organics

Much of the source of synthetic organics in the urban landscape is household cleaners and pesticides. Thus, education programs geared at reducing chemical and pesticide use, and proper storage and handling of these chemicals, can reduce their concentrations in urban runoff. In addition, land use modifications that replace turf with natural vegetation will reduce pesticide use.

6.3.1.8 Temperature

Most non-structural BMPs are not able to prevent the increase in temperature associated with urban development. One exception is the use of site designs that more closely mimic the natural hydrograph by reducing impervious cover and encouraging infiltration.

6.3.1.9 pH

The primary source of low pH in urban runoff is acid rain, and most non-structural BMPs are not used to treat this problem. BMPs that focus on proper materials handling and disposal can prevent dumping of chemicals with extremely high or low pH, but this is generally not a major problem in urban watersheds.

6.3.2 Hydrological and Habitat Benefits

As reviewed in Chapter 4, one major impact of urbanization is induced through the conversion of farmland, forests, wetlands, and meadows to rooftops, roads, and lawns. This process of urbanization has a profound influence on surface water hydrology, morphology, water quality, and ecology (Horner et al, 1994). In this section, the hydrologic and related habitat impacts are briefly discussed as well as the potential benefits that can be achieved by managing storm water runoff using structural and non-structural BMPs.

Many of these impacts can be directly or indirectly related to the change in the hydrologic cycle from a natural system to the urban system. Figure 4-1 illustrates the fundamental effects that occur along with the development process. In the natural setting, very little annual rainfall is converted to runoff and about half is infiltrated into the underlying soils and water table. This water is filtered by the soils, supplies deep water aquifers, and helps support adjacent surface waters with clean water during dry periods. In the urbanizing conditions, less and less annual rainfall is infiltrated and more and more volume is converted to runoff. Not only is this runoff volume greater, it also occurs more frequently and at higher magnitudes. The result is that less water is available to streams and waterways during dry periods and more flow is occurring during storms. A recent study in the Pacific Northwest found that the ratio of the two-year storm to the baseflow discharge increased more than 20 percent in developed sub-watersheds (impervious cover approximately 50 percent) versus undeveloped sub-watersheds (May et al, 1997).

As a result of urbanization, runoff from storm events increases and accelerates flows, increases stream channel erosion, and causes accelerated channel widening and down cutting (Booth, 1990). This accelerated erosion is a significant source of sediment delivery to receiving waters and also can have a smothering effect on stream channel substrates, thereby eliminating aquatic species habitat. As a result, aquatic habitat is often degraded or eliminated in many urban streams. The results are that aquatic biological communities are among the first to be impacted and/or simplified by land conversion and resulting stream channel modifications. Subsurface drainage systems which frequently serve urbanized areas also contribute to the problem, by bypassing any attenuation achieved through surface flows over vegetated areas.

A unifying theme in stream degradation is this direct link with impervious cover. Impervious cover, or imperviousness, is defined as the sum of roads, parking lots, sidewalks, rooftops, and other impermeable surfaces in the urban landscape. This unifying theme can be used to guide the efforts of the many participants in watershed protection. Figure 6-6 visually illustrates this trend in degradation for a series of small headwater streams in the Mid-Atlantic Piedmont. Here, four stream segments, each with approximately the same drainage area, and subjected to the same physiographic conditions, respond to the effects of increased impervious cover. Similar results have been observed in the Southern United States with studies in Virginia, North Carolina and Georgia evidencing this same decline in fish and macroinvertebrate populations with increasing impervious cover (Crawford and Lenant, 1989; Weaver and Garman, 1994; Couch et al, 1996)

Figure 6-6. Effects of Impervious Cover on Stream Quality

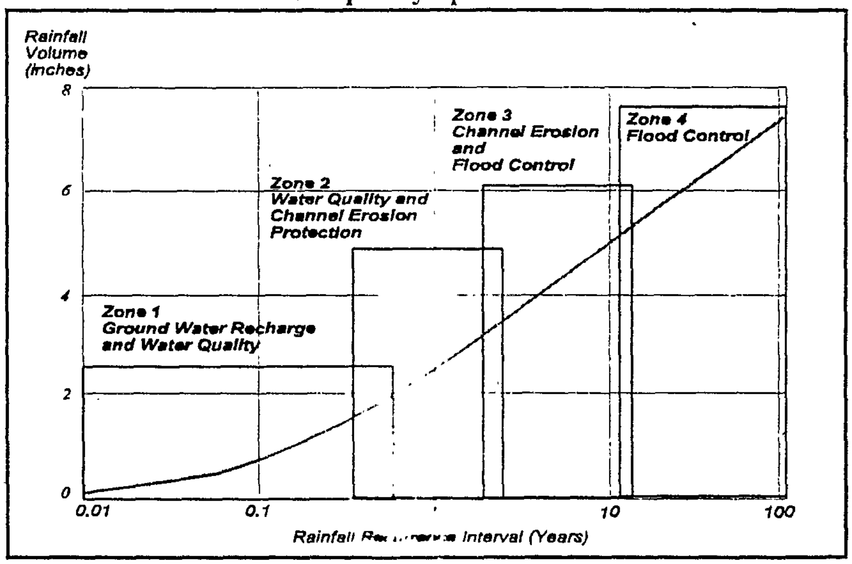
- *Highly Unstable Channel*
- *Poor Biodiversity*
- *Poor to Fair Water Quality*

Non-Supporting Stream →
(Impervious Cover $\approx$65%)
- *Poor to No Biodiversity*
- *Poor Water Quality*

To mitigate this impact, many local and state governments have required the installation of storm water management detention basins to attenuate this increased runoff volume. It is important to recognize that the change in hydrology caused by urbanization affects more than just a single storm return interval (e.g., the two-year event). Urbanization shifts the entire "rainfall frequency spectrum" (RFS) to a higher magnitude. As illustrated in Figure 6-7, the most significant change is to the smallest, most frequent storms that occur several times per year. In the undeveloped condition, most of the rainfall from these events is infiltrated into the underlying soil. In the developed condition, much of this rainfall is runoff. As the storm return interval increases, the difference between the undeveloped and developed condition narrows. Many jurisdictions only require management of specific storms, usually the two, ten and sometimes, the one hundred year events. The two-year storm is probably the most frequently used control point along this frequency spectrum. Hence, while BMPs may do a fairly good job of managing these specific control points, there have been very few locations across the country that have specific criteria in place to manage storm water over a wide range of runoff events. Claytor and Schueler (1996) describe the RFS as:

> ...classes of frequencies often broken down by return interval, such as the two year storm return interval. Four principal classes are typically targeted for control by stormwater management practices. The two smallest, most frequent classes [Zones 1 and 2] are often referred to as water quality storms, where the control objectives are groundwater recharge, pollutant load reduction, and to some extent control of channel erosion producing events. The two larger classes [Zones 3 and 4] are typically referred to as quantity storms, where the control objectives are channel erosion control, overbank control, and flood control.

Figure 6-7. Stormwater Control Points Along the Rainfall Frequency Spectrum



Source: Claytor and Schueler, 1996

R0010769

One recent study by MacRae (1997) concluded that stream channels below storm water detention basins designed to manage the two year storm experienced accelerated erosion at three times the pre-developed rate. His findings went on to suggest that the streams were eroding at much the same rate as if no storm water controls existed.

Other jurisdictions have employed an additional level of detention storage above and beyond that required for the two year storm. This concept is often called "extended detention" (ED). McCuen and Moglen (1988) conducted a theoretical analysis of this design criteria based on sediment transport capacity of the pre-developed channel versus that with ED control. This study found ED could produce an 85 percent reduction in the pre-developed peak flow of the two-year storm. What it did not analyze, however, was the erosion potential over a wide range of storms. MacRae (1993) suggested a different storm water control criterion called "distributed runoff control" (DRC). Here, channel erosion is minimized if the erosion potential along a channel's perimeter is maintained constant with pre-developed levels. This is accomplished by providing a non-uniform distribution of the storage-discharge relationship within a BMP, where multiple control points are provided along the runoff frequency spectrum.

6.3.2.1 Benefits of BMPs to Control Hydrologic Impacts

Numerous prior studies have documented the degradation of aquatic ecosystems of urban and suburban headwater streams. As stated above, in general, the studies point to a decrease in stream quality with increasing urbanization. Unfortunately, the benefits of BMPs to protect streams from hydrologic impacts have only recently been investigated and only for a few studies.

Maxted and Shaver (1997), Jones et al (1997), and Horner et al (1997) attempted to isolate the potential beneficial influence of local storm water best management practices on the impervious cover/stream quality relationship. Horner examined the possible influence of stream-side management on stream quality as a function of urbanization. Coffman et al (1998) recently presented data on the potential hydrologic benefits of alternative land development techniques. Called the "Low Impact Development Approach," this methodology attempts to mimic pre-developed hydrology by infiltrating more rainfall at the source, increasing the flow path and time of concentration of the remaining runoff, and providing more detention storage throughout the drainage network, as opposed to a one location at the end of the pipe.

The preliminary findings of Maxted and Shaver, and Jones et al, suggest that, for the BMPs examined, stream quality (as measured by a limited group of environmental indicators) cannot be sustained when compared to reference stream conditions. Jones assessed several BMPs by conducting biomonitoring (fish and macroinvertebrate sampling) above and below BMPs and comparing them to a reference watershed. He found that the biological community tended to be degraded immediately below BMPs as compared to the reference watersheds. One major flaw in the study was the lack of analysis in developed watersheds without BMPs. This would have compared the influence of BMPs on the aquatic community as compared to no BMPs.

Maxted and Shaver examined eight sub-watersheds with and without BMPs. Their study also concluded that BMPs did not adequately mitigate the impacts of urbanization once watershed impervious reached 20 percent cover. While this study was useful in defining the cumulative impacts of BMPs on watersheds, several critical questions remain. First, since no sub-watersheds with less than 22 percent impervious cover were analyzed, little is known about BMP ability to protect the most sensitive species seen in less developed watersheds. Data for sub-watersheds with BMPs was collected approximately three years after data for the sub-watersheds without BMPs, so climatic/seasonal constraints may have affected the outcome as much, or more than the BMPs themselves.

Horner et al (1997) evaluated several sub-watersheds, with varying levels of impervious cover, but only tangentially related the effectiveness of BMPs to protecting stream quality. Horner found that at relatively low levels of urbanization (approximately 4 percent impervious area) the most sensitive aquatic biological communities (e.g., salmonids) were adversely affected, and stream quality degradation (as measured by a several indicators) continued at a relatively continuous rate with increasing impervious area. Horner's study demonstrates a link between urbanization and stream quality in the Puget Sound region, but since the effects of BMPs were not directly assessed, the question of whether BMPs could "raise" these thresholds could not be answered.

Horner did find a positive relationship between stream quality and riparian buffer width and quality. Here, the otherwise direct relationship of degrading stream quality with increasing impervious cover was positively altered where good riparian cover existed. In other words, increasing the buffer width and condition tended to keep the stream systems healthier.

Coffman demonstrated techniques for maintaining pre-developed hydrologic parameters by replicating the curve number and time of concentration. The analysis indicated the amount of storage required on-site to accommodate the change in site imperviousness. The benefits of this type of development, while not yet fully monitored in a field study, are likely to include increased groundwater recharge, reduced channel erosion potential, and decreased flood potential.

One major hydrologic benefit of storm water management structures is the ability to mitigate for the potential flooding associated with medium to larger storms. Storm water detention and retention facilities have been applied in many parts of the country since about 1970 (Ferguson and Debo, 1990). These facilities include wet and dry basins, as well as rooftop and parking lot detention and underground storage vaults. These *storage facilities* attempt to reduce flooding downstream from developments by reducing the rate of flow out of the particular structure being used. Although the rate of flow is reduced, the volume of flow is generally not reduced. Instead, this volume is delivered downstream at a slower rate, and stretched out over a longer time. With the exception of properly design wet ponds, these structures do not provide any water quality benefit beyond the hydrologic modifications. This technique has proved to be a successful method of suppressing flood peaks when properly applied on a watershed-wide basis.

6.3.3 Human Health Benefits

Storm water can impact human health through direct contact from swimming or through contamination of seafood. Most human health problems are caused by pathogens, but metals and synthetic organics may cause increased cancer risks if contaminated seafood are consumed. Mercury, PCBs, and some pesticides have been linked to human birth defects, cancer, neurological disorders and kidney ailments. The risks may be greater to sensitive populations such as children or the elderly. BMPs that reduce pathogens, metals and synthetic organics will help to limit these health risks.

Economic benefits of avoiding human health problems can include swimming and recreation costs, as well as saved medical costs. One study in Saginaw, Michigan estimated that the swimming and beach recreation benefits associated with a CSO retention project exceeded seven million dollars (US EPA, 1998c). As another example, EPA initially estimated that proposed Phase II storm water controls would reduce the cost of shellfish-related illnesses by between $73,000 and $300,000 per year (US EPA, 1997d).

6.3.4 Additional and Aesthetic Benefits

Storm water BMPs can be perceived as assets or detriments to a community, depending on their design. Some examples of benefits include: increased wildlife habitat, increased property values, recreational opportunities, and supplemental uses. Detriments include: mosquito breeding, reduced property values, less developable land and safety concerns. These detriments can be mitigated through careful design.

6.3.4.1 Property Values and Public Perception

The impacts of BMPs on property values are site-specific. The presence of a structural BMP can affect property values in one of three ways: increase the value, decrease the value, or have no impact. BMPs that are visually aesthetic and safe for children can lead to increased property values. A practice becoming more prevalent is to situate developments around man-made ponds, lakes, or wetlands created to control flooding and reduce the impacts of urban runoff. Buffer zones and open areas that control runoff also provide land for outdoor recreation such as walking or hiking and for wildlife habitat. In many cases, developers are able to realize additional profits and quicker sales from units that are adjacent to such areas. A survey of residents in an Illinois subdivision indicates that residents are willing to pay between 5 percent and 25 percent more to be located next to a wet pond, but that being located next to a poorly-designed dry detention basin can reduce home values (Emmerling-Dinovo, 1995).

Safety is also a concern among the public. A childless adult may perceive a wet pond as an amenity, but a family might view it as a potential hazard to children. These concerns can be alleviated using such design features as gently sloping edges, a safety "bench" (a flat area surrounding a pond) and the use of dense vegetation surrounding ponds and infiltration basins to act as a barrier.

Aesthetic maintenance is also important when considering long term impacts on property values. Poorly-maintained wet ponds or constructed wetlands may be unsightly due to excess algal growth or public littering. Wet ponds and constructed wetlands can also become mosquito breeding grounds. However, mosquito problems can usually be reduced or eliminated through proper design and/or organic controls such as mosquito-eating fish. Successful designs avoid shallow or stagnant water, and reduce large areas of periodic drying, as occur in a dry detention basin (McLean, 1995). All BMPs need to have trash and debris removed periodically to prevent odor and preserve aesthetic values.

6.3.4.2 Dual-Use Systems

Since BMPs can consume a large amount of space, communities may opt to use these facilities for other purposes in addition to storm water management. Two examples are "water reuse" ponds and dual use infiltration or detention basins. In one study, a storm water pond was used to irrigate a golf course in Florida, decreasing the cost of irrigation by approximately 85 percent (Schueler, 1994b). In the southwestern United States, BMPs are often completely dry in between rain events. In these regions, it is very common to design infiltration basins or detention basins as parks that are maintained as a public open space (Livingston et al, 1997).

6.4 Review of Economic Analysis of the NPDES Phase II Storm Water Rule

The proposed storm water Phase II rule specifies that Phase II municipalities and operators of construction sites disturbing between one and five acres of land must apply for and receive a storm water permit. To meet this requirement, municipalities must develop a storm water pollution prevention plan that addresses six minimum measures[9]. Operators of construction sites are required to incorporate soil and erosion controls into their construction sites and implement a water pollution prevention plan. The analysis presented here is a summary of the most recent benefit-cost analysis prepared for the proposed Phase II storm water rule (Preliminary draft number 3). In order to address the issues raised in the public comments and during internal review, EPA gathered additional data and information to refine the analysis of potential benefits and costs conducted for the proposed Phase II rule. These data, analyses, and results are described in detail in the Preliminary Draft of the Economic Analysis of the Final Phase II Storm

[9] The six minimum measures are:
- Public Education and Outreach on Storm Water Impacts
- Public Involvement/Participation
- Illicit Discharge Detection and Elimination
- Construction Site Storm Water Runoff Control
- Post-Construction Storm Water Management in New Development and Redevelopment
- Pollution Prevention/Good Housekeeping for Municipal Operations (US EPA, 1998c).

Water Rule ("EA"), and are summarized in the sections that follow. All cost and benefit estimates are presented in 1998 dollars.

The reader should note that the Agency continues to revise the analysis based on internal review and new data and information. EPA envisions completing the economic analysis in conjunction with the Storm Water Phase II Final Rule. Hence, all estimates are subject to future refinement.

6.4.1 Analyses of Potential Costs

This section provides an overview of the methodology used to estimate costs and pollutant loading reductions for both municipalities and construction sites subject to the final Phase II rulemaking. The specific components of the analysis are discussed in detail in the Draft Final EA. Current Agency estimates of national compliance costs, which are subject to change, are also provided.

6.4.1.1 Municipal Costs

EPA estimated annual per household program cost for automatically designated municipalities (MS4s) using actual expenditures reported by 35 Phase I municipalities. Based on census data, EPA estimated the Phase II municipal universe to be 5,040 MS4s with a total population of 85 million people and 32.5 million households. An average annual per household administrative cost was estimated to address application, record keeping, and reporting requirements, which was added to the program per household cost to derive a total average per household cost. To obtain the national estimate of compliance costs, the Agency multiplied the estimated total per household compliance cost ($9.09) by the expected number of households in Phase II communities. EPA estimates the national Phase II municipal compliance costs to be approximately $295 million (see Section 4.2.1.3 in the draft EA)[10].

6.4.1.2 Construction Costs

In estimating incremental costs attributable to the final Phase II rule, EPA estimated a per site cost for construction sites of one, three, and five acres and multiplied the cost by the total number of Phase II construction starts in these size categories to obtain a national estimate of compliance costs. The Agency used construction start data from eleven municipalities that record construction start information to estimate the number of construction starts disturbing between one and five acres of land (see Section 4.2.2.1 in the Draft Final EA).

---

[10] Estimated annual per household cost of compliance ranged from $0.63 to $60.44. See Section 4.2.1.2 in the Draft Final EA for a discussion of how EPA chose the mean value of $9.09 per household. Note that the estimated per household cost does not include municipal expenditures for post-construction storm water controls.

In estimating construction BMP costs, EPA used standard cost estimates from R.S. Means (R.S. Means, 1997a and 1997b) and created 27 model sites of typical site conditions in the United States. The model sites considered three different site sizes (1, 3, and 5 acres), three slope variations (3, 7, and 12 percent), and three soil erosivity conditions (low, medium, and high). The Agency used a database compiled by the Water Environment Federation (1992) to develop and apply BMP combinations appropriate to the model site conditions. For example, sites with shallow slopes and a low erosivity require few BMPs, while larger, steeper, and more erosive sites required more BMPs. Detailed site plans, assumptions, and BMPs that could be used are found in Appendix B-3 of the Draft Final EA. Based on the assumption that any combination of site factors are equally likely to occur on a given site, EPA averaged the matrix of estimated costs to develop an average cost for one, three, and five acre starts for all soil erodibilities and slopes. The average BMP cost was estimated to be $1,206 for a one-acre site, $4,598 for a three-acre site, and $8,709 for a five-acre site.

Administrative costs for the following elements were estimated per construction site and added to each BMP cost: submittal of a notice of intent (NOI) for permit coverage ($74); notification to municipalities ($17); development of a storm water pollution prevention plan ($1,219); record retention ($2); and submittal of a notice of termination ($17) for a total cost of $1,329 per site. From this analysis, EPA estimated total average compliance costs (BMP plus administrative) for a Phase II construction site of $2,535 for sites disturbing between one and two acres of land, $5,927 for sites disturbing between two and four acres, and $10,038 for sites disturbing between four and five acres of land.

The total per site costs were then multiplied by the total number of Phase II construction sites within each of those size categories to obtain the national compliance cost estimate. EPA estimated construction costs for 15 climatic zones to reflect regional variations in rainfall intensity and amount. Once the Phase II storm water rule is fully implemented, the total annual compliance cost is expected to be approximately $512 million (assuming 109,652 construction starts in 1998).

6.4.1.3 Pollutant Loading Reductions

To estimate municipal pollutant loading reductions for the final Phase II rulemaking, EPA used the results from a 1997 EPA draft report that calculated national municipal loading reductions for TSS based on the NURP study (US EPA, 1997d). To estimate pollutant loading reductions from Phase II construction starts, the U.S. Army Corps of Engineers developed a model based on EPA's 27 models sites to estimate sediment loads from construction starts with and without Phase II controls (US ACE, 1998). Estimating the pollutant loading reduction for TSS does not capture the full extent of potential loading reductions that result from implementing storm water controls, but provides a minimum estimate of the reductions that may result from the

Phase II rule[11]. EPA also anticipates that the rule will result in reductions in oil and grease, nitrogen, phosphorus, pathogens, lead, copper, zinc and other metals. Estimated annual TSS loading reductions range from 639,115 to approximately 4 million tons for municipalities and 2 million to 8 million tons for construction sites assuming BMP effectiveness of 20 to 80 percent.

6.4.2 Assessment of Potential Benefits

A number of potential problems are associated with assessing the benefits from the Phase II rule, including identifying the regulated municipalities as sources of current impairment to waters and determining the likely effectiveness of various measures; difficulties in water quality modeling; difficulties in modeling construction site BMP effectiveness; and most importantly, the inability to monetize some categories of benefits with currently available data.

The national benefits of Phase II controls will depend on a number of factors, including the number, intensity, and duration of wet weather events; the success of municipal programs; the effectiveness of the selected construction site BMPs; the site-specific water quality and physical conditions of receiving waters; the current and potential use of receiving waters; and the existence of nearby "substitute" sites of unimpaired waters. Because these factors will vary substantially from site to site, data are not available with which to develop estimates of benefits for each site and aggregate to obtain a national estimate. As a result, the Agency developed national level estimates of benefits based largely on a benefits transfer approach. This approach allows estimates of value developed for one site and level of environmental change to be applied in the analysis of similar sites and environmental changes.

6.4.2.1 Anticipated Benefits of Municipal Measures

As part of an effort to quantify the value of the United States' waters impaired by storm water discharges, EPA applied adjusted Carson and Mitchell (1993) estimates of willingness to pay (WTP) for incremental water quality improvements to estimates of waters impaired by storm water discharges as reported by states in their biennial Water Quality Inventory reports[12]. Potential Phase II benefits are assumed to equal the WTP for the different water quality levels multiplied by the water quality impairment associated with Phase II municipalities multiplied by the relevant number of households (WTP x percent impaired x number of households).

The Carson and Mitchell estimates apply to all fresh water, however it is not clear how these values would be apportioned among rivers, lakes and the Great Lakes. Lakes are the water

---

[11] To date, there are no national studies that estimate pollutant loading reductions due to the implementation of municipal storm water controls for the other pollutants found in storm water runoff and discharges.

[12]EPA adjusted the WTP amounts to account for inflation growth in real per capita income, inflation, and a 30 percent increase in attitudes towards pollution control.

bodies most impaired by urban runoff and discharges, followed closely by the Great Lakes and then rivers. Hence, EPA applied the WTP values to the categories separately and assumed that the higher resulting value for lakes represents the high end of the range and the lower resulting value for rivers represents the low end of a value range for all fresh waters (i.e. high end assumes that lake impairment is more indicative of national fresh water impairment while low end assumes that river impairment is more indicative).

The extent to which impairment will be eliminated by the municipal measures is uncertain; hence, estimates are adjusted for a range of potential effectiveness of municipal measures. EPA expects that municipal programs will achieve at least 80% effectiveness, resulting in estimated annual benefits from fresh water use and passive use in the range of $67.2 to $241.2 million. The potential value of improvements in marine waters and human health benefits have not been quantified at this time.

6.4.2.2 Anticipated Benefits of Construction Site Controls

EPA estimates the benefits of construction site controls using a benefits transfer approach applying WTP estimates for an erosion and sediment control plan from Paterson et al (1993) contingent valuation (CV) survey of North Carolina residents. The adjusted WTP estimates are intended to reflect potential benefits of erosion and sediment control programs that protect all lakes, rivers, and streams. In order to transfer adjusted WTP results to estimate the potential benefits of the Phase II rule, EPA calculated the percentage of Phase II construction starts that are not covered by a state program or CZARA for each state. This percentage is multiplied by the number of households in the state and the adjusted mean WTP of $25. The results were then summed across all states and indicate that WTP for the erosion and sediment controls of the Phase II rule may be as high as $624.2 million per year.

6.4.3 Comparison of Benefits and Costs

EPA estimates the total compliance costs of the rule to be $807.2 million. The largest portion of the total cost, $512 million, is associated with erosion and sediment controls at construction sites. EPA was able to develop a partial monetary estimate of expected benefits of both the six minimum municipal measures and the construction components of the rule. The sum of these benefits ranges from $700 to $865 million annually [assuming 80 percent effectiveness of municipal programs and using the mean WTP ($25) from Paterson]. The largest portion of benefits, $624 million, are associated with erosion and sediment controls for construction sites.

6.5 Financial Issues

Effective storm water programs require both the existence of well-performing, cost-effective BMPs and sufficient funding. Financing issues are discussed extensively in other Agency reports and only briefly reviewed below.[13] Section 6.5.1 focuses on financing options for municipal storm water programs but does not discuss regulatory impacts on municipalities.

6.5.1 Municipal Financing of Storm Water Programs

Around the nation, local government general tax funds are the most commonly used source of funding for storm water programs. However, this may be the least suitable source of storm water program or maintenance funding. General tax revenues originate at a number of sources and are used to finance an equally diverse number of public programs, including education, police and fire protection, civil and criminal courts, and social and economic support programs. Storm water programs and maintenance must compete against a large number of other vital public programs for a very limited number of tax dollars. This problem has been compounded in recent years by tax caps and the public's general opposition to new or higher taxes.

The unreliability of general tax funds has led many communities around the country to develop storm water utilities. Storm water utilities rely on dedicated user charges related to the level of service provided. Charges are typically paid by property owners and managed in a separate enterprise fund. A variety of methods are used to determine charges, but are usually based on some estimate of the amount of storm water runoff contributed by the property, such as the total impervious surface or a ratio of impervious surface to total property area. Generally a flat rate is charged for residential properties.

There are several advantages of using utility fees to finance storm water programs. Unlike general tax revenues, utility charges are a dedicated, stable, and predictable source of funds and are not subject to state "tax cap" limitations. Also, because charges are based on the user's contribution to storm water runoff, it is often seen as more equitable or fair. Finally, utility fees provide a mechanism to incorporate economic incentives for implementation of on-site storm water management through reduced charges. For example, credits or discounts are often provided for on-site retention of storm water by nonresidential property owners. Providing such incentives creates greater flexibility by allowing each user to choose the cheaper option - paying the utility charge or implementing on-site controls. Storm water utilities are now well established as an effective financing option. As of 1991, over 100 communities across the country had instituted storm water utilities (US EPA, 1994a).

Similar to utility fees, the use of inspection or permit fees to help publicly finance storm water programs represents a relatively new application of an established component of government revenues. Often, these fees are associated with the issuance of a permit, such as a

[13] EPA has prepared publications to assist local governments in planning for program funding (US EPA, 1994b). More recently the Agency has established an internet site with current information, the "Environmental Finance Information Network." The website address is http://www.epa.gov/efinpage/efin.htm .

building permit, clearing permit, storm water permit, or sewer connection permit. A permit program based upon fees for annual inspections, such as a storm water discharge or storm water operating permit, can provide a continuing source of funds. However, many permit or inspection fees are a one time charge, typically when the facility is first constructed. These are generally not a good funding source for continuing storm water system maintenance.

Finally, the use of dedicated contributions from land developers may be used to finance public maintenance of storm water systems. Under this program, the local government assumes the operation and maintenance of a storm water system constructed as part of a private development. All or a portion of the estimated required funding for the O&M is obtained through a one-time contribution by the land developer to a dedicated account which is controlled by the local government. Often the developer is responsible for O&M during a "warranty period," frequently the first two years. Dedicated contributions provide a secure, dedicated funding source that is not subject to state tax cap limits. A disadvantage is that dedicated contributions are only applicable to new storm water systems.

6.6 Summary

The use of BMPs to control storm water runoff and discharges where none previously existed will ultimately result in a change in pollutant loadings, and there are indications that in the aggregate BMPs will improve water quality. The actual manner in which the loadings reductions are achieved will depend on the BMPs selected, which will determine the associated costs. The physical-chemical properties of receiving streams and consequent linkages to biologic/ecologic responses in the aquatic environment, and human responses and values associated with these changes will determine the benefits.

Preface

This document contains information on the cost of implementing the new minimum stormwater control requirements for new developments and redevelopments as set forth by the Washington Department of Ecology (Ecology) in its *Stormwater Management Manual for Western Washington* (Ecology 2001). The minimum requirements include provisions for controlling erosion and sediment transport during construction, as well as permanent facilities for treating and controlling peak runoff flows from developed sites. This cost analysis considers only the stormwater system components required for erosion and sediment control, stormwater treatment, and stormwater detention and/or infiltration that go beyond conventional stormwater systems. Thus, the costs of installing stormwater system components such as catch basins and conveyance pipes that are independent of the Ecology requirements are not addressed in this cost analysis.

The cost estimates for satisfying Ecology's new minimum requirements that are provided in this report should be considered as approximate, and should be viewed in the context of the hypothetical sites for which they were developed. Individual site conditions, selected components of stormwater control plans, costs of land, costs of engineering and construction services, and many other factors can vary considerably throughout western Washington and from project to project. Some projects will be faced with costs associated with construction of stormwater management facilities that are not captured in this analysis, such as traffic control costs, additional property costs, and mitigation costs for sensitive areas that are impacted by placement of stormwater management facilities. Therefore, for a particular development or redevelopment of comparable size to the hypothetical sites discussed in this report, the costs of satisfying Ecology's minimum requirements may differ from the costs given in this analysis. This analysis does not address the costs that stormwater design engineers, site designers, developers, and development reviewers may incur in learning the updated requirements and preparing the resultant technical documentation that will likely require greater detail.

1. Introduction

This report provides information on costs of stormwater control measures required for new single-family residential and commercial developments in western Washington based on the minimum requirements set forth by the Washington Department of Ecology (Ecology) in the *Stormwater Management Manual for Western Washington*, referred to hereafter as "the manual" (Ecology 2001, final version pending as of the date this report was completed). The manual describes the stormwater management requirements applicable to various development and redevelopment scenarios, including many types of development other than single-family residential and commercial land use. There are a multitude of development scenarios that could potentially be evaluated for stormwater management implementation costs but doing so would require extensive amounts of time and effort. This report discusses the range of stormwater management costs that could be expected for some representative examples, and the reader must necessarily use the information as a general guide to understand the cost implications for a specific project of interest.

Development Examples

This report addresses three hypothetical development examples and presents the associated costs for compliance with Ecology's new minimum requirements. These three hypothetical development sites include the following: a 10-acre single-family residential development (site 1), a 1-acre commercial development (site 2), and a 10-acre commercial development (site 3). These examples assume that new development is occurring on the hypothetical sites, that there is no existing development on the sites, that greater than 2,000 square feet of impervious surface is added, and that greater than 7,000 square feet of land area is cleared. Therefore, all of the minimum requirements set forth in the manual are applicable to these examples. Because the decisions regarding how to manage stormwater for a particular site are often directly tied to soil characteristics, this report addresses a range of control measures that may be used in differing soil conditions. For each of the three example sites, the costs to implement the minimum requirements were analyzed for two different soil conditions (soils that would promote infiltration of runoff [type A soils] and soils that are not suitable for infiltration [type C soils]).

This report may be viewed as an update to a similar report prepared in 1993 entitled *Cost Analysis, Minimum Requirements for Stormwater Management in New Developments and Redevelopments* (Herrera 1993), which contained an analysis based on requirements set forth in the *Stormwater Management Manual for the Puget Sound Basin* (Ecology 1992). The analysis in this report repeats the hypothetical development examples from the 1993 report, and the analysis is based on the minimum requirements, design guidelines, and stormwater facility sizing procedures in the updated 2001 Ecology manual. Where applicable, this report refers to the 1993 cost analysis report to enable comparison of the differences in stormwater management costs between the older and newer requirements for the same site conditions.

Soil type is an important difference between the 1993 report and this report. The 1993 report used type B soils for the examples where infiltration was assumed feasible, whereas the present analysis assumed type A soils (i.e., glacial outwash or alluvial deposits that are more permeable than type B soils) for the examples where infiltration is assumed feasible. This distinction is important because it affects the selection and configuration of the permanent stormwater facilities. Specifically, the 1993 report assumed infiltration treatment would occur in type B soils, with overflow to a detention facility in higher storms. This analysis assumes pretreatment followed by flow disposal in the highly permeable type A soils. The decision to switch to Type A soils was based on the type of soil input data that the pending Ecology hydrologic model will allow, and a desire to have the case study examples match the model input options as directly as possible. To enable a fair cost comparison of 1992 requirements versus 2001 requirements for the examples where infiltration is feasible, the soil type must be consistent. Therefore, the permanent stormwater management system quantities and costs associated with type B soils in the 1993 report were disregarded, and new costs were developed for those examples assuming type A soils. As discussed in Appendix C of this report, quantities and costs were re-analyzed for the three sites assuming pretreatment and discharge of all runoff to an infiltration basin, using the 1992 design requirements to derive the sizes of those facilities. Thus, the comparison of permanent stormwater management costs associated with the previous requirements and the new requirements, presented at the end of this report, is based on updates to the 1993 cost figures for the non-infiltration examples and new cost figures for the infiltration examples.

Ecology's Minimum Requirements

Ecology's stormwater management requirements have changed substantially since 1992. In order to demonstrate compliance with Ecology's minimum requirements, preparation of a construction stormwater pollution prevention plan (SWPPP) and a permanent stormwater site plan is required for all new development sites that will create more than 2,000 square feet of impervious surface or clear more than 7,000 square feet of land area. The updated minimum requirements, which are discussed in detail in the manual (Ecology 2001), are summarized below with the changes highlighted:

1. **Preparation of Stormwater Site Plans** – All projects shall prepare a stormwater site plan for local government review.

   Significant Change: Demonstration of compliance with the 1992 manual required preparation of a Stormwater Site Plan. However, such plan preparation was not specifically identified as a minimum requirement. The updated manual specifically identifies the preparation of such plans as a minimum requirement. This is not a change that increases project costs.

2. **Construction Stormwater Pollution Prevention (SWPP)** – All new development and redevelopment shall comply with the 12 construction SWPP elements found in the manual.

Significant Changes: A new element to "Manage the Project" has been added. This includes phasing of construction activities, seasonal work limitations, coordination with utilities, inspection and monitoring of BMPs, retention of a certified professional in erosion and sediment control, and maintenance of a Stormwater Pollution Prevention Plan (SWPPP). Significant BMP additions that need to be considered in SWPPPs include chemical treatment, land application of polyacrylimide for soil stabilization, wheel washing, concrete handling, and sawcutting and surfacing.

3. **Source control of pollution** – All known, available and reasonable source control best management practices (BMPs) shall be applied to all projects.

   Significant Changes: There are 18 new source control BMPs described in the 2001 manual.

4. **Preservation of natural drainage systems and outfalls** – Natural drainage patterns shall be maintained, and discharges from the site shall occur at the natural location, to the maximum extent practicable.

5. **Onsite stormwater management** – Projects shall employ onsite stormwater BMPs to infiltrate, disperse, and retain stormwater runoff onsite to the maximum extent practicable without causing flooding or erosion impacts.

   Significant Change: This new requirement specifies use of flow dispersion or infiltration BMPs for concentrated runoff from impervious surfaces at residential sites, and for all areas not covered by impervious surfaces, the retention or enhancement of the soil moisture holding capacity of the original undisturbed soil native to the site. Specifically, the requirements include provision of a topsoil layer with a minimum organic matter content of ten percent dry weight and a pH from 6.0 to 8.0 or matching the pH of the original undisturbed soil.

6. **Runoff treatment** – Projects that meet specific thresholds are required to construct stormwater treatment facilities that are sized to treat runoff from the water quality design storm (the 24-hour rainfall amount with a 6-month return frequency).

   Significant Changes: Treatment is required for pollution-generating pervious surfaces (PGPS), such as managed turfgrass, in addition to pollution-generating impervious surfaces (PGIS). The Water Quality Design Storm Event is still a 6-month, 24-hour storm, but the generic estimate for precipitation depth in such a storm event is increased from 64% to 72% of the 2-year, 24-hour storm precipitation depth.

7. **Flow control** – Projects that meet specific thresholds must provide flow control to reduce the impacts of increased stormwater runoff from new impervious surfaces and land cover conversions.

   Significant Changes: A flow duration standard is now the default requirement. The flow control standard in the 1992 manual was primarily targeted at matching pre-developed peak flow rates. The newer standard still requires matching of pre-developed peak flow rates but also requires matching of pre-developed flow durations to prevent prolonged discharges of the peak flows. In addition, the pre-developed site condition for runoff modeling purposes must be assumed forested unless reliable information establishes the pre-settlement conditions as pasture or prairie. The 1992 manual allowed use of the "existing site condition," as defined in the glossary, as the pre-developed condition to which peak flows of the developed condition are compared.

8. **Wetlands protection** – Discharges to wetlands shall maintain the hydrologic conditions, hydrophytic vegetation, and substrate characteristics necessary to support existing and designated uses unless an assessment is completed consistent with specific criteria referenced in the manual.

9. **Basin/watershed planning** – Projects may be subject to equivalent or more stringent minimum requirements for erosion control, source control, treatment, wetlands protection, and operation and maintenance, and alternative requirements for flow control as identified in basin/watershed plans.

10. **Operation and maintenance** – An operation and maintenance manual that is consistent with the local government standards shall be provided for all proposed stormwater facilities and BMPs, and the party (or parties) responsible for maintenance and operation shall be identified.

The Stormwater Pollution Prevention Plan

The SWPPP must incorporate sufficient best management practices (BMPs) to prevent adverse offsite impacts during construction through a variety of measures as specified in minimum requirement number two. Twelve distinct elements of effective construction site pollution prevention must be included in the SWPPP to the extent they pertain to the site.

The Permanent Stormwater Site Plan

The permanent stormwater site plan must include the following elements to comply with the minimum requirements:

- Minimum requirement three: additional BMPs for prevention of runoff pollution, or source control

- Minimum requirement five: This important new requirement relates to implementation of onsite stormwater management measures to minimize the hydrologic changes that occur on the site (i.e., to minimize the increase in runoff that is inherent with development). The cost analyses discussed in this report incorporate this requirement. The effects of new onsite runoff reduction measures on the size and cost of permanent runoff treatment and flow control facilities are discussed for each development example.

- Minimum requirement six: treatment of onsite runoff to protect downstream water quality

- Minimum requirement seven: control of peak runoff flows that may otherwise cause damage to natural resources and constructed facilities downstream

- Minimum requirement ten: long-term operation and maintenance commitments for permanent stormwater management systems

Thoughtful selection and proper implementation of BMPs are critical to satisfying Ecology's minimum requirements for stormwater management for new development or redevelopment. In this analysis, the rationale for selection of particular BMPs is provided for each of the hypothetical development plans to illustrate the process by which BMPs were chosen.

Organization of the Cost Analysis

The remaining portion of section 1 outlines the assumptions used in creating hypothetical development site layouts. Also discussed are the assumptions and calculation methods used in analyzing minimum requirements for stormwater control and for sizing and selecting stormwater management BMPs.

Section 2 describes the hypothetical site characteristics and associated SWPPP and stormwater site plan details developed for the purpose of estimating costs to satisfy the minimum requirements. The estimated costs for planning, designing, constructing, and maintaining the chosen BMPs for each site are also provided in Section 2. Section 3 presents a summary of the construction and maintenance cost estimates for satisfaction of the minimum requirements, and discusses comparisons to the costs presented in the 1993 report associated with the previous minimum requirements. Appendix A contains itemized costs for planning, design, construction, and maintenance of the BMPs for each of the development sites, as well as assumptions and references used in developing the cost estimates. The technical assumptions, runoff modeling parameters, and design parameters used in the analysis of stormwater BMPs for each of the sites are outlined in Appendix B.

The SWPPP and stormwater site plan developed for each of the hypothetical sites are intended to be representative in their coverage of BMP concerns, but they do not include all of the information required of actual SWPPPs and stormwater site plans. Because this analysis focuses primarily on costs, details regarding site features such as setback requirements, existing vegetation to be retained, rights-of-way, and storm sewers, among other issues, are limited.

General Assumptions Used in Creating Hypothetical Site Layouts, Analyzing Minimum Requirements, and Selecting and Sizing Stormwater Management Facilities

The hypothetical development site layouts and associated stormwater facilities are based upon the assumptions outlined below:

- Each site is serviced by separate sanitary sewer and storm drainage systems. The cost of installing ditches or storm sewers beyond the site boundaries is a separate concern; this analysis addresses only the additional storm drainage facilities needed for treatment, infiltration and/or detention of runoff on the example site.
- Ground slopes on all of the sites are less than 5 percent.
- The land uses adjacent to the sites on all sides are unknown.
- Stormwater runoff on all of the sites eventually drains to a fish-bearing stream. For the commercial site examples (sites 2 and 3) this means that "enhanced treatment" of runoff is required.
- Phosphorus control is not required at any of the sites.
- Other more stringent local stormwater management requirements do not apply, and a jurisdictional basin plan does not exist for any of the site areas.

Costs for complying with the minimum requirements at each of the development sites are based on two scenarios: the first scenario assumes the site has outwash soils that are suitable for infiltration of all, or nearly all, of the stormwater runoff; the second scenario assumes till soils that are unsuitable for infiltration. Two separate cost estimates are provided for implementation of the minimum stormwater management requirements at each site, reflecting the two types of soils assumed at each site. Other than differences in the soil type present, the site characteristics are identical for the two scenarios evaluated at each site.

Calculation Methods

A combination of hydrologic modeling methods was used to perform conceptual sizing of stormwater management facilities for this analysis, including some modeling methods that are not described in the manual. The hydrologic model that eventually will be used for analysis and design of stormwater management systems in accordance with the manual's design criteria was in the developmental stage at the time this report was prepared; therefore, alternative methods were necessary. The 6-month recurrence interval water quality design storm hydrographs for the case study development examples were derived using StormShed™ computer software (Engenious Systems 2000), which incorporates the Santa Barbara Urban Hydrograph (SBUH) method. The model inputs are summarized in Appendix B. The performance of detention systems, including matching of pre-developed flow durations, was modeled using the King County Runoff Time Series (KCRTS) program. The KCRTS program offers a calculation method for evaluating flow durations that are central to the detention requirements set forth in the manual. Sand filter sizes were also evaluated using KCRTS. The KCRTS hydrographs corresponding to the 2-year recurrence interval peak flow discharged from detention facilities were routed through the KCRTS infiltration basin sizing routine, with vertical permeabilities corresponding to sand as opposed to soil, to determine the sand filter bed area needed to effectively treat those design flows. Infiltration facilities were sized using a spreadsheet based on Darcy's Law and the 100-year SBUH storm event hydrographs. The spreadsheet enabled confirmation of the time limits required for water level drawdown following design storm events.

2. Sample Sites and Associated Construction SWPPPs and Permanent Stormwater Site Plans

This section describes the three hypothetical development sites and provides details of corresponding construction SWPPPs and permanent stormwater site plans. Plan elements were chosen to provide examples of elements that satisfy the minimum requirements outlined in the manual. Also provided are implementation costs to satisfy the minimum requirements and operation and maintenance requirements and costs.

Site 1—Single-Family Residential Development

Site 1 is a 10-acre single-family residential development with 5.5 dwelling units per acre. Figure 1 shows the layout of the site as planned for development without stormwater control facilities to satisfy the minimum requirements. There is one entrance to the development. The topography of the site in its undeveloped state causes runoff to flow to the lower left-hand corner via a few defined drainage courses, the largest of which is indicated near the bottom of the plan view shown in Figure 1. These drainage courses are not streams and provide negligible ecological benefits. Because the development plan does not include extensive regrading of the slopes on the site, drainage would proceed in the same general direction after development. It is assumed that after development, any treated runoff (see below for treatment plans) from the site that does not infiltrate into the soil would be conveyed downstream of the site to a stream. An important distinction between this site and the other two sites analyzed in this report is that surface runoff discharged from a single-family residential development to a fish-bearing stream does not require "enhanced treatment" according to the manual requirements.

The topographic layout of site 1 is conducive to stormwater runon from adjacent land and through-flow in the main drainage course. It is assumed that a decision would be made to minimize the size (and cost) of temporary erosion and sediment control facilities and of permanent stormwater management facilities by separating the offsite runon from the onsite drainage. For the purposes of this analysis it is assumed that one or more culverts and/or intercepting ditches (or similarly effective diversion/conveyance facilities) would be provided to convey those flows around the site. Because these provisions are necessary due to hypothetical site conditions, costs are not included for them.

Site 1 Construction Stormwater Pollution Prevention Plan

For all new development and redevelopment projects that add or replace 2,000 square feet or more of impervious surface or clear more than 7,000 square feet, such as site 1, the manual requires preparation of a SWPPP (minimum requirement two) to guide selection and implementation of a variety of BMPs during construction. The minimum requirements for stormwater pollution prevention during construction include the following 12 elements:

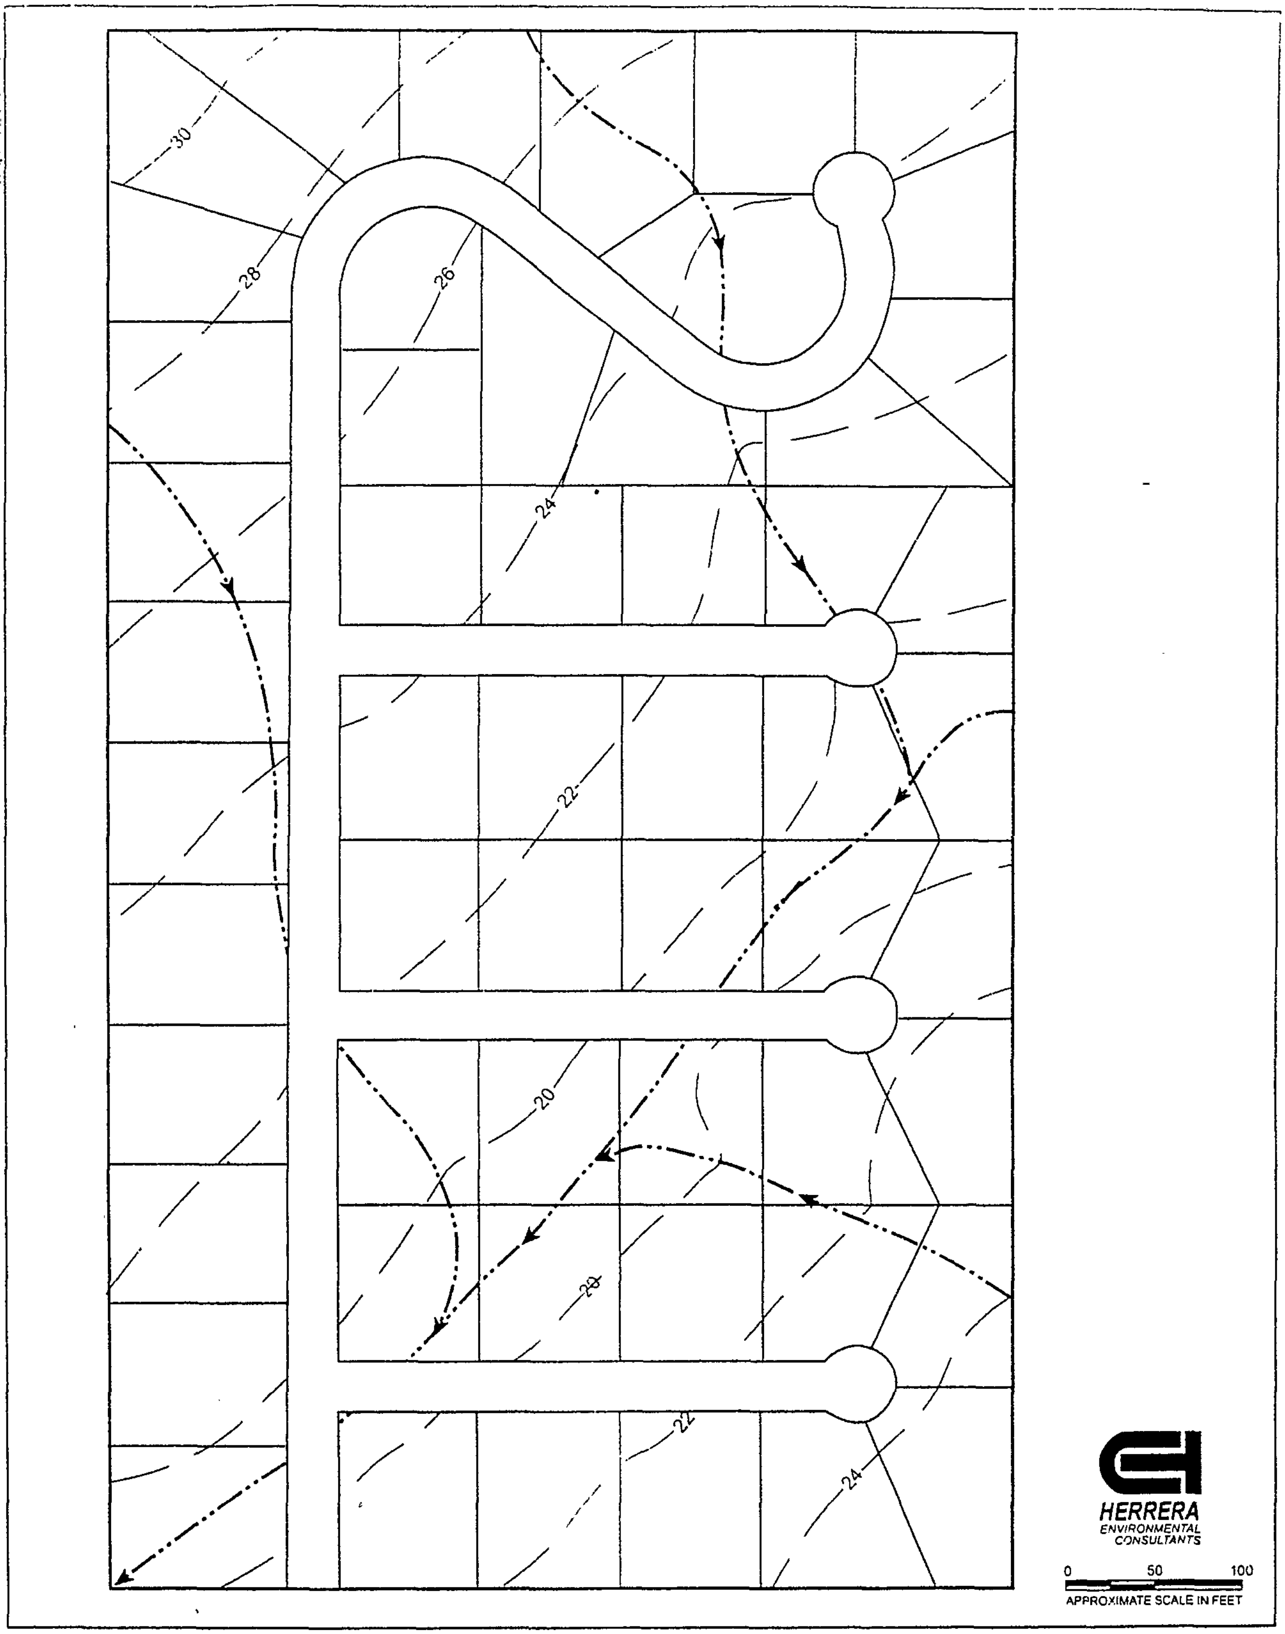

Figure 1. **Ten-acre residential development plan, without stormwater facilities, superimposed on natural (pre-development) topography and drainage features.**

1. Mark clearing limits
2. Establish construction access
3. Control flow rates
4. Install sediment controls
5. Stabilize soils
6. Protect slopes
7. Protect drain inlets
8. Stabilize channels and outlets
9. Control pollutants
10. Control de-watering
11. Maintain BMPs
12. Manage the project

It is assumed that construction would require 12 months of site work to complete. Two versions of a SWPPP were evaluated for the condition with type C soils on this site, one accounting for a stoppage of site grading activities from November through March (i.e., assuming that the project would be managed to greatly minimize potential for water quality problems in the wet season) and the other assuming that construction would proceed through the winter months. Thus, the total duration of construction for one SWPPP scenario is 17 months, and for the other SWPPP scenario is 12 months. For both cases it was assumed that the contractor would build the entire 10-acre residential development (houses included), rather than grading the site, providing basic infrastructure and utilities, and leaving individual building sites for future contractors. The comparison of SWPPP costs with and without a winter shutdown is made only for the site condition with type C soils. Type A soils are often associated with construction site erosion problems, and concerns for seasonal clearing and grading restrictions, but type C soils are typically more conducive to turbidity problems. This analysis reflects the likelihood that seasonal clearing and grading restrictions would be more common in type C soils. Of the 12 elements listed above, the only one that would not incur measurable costs in the context of this cost analysis is element 9. The potential opportunity cost to the developer of managing the project to avoid grading activity in the winter was not assessed for this study.

To control transport of sediments off the site and to protect downstream properties and waterways during construction, a combination of BMPs would be used including fenced clearing limits, stabilized site roads, equipment parking areas, storm drain inlet protection on the adjacent street, temporary ground cover in disturbed areas, stabilized conveyance ditches, a large sediment pond, and silt fencing. To satisfy the minimum requirements, these BMPs would be in place prior to beginning construction activities. It is assumed that de-watering would be required at this site, and that those flows could be managed effectively with a filtration device such as a dewatering filter bag or pipe filter sock and then discharged from the site. Therefore, the sizing of sedimentation facilities did not account for de-watering discharges.

Figure 2 shows the locations of the erosion and sediment control BMPs selected for the residential development site. The BMPs are the same for outwash (type A) soils (suitable for infiltration) and till (type C) soils (unsuitable for infiltration). However, the size of the temporary sediment pond differs because of the effect soil type has on runoff peak flows and volumes. The manual specifies that sediment ponds be designed based on the 2-year, 24-hour storm peak runoff flow rate. The 2-year post-developed peak runoff rate used for sediment pond sizing is estimated to be 0.48 cubic feet per second (cfs) with outwash soils (i.e., Type A soils) on the site, and 0.62 cfs with till soils on the site (i.e., type C soils). Figure 2 indicates the sediment pond size corresponding to type C soils. Silt fencing would be used as a divider within the temporary sediment pond to enhance the removal of suspended sediments.

Temporary interceptor swales and conveyance channels lined with suitable geotextiles or organic blankets, or stabilized with seed and mulch, would be used to convey all site runoff to the sediment pond. Silt fencing would be used on downslope edges of the site boundary to prevent sediment discharge. The site entrance would be stabilized with quarry spalls (large rocks), and construction roads on the site and one main parking/staging area would be stabilized with crushed rock. Mulch would be applied extensively to areas of exposed soil during staged construction.

Other BMPs such as vehicle tire washing, occasional street sweeping, and spraying of dusty areas would be implemented during construction. For the scenario where grading work is stopped for the period of November through March it is assumed that greater attention to soil stabilization (such as application of polyacrylamides on a large area) would be needed to prevent erosion on disturbed ground for several months, particularly in Type C soils. For the scenario where grading work occurs through the winter months it is assumed that greater attention to sediment pond maintenance, street sweeping, vehicle tire washing, and replacement of storm drain inlet protection devices would be needed. Following construction of homes on the site, grassed lawns would be planted, and sidewalks and streets would be paved to permanently stabilize disturbed areas.

Maintenance of the erosion and sediment control BMPs is a key component of the construction SWPPP. It is assumed that routine BMP maintenance checks would be performed once weekly and after runoff-producing storm events during the dry season, and daily during the wet season to ensure that BMPs continue to function effectively. The sediment pond must be checked periodically for sediment buildup, especially following storms. Excess sediment accumulation must be removed from the pond and disposed of off the site or spread in a controlled location on the site. Silt fencing must be checked periodically, especially following storms, to determine if repairs or replacement fabric sections are needed. Mulch used to cover stripped site areas would be relocated and replaced as needed, as portions of the site are permanently stabilized. If sediment is tracked offsite onto neighboring streets, it must be swept and collected as necessary.

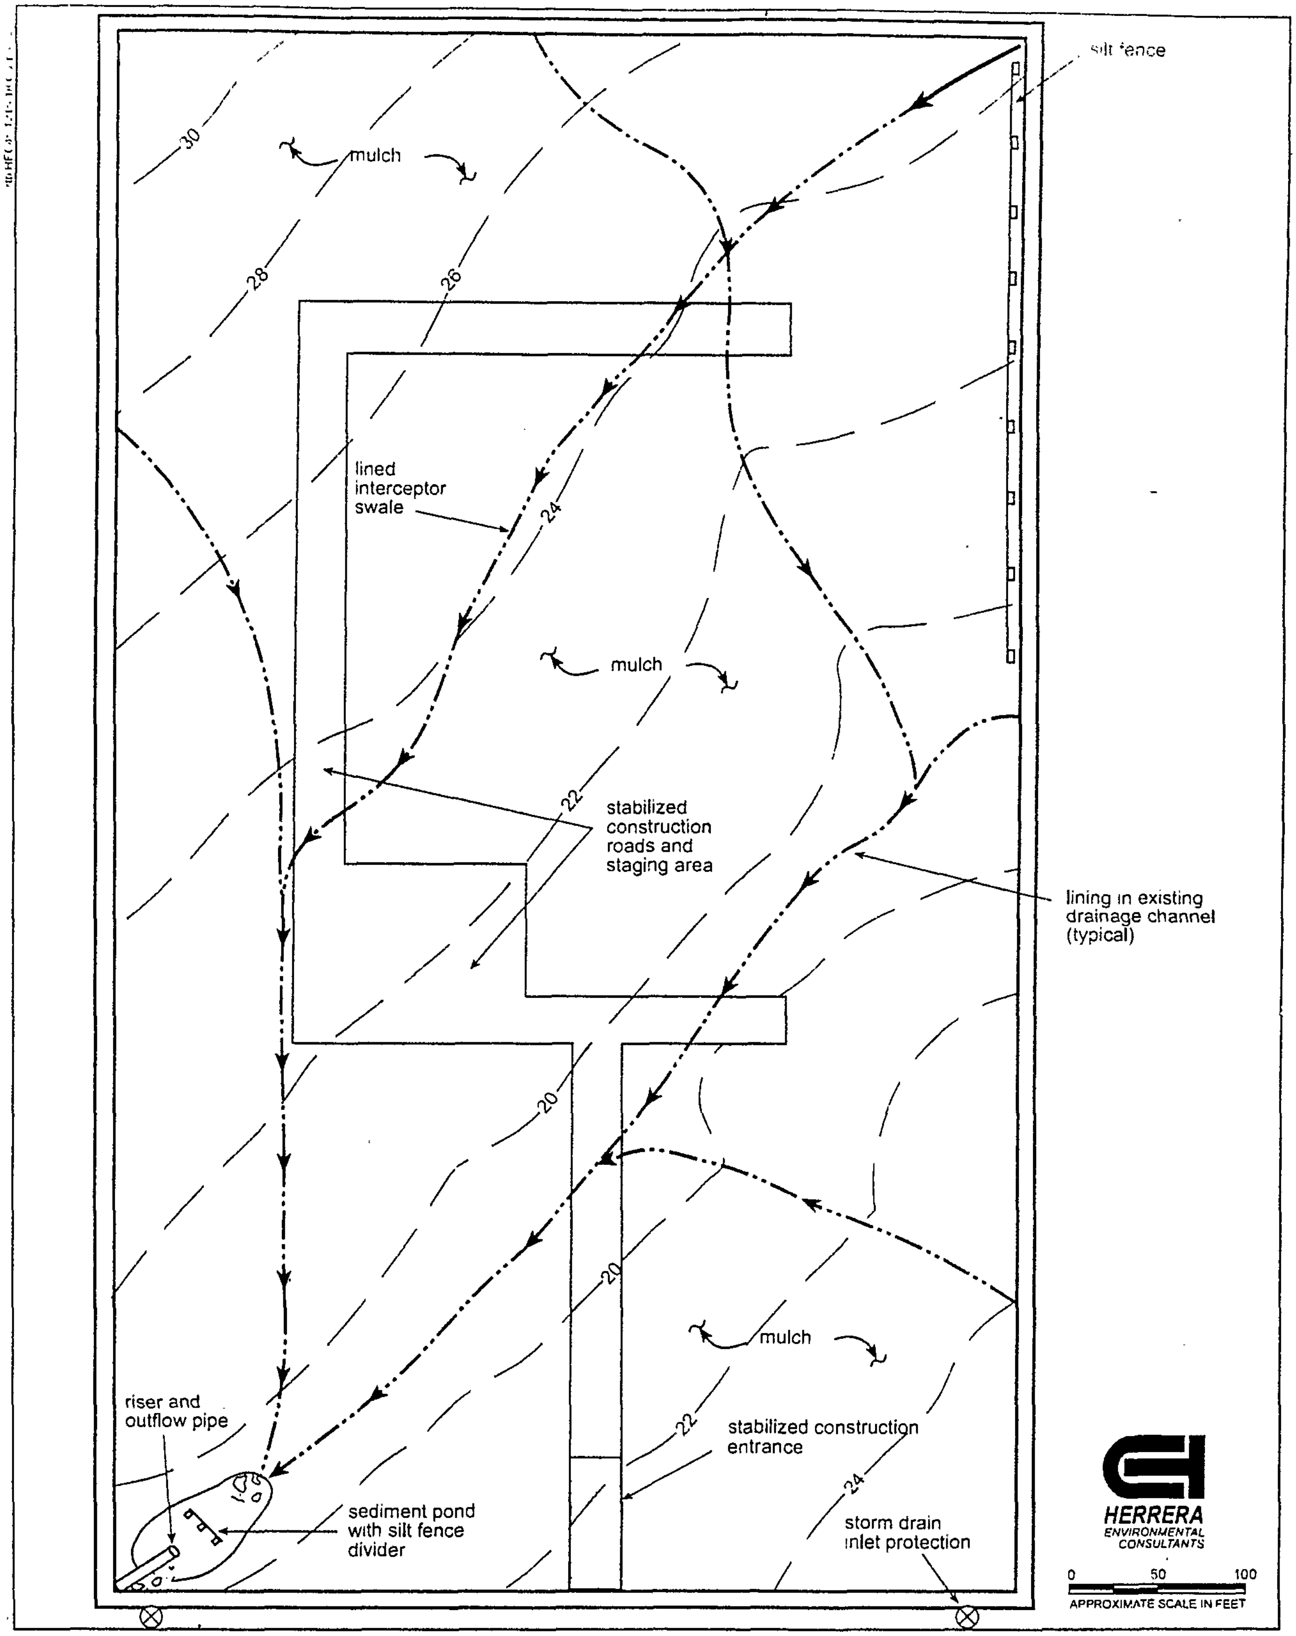

Figure 2. Erosion and sediment control BMPs for 10-acre residential development.

Costs for Construction Stormwater Pollution Prevention Plan

Without Wet Season Shutdown

For the scenario where it is assumed that grading activity continues on the site through the winter, the construction cost for the SWPPP BMPs is estimated at approximately $40,000 for type A soils and $49,000 for type C soils. Tables 1 and 4 in Appendix A, respectively, show itemized costs for the various BMP components and their associated construction procedures and materials. These costs do not include engineering planning and design fees, permit fees, performance bonding (or other appropriate financial instruments to ensure compliance with the approved SWPPP), and contingencies for unforeseen difficulties. Maintenance of the erosion and sediment control BMPs (included in the SWPPP BMP costs noted above) over the course of the 12-month construction period is estimated to cost approximately $8,400 for type A soils and $14,500 for type C soils (see Tables 3 and 7, respectively, in Appendix A). Appendix A provides further details on assumptions used to develop these costs.

With Wet Season Shutdown

For the scenario where it is assumed that the site is managed to avoid grading activity from November through March, the construction cost for the SWPPP BMPs is estimated at approximately $41,000 for type C soils. Table 5 in Appendix A shows itemized costs for the various BMP components and their associated construction procedures and materials. These costs do not include engineering planning and design fees, permit fees, performance bonding (or other appropriate financial instruments to ensure compliance with the approved SWPPP), and contingencies for unforeseen difficulties. As discussed below, the construction SWPPP costs are rolled into the permanent stormwater site plan costs to create a total implementation cost, and those estimates include engineering, permitting, and contingency costs. Maintenance of the erosion and sediment control BMPs over the course of the 17-month construction period (included in the SWPPP BMP cost noted above) is estimated to cost approximately $9,100 (see Table 8 in Appendix A). Appendix A provides further details on assumptions used to develop these costs.

Effects of Wet Season Site Work on SWPPP Cost

The total SWPPP implementation and maintenance cost varies slightly depending on whether clearing and grading activity occurs in the wet winter months. For the scenario where the site is stabilized for the period of November through March, it is estimated that the total SWPPP cost would be $7,400 less compared to the scenario where site activities continue through the winter. Avoidance of grading activities in the wet season is assumed to result in reduced costs for street sweeping, BMP inspections following storms, and catch basin cleaning, but increased cost for soil stabilization during the winter. Most of the SWPPP costs are independent of work scheduling in the wet season for this site. For example, the sedimentation pond size, the need for temporary lined conveyance ditches, and the need for stabilization of construction roads and construction staging areas are the same regardless of wet season work scheduling.

Site 1 Permanent Stormwater Site Plan

The stormwater site plan must include provisions for maintaining natural drainage patterns, using source control BMPs to prevent pollutants from entering stormwater runoff, reducing hydrologic changes through onsite stormwater management techniques, treating runoff from smaller storm events, detaining runoff from larger storm events to prevent stream bank erosion due to high flows, and maintaining the BMPs that are chosen and implemented. Minimum requirement eight, pertaining to wetlands, and minimum requirement nine, pertaining to basin planning, are assumed to be not applicable to this hypothetical site and this analysis. In accordance with the manual, two preliminary considerations guided BMP selection for site 1. Oil control and special phosphorus control measures must be considered; they are not required for this site. The standard western Washington peak flow control to match pre-development flow peaks and durations must be considered and is required because the site discharge is conveyed to a small stream (if site discharge is conveyed directly to a major water body, the standard does not apply).

Pollution Source Control BMPs

Pollution source control BMPs are important components of a stormwater site plan for site 1 to satisfy minimum requirement three. Several of the source control BMPs outlined in the manual are applicable to this development. However, only a few of the source control BMPs that should be applied to this development incur direct, calculable costs. Source controls such as environmentally sensitive vegetation management and protection of storage areas housing containers for chemicals, garbage, and other wastes are important and should be emphasized to homeowners. However, they are difficult to quantify in terms of costs. Moreover, some of these source controls are not required for residences. An actual stormwater site plan for this type of residential development site should mention these items; however, the cost estimates given herein do not include costs to implement source control BMPs that are educational in nature, as opposed to physical actions. The cost estimates for this site include only two source control BMPs from the manual: maintenance of storm drainage facilities (BMP S2.00) and street sweeping (BMP S2.20).

Onsite Stormwater Management Measures

In addition to pollution source control BMPs, onsite stormwater management measures must also be implemented to infiltrate, disperse, and retain stormwater runoff onsite where practicable (minimum requirement number 5). Some examples of onsite stormwater management BMPs applicable to this residential development include roof downspout infiltration and dispersion, use of permeable/porous pavements, and vegetated rooftops. For this site, the use of "alternative" roof downspout infiltration trenches was assumed with infiltratable soils on site (type A). These infiltration systems are suitable for coarse soils, and have a simpler design than downspout infiltration systems in soils with fine particles. Permanent stormwater facilities were sized, and the associated cost estimate developed, with roof downspout infiltration included. The contributing drainage area for the permanent pond facilities is considerably reduced as a result.

For the scenario with noninfiltratable type C soils, it was assumed that roof downspout dispersion systems would be provided for half of the total rooftop areas. The sizing of permanent stormwater treatment and flow control facilities accounted for 50 percent of the rooftop runoff, assuming that 50 percent could be dispersed through sufficient grassy areas and that the other 50 percent of the rooftop runoff would drain relatively quickly to conveyance systems carrying flow to the stormwater pond facilities. If all rooftop runoff could pass through grassy areas greater than 50 feet in length, the modeling of site runoff could assume that all of the rooftops are equivalent to grass and the size of the stormwater pond facilities would be reduced accordingly. The cost estimate for rooftop drainage dispersion systems assumes simple splashblocks that disperse flow across a long grassy area as opposed to rock-filled trenches with notched grade boards. Although it was assumed that porous pavements could be used for individual driveways, the sizing of the permanent stormwater treatment and flow control facilities conservatively assumed that all driveway runoff would reach the ponds relatively quickly. Thus, the cost estimate for this scenario is representative of a worst-case for the amount of flow to be managed. If earth-filled concrete paver blocks or similar materials were used for driveways, the modeling of site runoff could assume that 50 percent of the driveway areas are equivalent to grass and the size of the stormwater pond facilities would be reduced accordingly.

Permanent Stormwater Control Facilities by Soil Type

The permanent stormwater control facilities selected for the residential site to satisfy the minimum requirements are dependent on soil type.

Type A Soils – With Infiltration

Infiltration is the preferred method of stormwater treatment and surface flow reduction, but infiltration requires suitable soils. For the scenario with type A soils, an infiltration basin preceded by a wetpond provides stormwater treatment and flow control. Figure 3 shows the layout of the site with the permanent stormwater control facilities for this condition.

While type A soils are suitable for discharging the site runoff to ground water, they are too porous to accomplish water quality treatment. The design includes a wetpond that performs water quality treatment and serves as a presettling facility in front of the infiltration basin. The wetpond is designed to treat all runoff from the 6-month, 24-hour storm event and is divided into two separate cells. Both wetpond cells would be excavated approximately 6 feet below grade, with an additional foot of depth in the first cell for sediment storage.

The infiltration basin, which would also be excavated 6 feet below grade, was sized to completely infiltrate all runoff up to the 100-year, 24-hour storm event, even though in pre-developed conditions there would be slight runoff from the site in extreme storm events. The wetpond overflows to the infiltration basin, and the infiltration basin has an overflow structure for safe conveyance of extreme high flows.

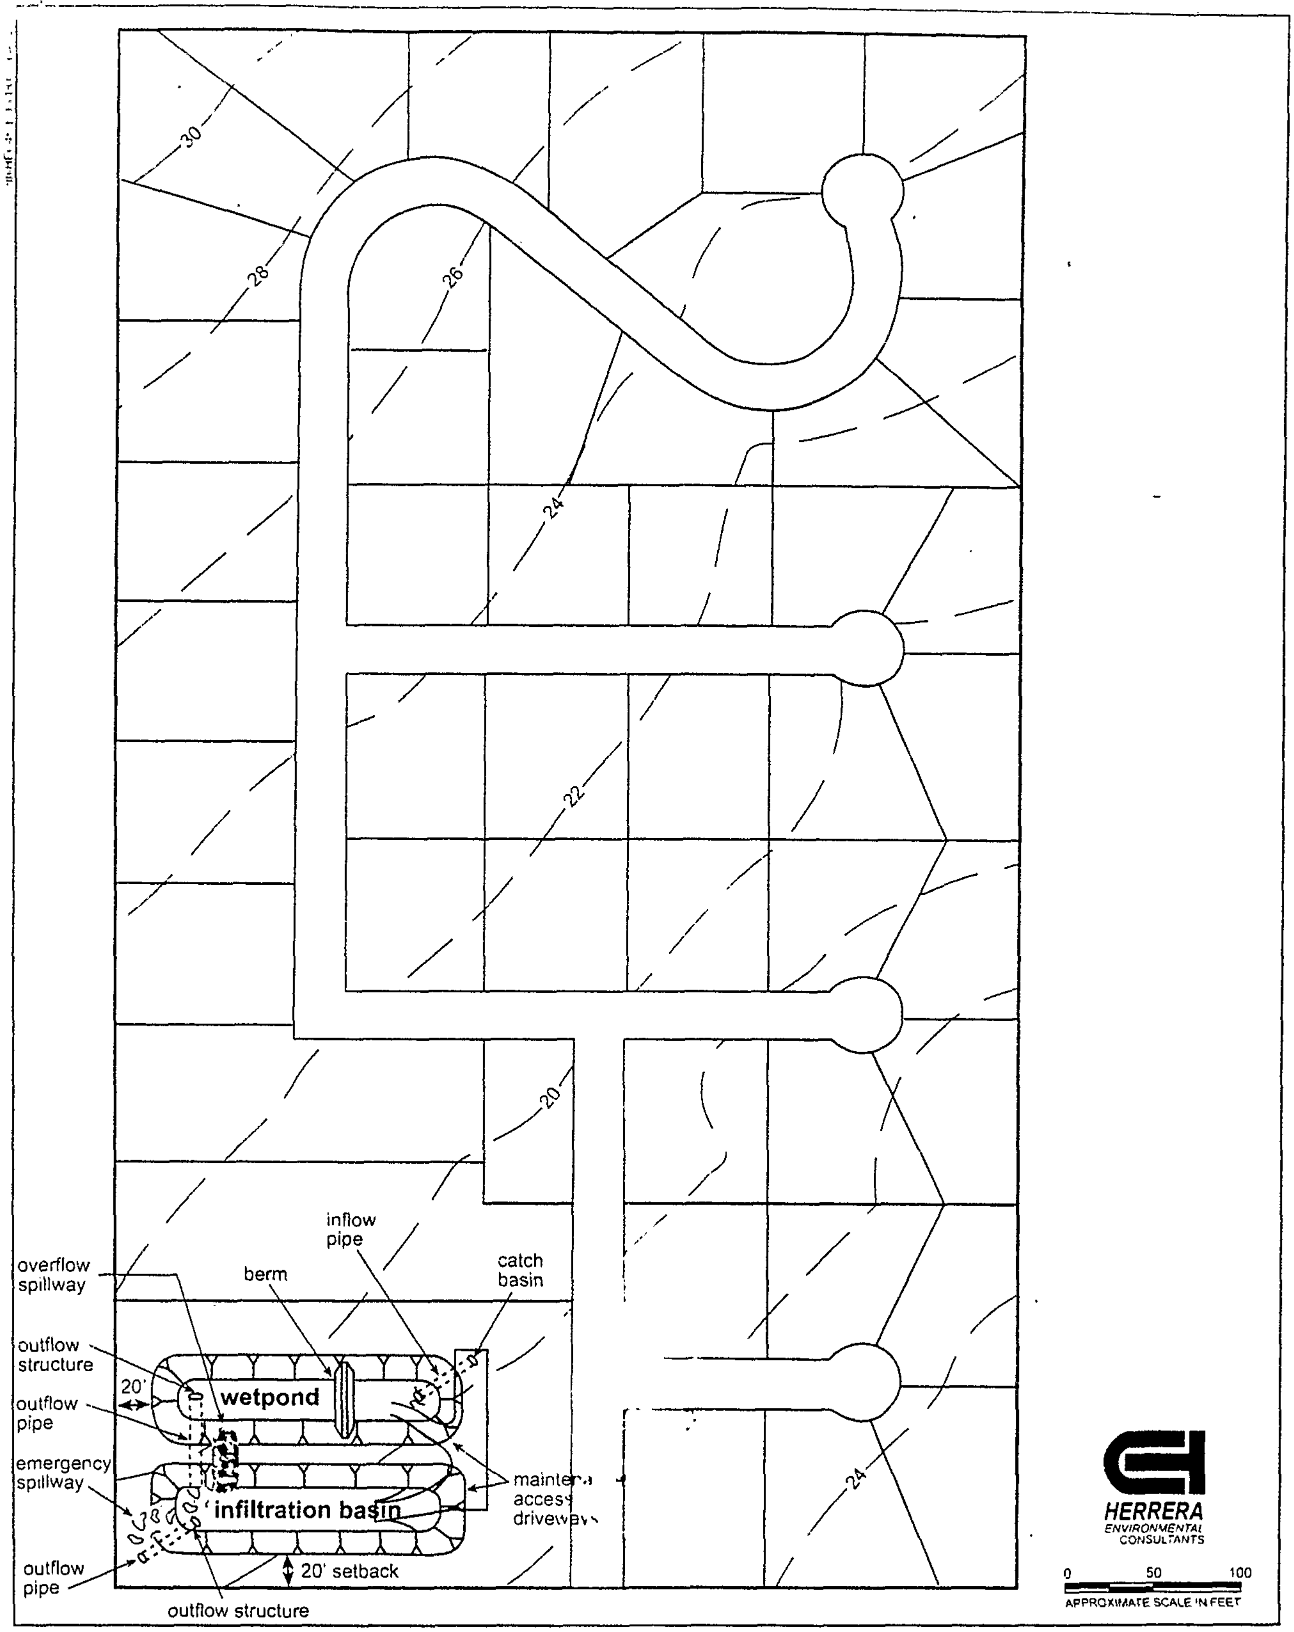

Figure 3. Permanent stormwater site plan BMPs for 10-acre residential development with infiltration.

Type C Soils– Without Infiltration

The scenario without infiltration (type C soils) contains a combined wet/detention pond with a permanent pool for water quality treatment and excess storage capacity for peak flow control. Figure 4 shows the layout of the site with the permanent stormwater control facilities for this condition. The pond does not require special design features for enhanced phosphorus removal.

The center of the pond is a permanent treatment pool with two cells separated by an earthen berm. The first cell is excavated approximately 10 feet below existing grade, and the second cell is excavated nine feet below grade. Each cell provides four feet of water depth to create a permanent pool (during the wet months) for water quality treatment. The first cell has an additional one foot of sediment storage capacity in the bottom. An additional four feet of storage space on top of the permanent pool provides detention capacity for the 100-year runoff event. The extra foot of freeboard allows for an emergency overflow spillway. The outer portion of the pond, which surrounds the permanent pool, provides detention storage. Because the detention storage volume needed is large in relation to the water quality treatment volume needed, the pond footprint area expands significantly in the upper detention zone. The pond has a multiple-orifice outflow restrictor above the permanent pool level to maintain predevelopment site discharge rates and flow durations.

The permanent BMP facilities, both with infiltration and without infiltration, are located so that they receive runoff from the entire development and maintain the natural drainage pattern of the site. The excavation for the temporary sediment pond is expanded for the permanent stormwater control facilities. A catch basin is provided at the site discharge location; it is assumed that the catch basin outflow is piped into the storm drainage system adjacent to the site.

Site 1 Implementation Costs to Satisfy the Minimum Requirements

Costs With Infiltration

The total cost of planning, designing, and constructing the BMPs in the construction SWPPP and permanent stormwater site plans for the scenario with infiltration is estimated at approximately $240,000, including engineering design and permitting costs, contingencies (25 percent of the total construction cost), and tax on the total cost with contingencies. The total cost for the scenario with the infiltration basin also includes the cost of performing a hydrogeologic evaluation to confirm infiltration suitability and/or determine the site-specific infiltration rate. The cost of the permanent stormwater facilities in the stormwater site plan is approximately 64 percent of the total implementation cost.

Costs Without Infiltration

The total cost of planning, designing, and constructing the BMPs in the construction SWPPP and permanent stormwater site plans for the scenario without infiltration is estimated at approximately $230,000. The cost of the permanent stormwater facilities in the stormwater site plan under this scenario is approximately 60 percent of the total implementation cost.

R0010800

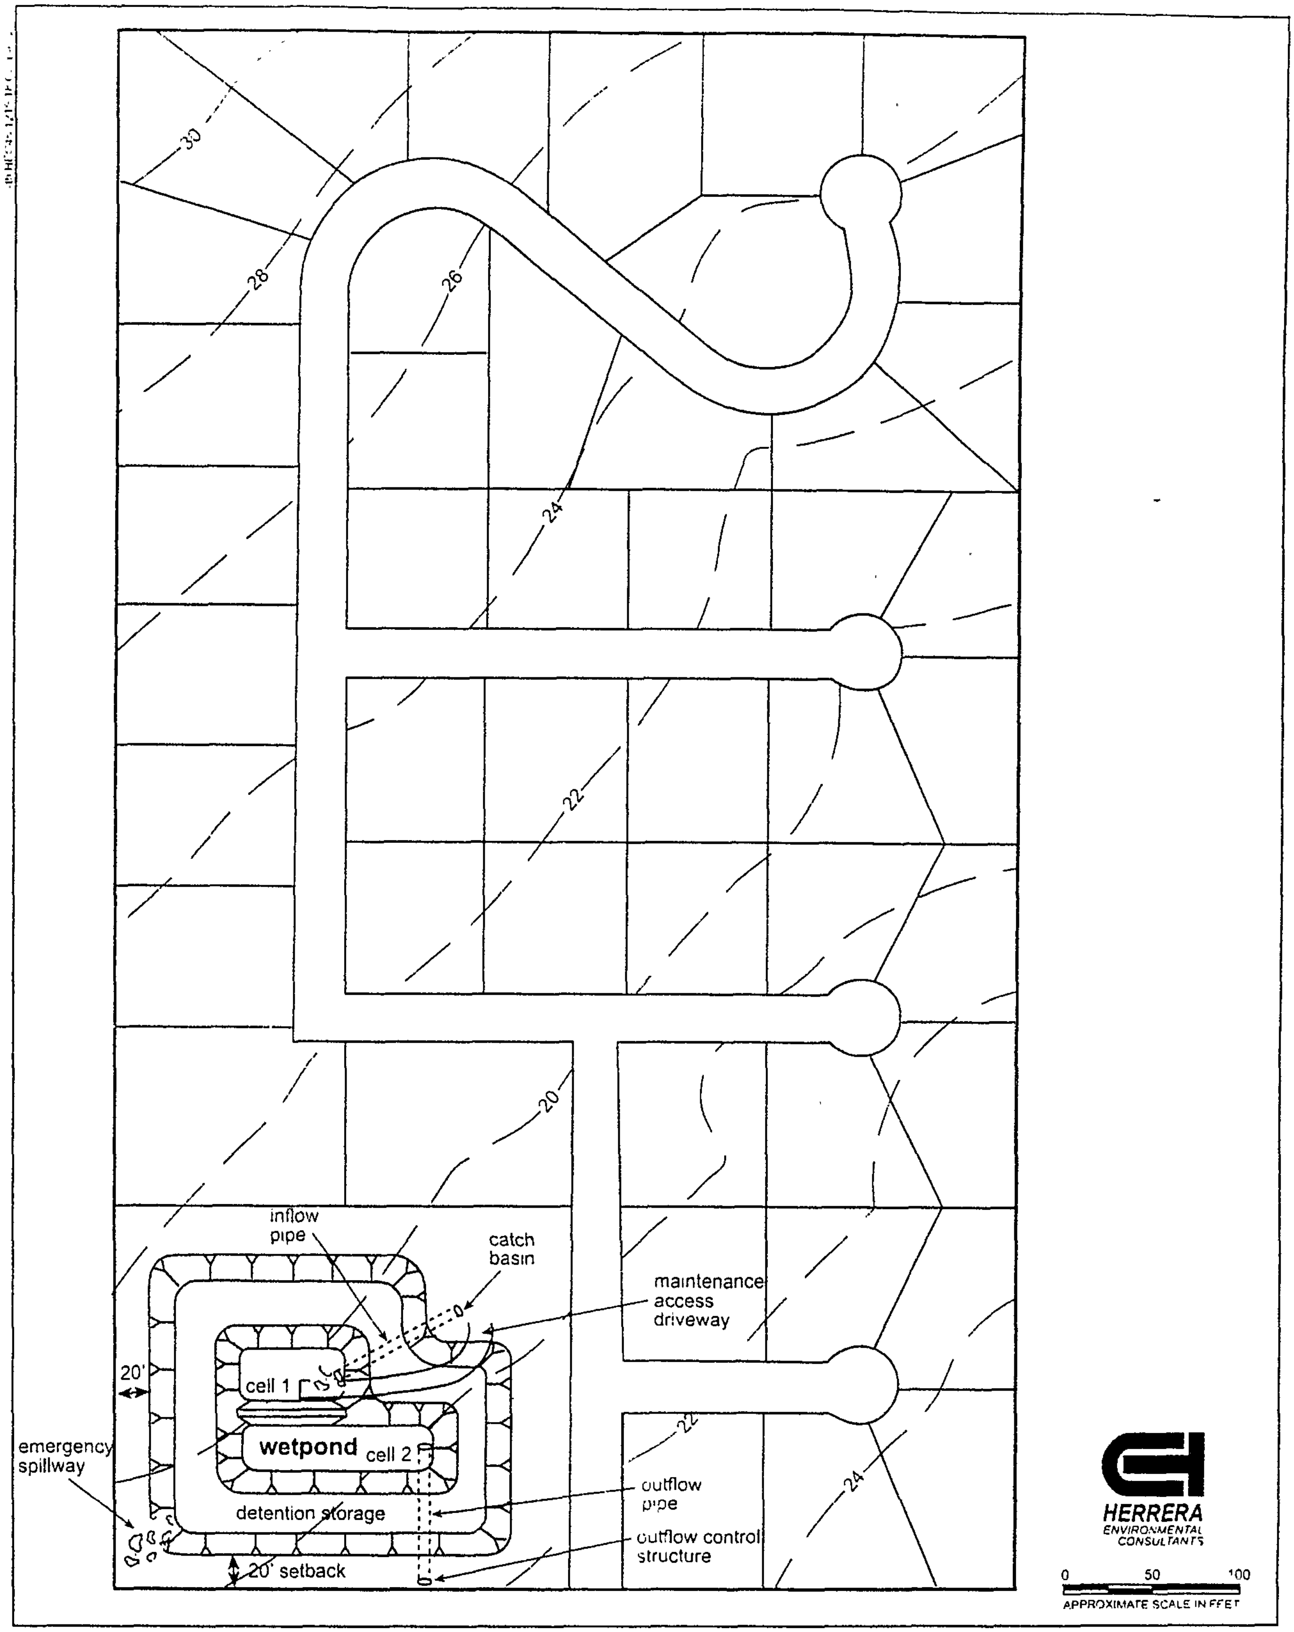

Figure 4. Permanent stormwater site plan BMPs for 10-acre residential development without infiltration.

Itemized costs for the components of the stormwater site plan are given for the two scenarios in Tables 2 and 6 of Appendix A. Appendix A also provides further details on assumptions used to estimate costs.

Comparison of Pond Storage Volumes to 1993 Estimates

For the scenario where infiltration is feasible in type A soils and a wetpond is used for treatment of the runoff prior to infiltration, both the wetpond and the infiltration basin are now smaller in comparison to the sizes under the 1992 requirements. This is due to the requirement for onsite stormwater management (roof downspout infiltration). The volume of runoff assumed to reach the wetpond and infiltration basin is significantly less in comparison to the calculations associated with the 1992 requirements. The wet/detention pond in type C soils analyzed in this case study is larger in size compared to the same type of facility analyzed for this same site scenario in the 1993 report (Herrera 1993). This is because the wetpond storage volume has increased as a result of the design criteria for the 6-month storm precipitation depth and the detention storage volume has increased considerably as a result of the requirement to match flow durations in addition to controlling peak flow rates.

The comparison of pond storage volumes in type A soils is as follows:

- 1993 analysis (re-analyzed as discussed in Appendix C) -- wetpond treatment pool volume = 23,950 cubic feet; infiltration basin storage volume = 60,900 cubic feet
- Present analysis -- wetpond treatment pool volume = 13,700 cubic feet; infiltration basin storage volume = 41,900 cubic feet;

The comparison of these storage volumes in type C soils is as follows:

- 1993 analysis -- wetpond treatment pool volume = 25,700 cubic feet; detention storage volume = 50,300 cubic feet; total pond storage volume = 76,000 cubic feet
- Present analysis -- wetpond treatment pool volume = 28,600 cubic feet; detention storage volume = 98,000 cubic feet; total pond storage volume = 127,000 cubic feet

Site 1 Operation and Maintenance Requirements and Costs

Operation and Maintenance Assumptions

Routine maintenance of the permanent stormwater facilities includes such tasks as conducting annual inspections; mowing the grass in the infiltration basin and wetpond, or combined wet/detention pond, at least twice per year; removing accumulations of debris and floating materials once per year; removing accumulated sediments in the wetpond once the sediment storage depth in the bottom is full (assumed to be once every 5 years); tilling the infiltration basin soil or otherwise re-establishing maximum infiltration capacity as needed (assumed to be once every 2 years); seeding of grassed areas that turn bare at least once per year; adding quarry spalls and/or gravel to overflow spillways and access driveways as needed; replacing miscellaneous parts and materials as needed; and cleaning out connecting pipes. In addition, streets within the development should be swept frequently to limit the amount of sediment that enters the permanent stormwater control facilities, enabling them to function more effectively. All catch basins and storm drains in the development should be cleaned frequently to prevent clogging and to remove some of the pollutants that otherwise could be flushed into the treatment and detention facilities during large storm events.

Operation and Maintenance Costs, With and Without Infiltration

The annual cost of routine maintenance procedures for the scenario with the infiltration basin and wetpond is estimated at $7,200 (see Table 3 in Appendix A). The annual maintenance cost for the scenario with a combined wet/detention pond (without infiltration) is estimated at $9,000 (see Tables 7 and 8 in Appendix A). Most of the annual operation and maintenance costs are associated with street sweeping and conveyance system cleaning rather than pond maintenance.

Further details on assumptions used to estimate operation and maintenance costs are given in Appendix A.

Site 2—Small Commercial Development

Site 2 is a 1-acre commercial development assumed to be a typical restaurant. Figure 5 shows the layout of the site as planned for development, without stormwater control facilities to satisfy the minimum requirements. The site has 90 percent impervious cover. There is one main site entrance for construction access (see Figure 6). This relatively flat site drains from the upper left to the lower right (as shown in Figure 5) in its undeveloped state, with the potential for stormwater runon from adjacent land. Because the site would not be graded extensively, after development drainage would flow in the same direction.

It is assumed that the developed site would have underground storm sewer pipes to convey runoff to the permanent stormwater control facilities. It is assumed that some mechanism is provided to divert offsite runoff around the site (such as that mentioned for the residential site), the costs of which are not included in this analysis. It is also assumed that developed site runoff that is not infiltrated is discharged to an offsite storm sewer, eventually reaching a stream.

Site 2 Construction Stormwater Pollution Prevention Plan

For all new development and redevelopment projects that add or replace 2,000 square feet or more of impervious surface or clear more than 7,000 square feet, such as site 2, the manual requires preparation of a SWPPP to guide selection and implementation of a variety of BMPs during construction. The 12 minimum requirements for stormwater pollution prevention during construction are listed above for site 1. It is assumed that construction would take 2 months to complete.

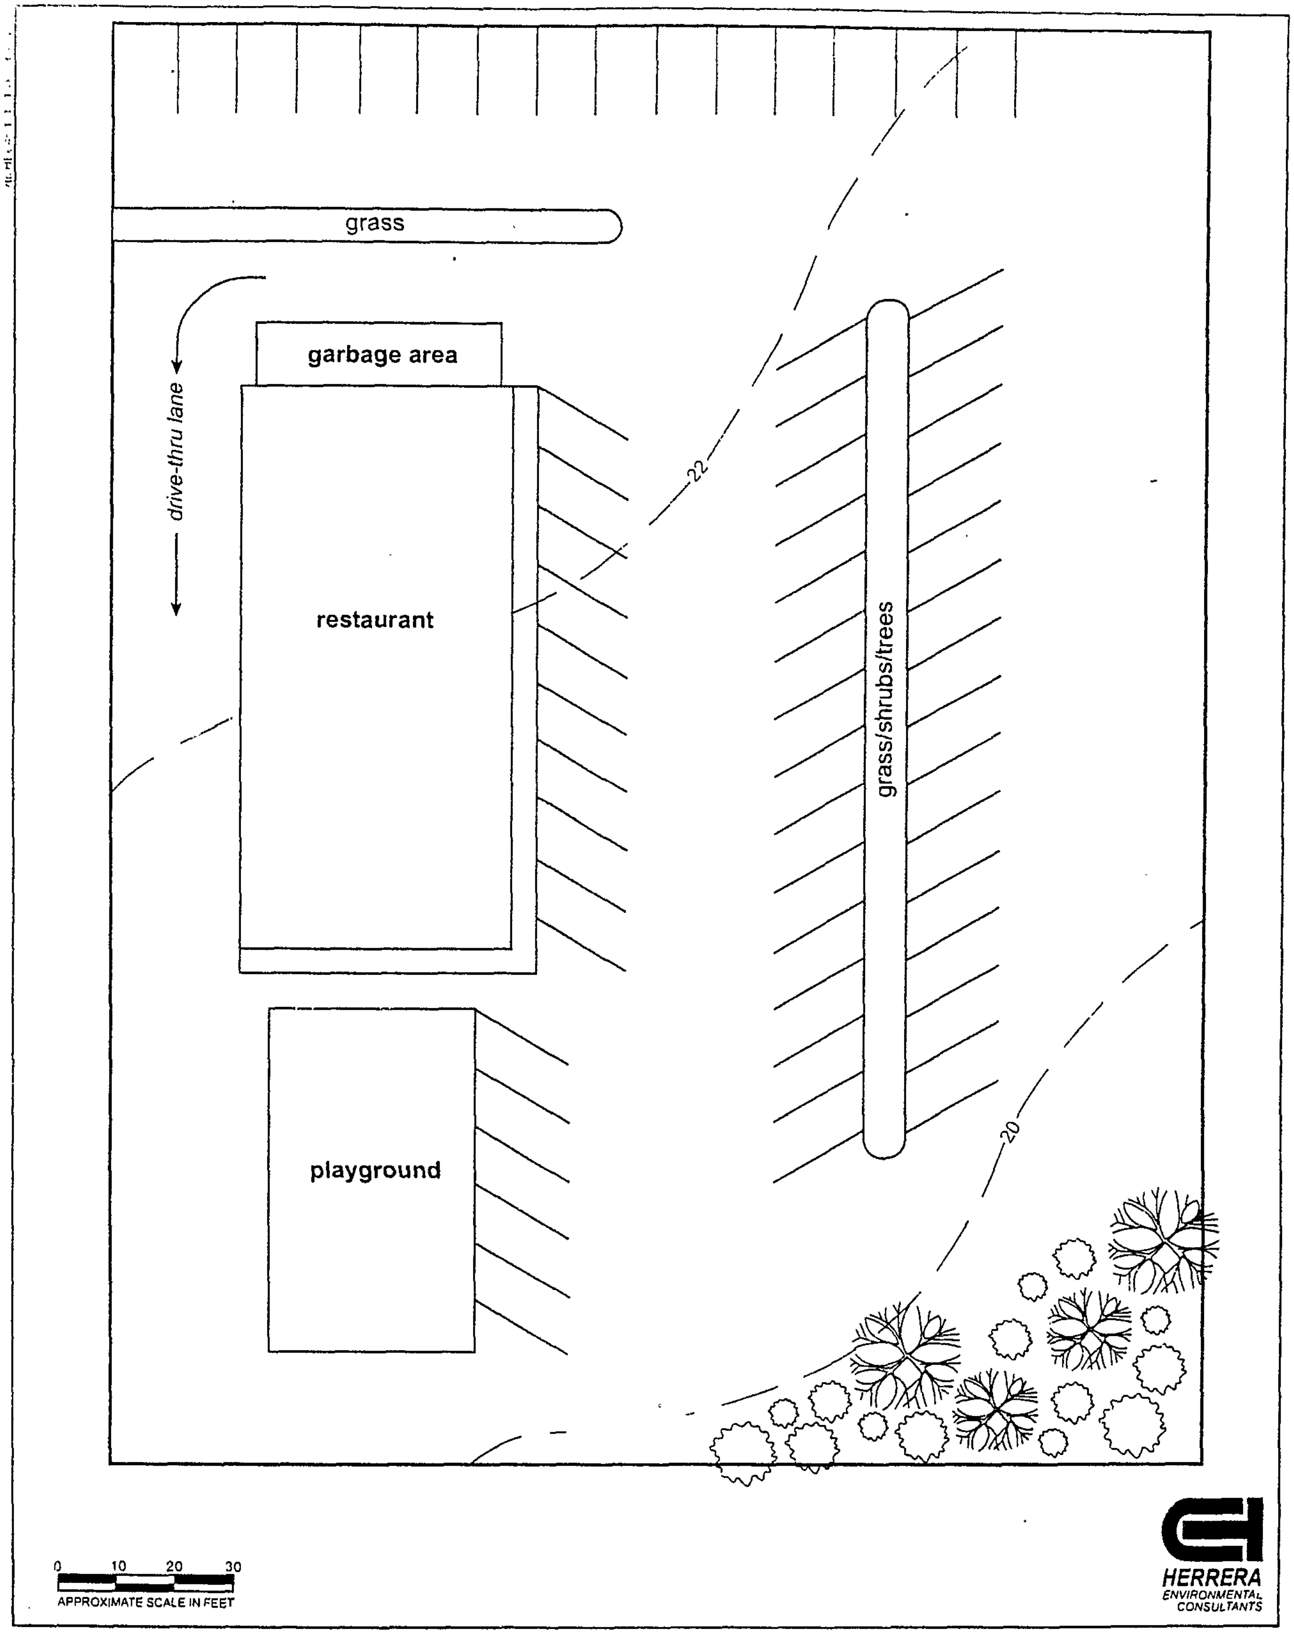

Figure 5. One-acre commerical development plan, without stormwater facilities, superimposed on natural (pre-development) topography and drainage features.

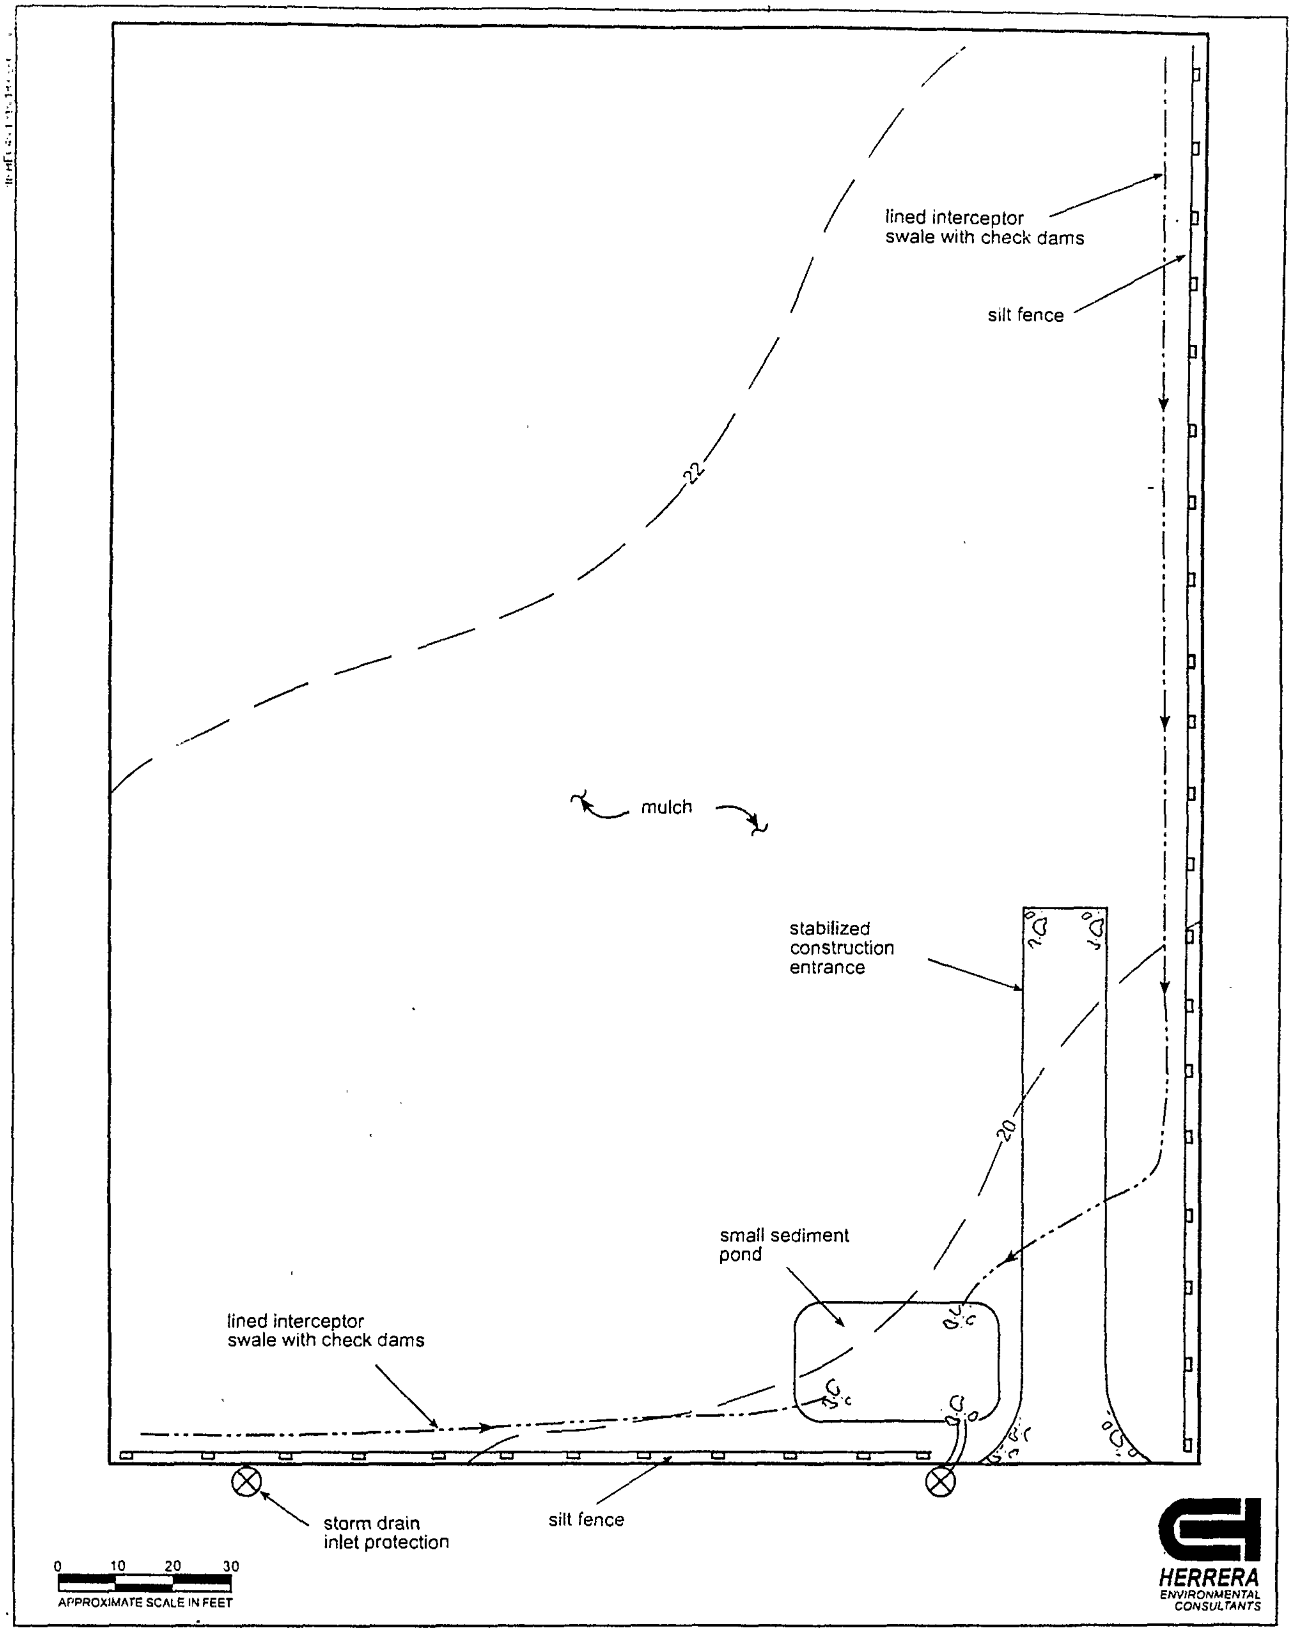

Figure 6. Erosion and sediment control BMPs for 1-acre commercial development.

Several BMPs are necessary to control site runoff and erosion during the construction phase of site 2. A combination of intercepting swales with check dams, a small sediment pond, a stabilized site entrance and equipment parking area, mulch application to bare areas, storm drain inlet protection on the adjacent street, and silt fencing on the downslope perimeter would be used to control transport of sediments off the site and to protect downstream properties and waterways during construction. These BMPs would be in place prior to construction activities to satisfy the minimum requirements.

Figure 6 shows the locations of the erosion and sediment control BMPs selected for the small commercial development site. The BMPs are almost all the same for type A soils (suitable for infiltration) and type C soils (unsuitable for infiltration). The size of the temporary sediment pond differs for the two soil types because of the effect soil type has on runoff peak flows and volumes. Figure 6 indicates the sediment pond size corresponding to type C soils, which is larger than the pond for type A soils.

It is assumed that interceptor swales for runoff collection would not be needed in type A soils. The intercepting swales along the edges of the site would be used to convey almost all of the construction site runoff to the sediment pond (in type C soils). The sediment pond would contain a silt fence divider to enhance trapping of suspended sediments. Silt fencing would be used to contain sediments on the site periphery that may be present in runoff that does not reach the interceptor swales. The site entrance would be stabilized with quarry spalls. Mulch would be applied as needed to areas of exposed soil during construction.

It is assumed that two catch basins on the adjacent street would require inlet protection. Due to the relatively short time frame for construction, it is assumed that cleaning of the catch basins on the adjacent street would not be necessary following construction, and that the small sediment pond would not require sediment cleanout prior to its removal. Other BMPs such as vehicle tire washing and spraying of dusty areas would be implemented during construction as needed.

Maintenance of the erosion and sediment control BMPs is a key component of the construction SWPPP. It is assumed that routine BMP maintenance checks would be performed once weekly and after runoff-producing storm events during the dry season, or daily during the wet season to ensure that BMPs continue to function effectively. Silt fencing must be checked periodically, especially following storms, to determine if repairs or replacement fabric sections are needed. Mulch used to cover stripped site areas would be relocated and replaced as needed, as portions of the site are permanently stabilized. If sediment is tracked offsite onto neighboring streets, it must be swept and collected as necessary.

Costs for Construction Stormwater Pollution Prevention Plan

The construction cost for these SWPPP BMPs is estimated at approximately $6,900 for type A soils and $8,600 for type C soils. Tables 9 and 12 in Appendix A show itemized costs for the various BMP components and their associated construction procedures and materials. These costs do not include engineering planning and design fees, permit fees, performance bonding (or other appropriate financial instruments to ensure compliance with the approved SWPPP), and contingencies for unforeseen difficulties. Maintenance of the erosion and sediment control BMPs over the course of the 2-month construction period (included in the SWPPP BMP costs noted above) is estimated to cost approximately $1,300 for type A soils and $1,900 for type C soils (see Tables 11 and 14 in Appendix A, respectively). Appendix A provides further details on assumptions used to develop these costs.

Site 2 Permanent Stormwater Site Plan

The stormwater site plan must include provisions for maintaining natural drainage patterns, using source control BMPs to prevent pollutants from entering stormwater runoff, reducing hydrologic changes through onsite stormwater management techniques, treating runoff from smaller storm events, detaining runoff from larger storm events to prevent stream bank erosion due to high flows, and maintaining the BMPs that are chosen and implemented. Minimum requirement eight, pertaining to wetlands and minimum requirement nine, pertaining to basin planning are assumed to be not applicable to this hypothetical site and this analysis.

In accordance with the manual, two preliminary considerations guided BMP selection for site 2. Oil control is assumed to be required for this site due to high vehicle turnover rates that meet the high use site definition. Phosphorous control is not required. The standard western Washington peak flow control to match pre-development flow peaks and durations is required because the site discharge is conveyed to a small stream (if site discharge is conveyed directly to a major water body, the standard does not apply).

Pollution Source Control BMPs

Pollution source control BMPs are important components of the stormwater site plan for site 2 to satisfy minimum requirement three. Several of the source control BMPs outlined in the manual are applicable to this development. The area designated for garbage containers adjacent to the restaurant should be covered or contained to prevent precipitation from contacting waste containers and to prevent the runoff from entering the nearby storm drainage system. The interior of this area must drain to the sanitary sewer if possible (BMP S1.50). Other materials and wastes that may introduce pollutants to stormwater should also be placed in the protected area. Cooking equipment such as vents and filters must not be cleaned outdoors unless a sanitary sewer drain is provided. In addition, storm drainage facilities must be maintained (BMP S2.00), and the parking lot should be swept frequently to collect and properly dispose of accumulated sediments and other materials that may contain pollutants (BMP S1.22).

Onsite Stormwater Management Measures

In addition to pollution source control BMPs, onsite stormwater management measures must also be implemented to infiltrate, disperse, and retain stormwater runoff onsite where practicable (minimum requirement five). Some examples of onsite stormwater management BMPs applicable to this commercial development include roof downspout infiltration, use of permeable/porous pavements in low traffic areas, and vegetated rooftops. For this site, the use of "typical" roof downspout infiltration trenches (with inlet catch basins and perforated pipe) was assumed with infiltratable soils on site (type A). The simpler ("alternative") infiltration trench design that is allowed in coarse soils, as assumed for Site 1, would require a wide strip of grass between the building and the trenches, and this type of site would not likely have available space for such a grass strip. Permanent stormwater facilities were sized, and the associated cost estimate developed, with roof downspout infiltration included.

For the scenario with type C soils, it was assumed that roof downspout dispersion systems would not be feasible due to limited area of grass or other open space. The sizing of permanent stormwater treatment and flow control facilities accounted for all rooftop runoff because it was assumed that this runoff would reach the stormwater control vaults quickly. Although it was assumed that porous pavements could be used for low traffic areas of the site, the sizing of the permanent stormwater treatment and flow control facilities conservatively assumed that all driveway and parking lot runoff would reach the vaults quickly.

Permanent Stormwater Control Facilities by Soil Type

The permanent stormwater control facilities selected for the small commercial development site to satisfy the minimum requirements are dependent on soil type. Regardless of soil type, it is assumed that the stormwater facilities would be placed underground to maximize surface area for vehicle parking. This is a departure from the assumption in the 1993 cost analysis report (Herrera 1993) that all stormwater management facilities would be placed above ground, regardless of the implications for available parking area, and results in significant cost differences. The oil control requirement also applies regardless of soil type. It is assumed that catch basin filter inserts would be used for this oil control.

Type A Soils – With Infiltration

Infiltration is the preferred method of stormwater treatment and flow control, but infiltration requires suitable soils. For the scenario with type A soils (suitable for infiltration), underground infiltration tanks preceded by a wet vault provides stormwater treatment and flow disposal. Figure 7 shows the layout of the site with the permanent stormwater control facilities for this condition. For cost estimating purposes, it was assumed that two sections of 8-foot diameter asphalt-treated steel pipe would be used to construct the wet vault, and that 5-foot diameter aluminized steel pipe with perforations would be used for the infiltration tanks. These structures would support traffic loads from above provided there is approximately 2 feet of cover beneath the parking lot pavement. The infiltration tanks and associated inflow piping are assumed to store and dispose of all runoff up to the 100-year event even though slight flows occur in the pre-development condition. Steel pipe was assumed for this analysis as a cost saving measure. In many cases concrete vaults may be necessary, and that would lead to increased costs.

Type A soils are not suitable for water quality treatment via infiltration; therefore, a wet vault (discussed below) provides pretreatment for ground water protection. The wet vault also provides protection for the infiltration system by significantly reducing the sediment loading that could potentially clog the infiltration media. With infiltration of all runoff, enhanced treatment is

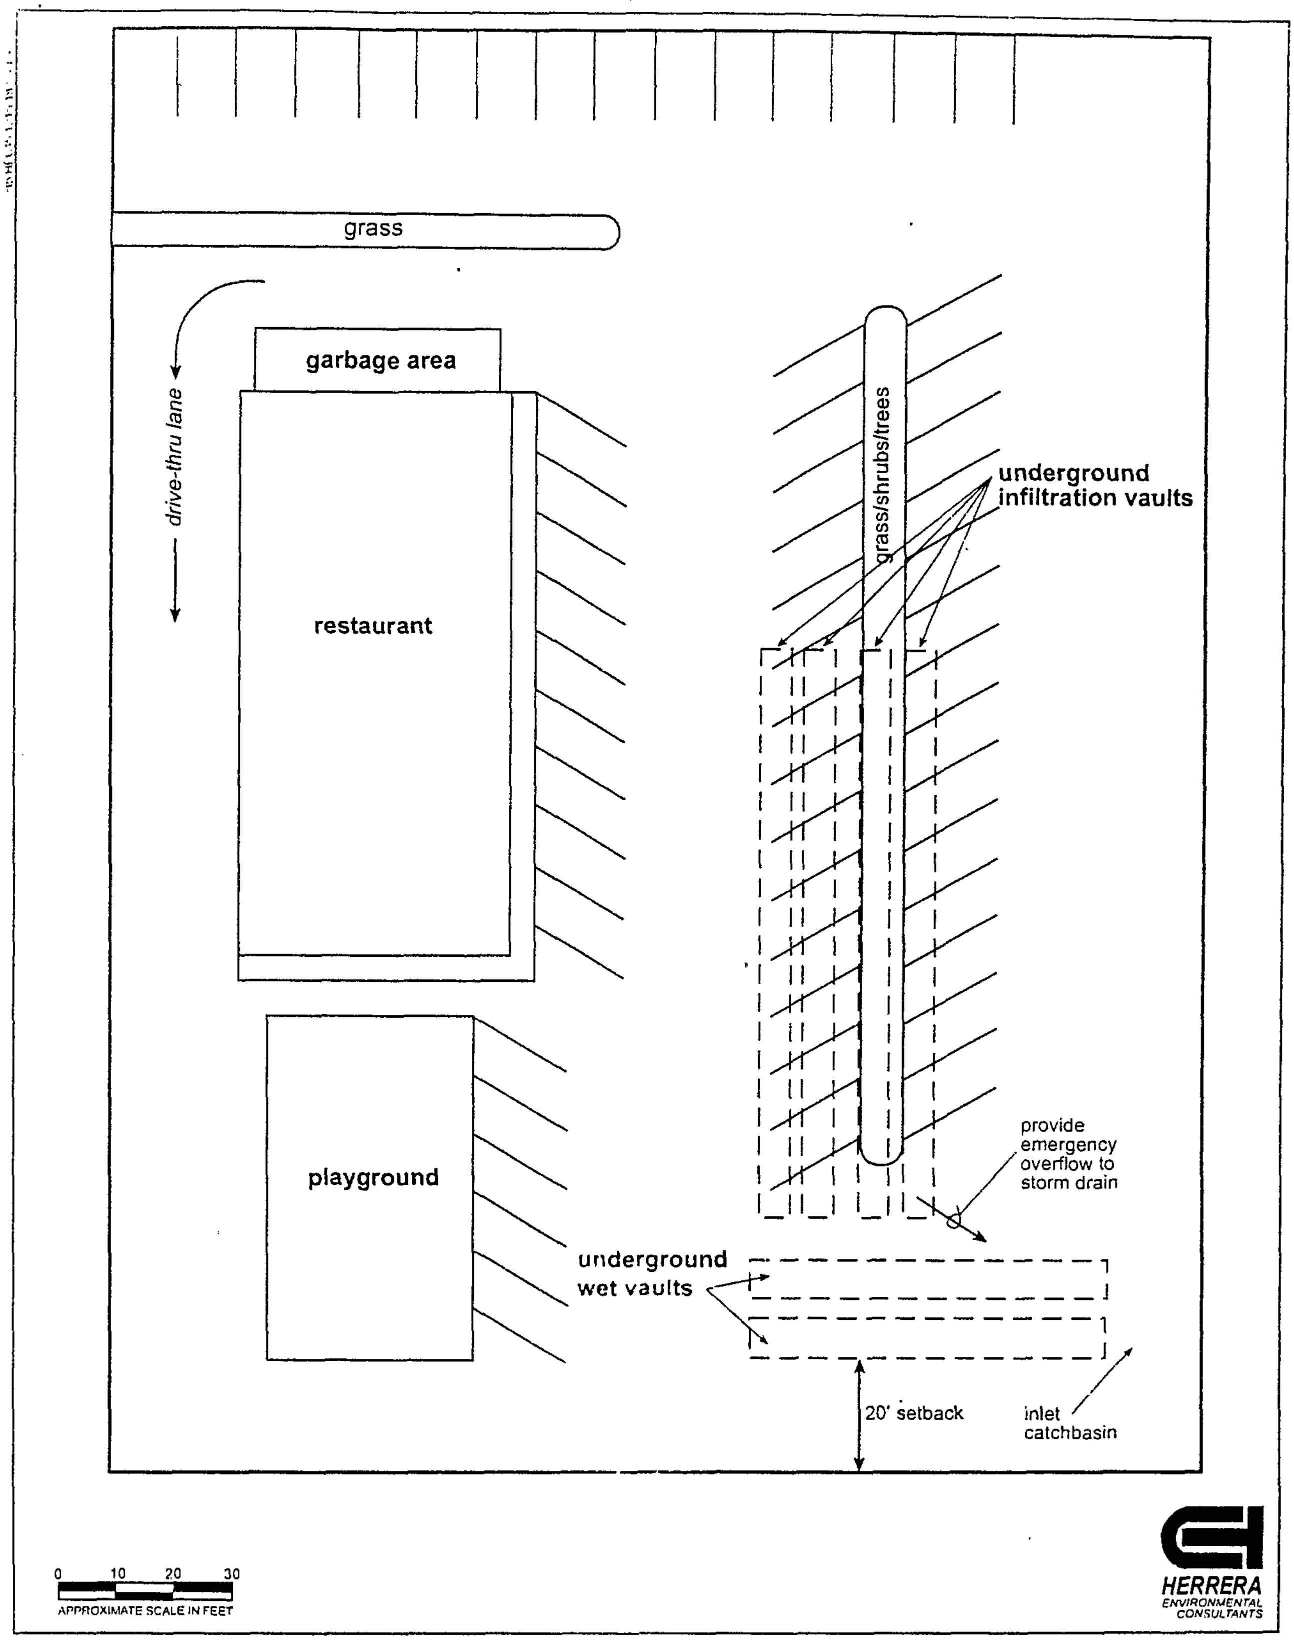

Figure 7. Permanent stormwater quality control BMPs for 1-acre commercial development with infiltration.

not required. It is assumed that downspout infiltration trenches (shown conceptually on Figure 7) would be provided in this scenario. Therefore, the rooftop runoff does not reach the wet vault or infiltration vaults and their sizes are reduced accordingly (by approximately 20 percent).

The wet vault is sized with a treatment pool volume equivalent to the site runoff volume (excluding rooftop area) of the 6-month, 24-hour storm event. This vault overflows to the buried infiltration tanks. Under extreme storm conditions (but less than the 100-year event), flows can back up through the infiltration tanks and wet vault and can be stored in the conveyance piping. The depth of the wet vault treatment pool is assumed to be 6 feet (with 1 foot of sediment storage on the bottom and 1 foot of freeboard on top), and the maximum depth of ponding inside the infiltration tanks is assumed to be 3 feet.

Type C Soils – Without Infiltration

For the scenario without infiltration, a wet vault with a permanent pool performs water quality treatment and adjacent detention pipes provide storage capacity for flow control. An additional sand filter vault provides the enhanced treatment required with a surface discharge to fish-bearing waters. Figure 8 shows the layout of the site with a wet vault, detention pipes, and separate sand filter vault in place. The treatment pool in the wet vault and the sand filter constitute a two-facility treatment train to perform the enhanced water treatment that is required. The wet vault does not require special design features for phosphorus removal. Because the detention storage volume needed is relatively large in comparison to the treatment volume, it is assumed that separate pipes of different diameter provide a detention function only. It is assumed that the wet vault would be built with 8-foot diameter asphalt-treated steel pipe and that the detention storage would be provided by four sections of 5-foot diameter aluminized steel pipe and a connecting manifold system. The detention pipes are of smaller diameter because the bottom elevation of the detention storage is set above the adjacent sand filter bed elevation, and a deeper detention storage outlet would result in a deeper sand filter vault. If the sand filter vault were excessively deep it would probably not be able to drain into the nearby storm sewer system. The detention pipe system is connected to a catch basin with a multiple-orifice outflow restrictor to maintain predevelopment site discharge rates and flow durations. The outlet control structure discharges to the sand filter vault. The sand filter is assumed to be housed in a concrete vault structure comprised of precast sections 20 feet in width and laid parallel, with pipes connecting the parallel vault sections. The sand filter bed is sized to treat the peak 2-year storm flow discharged from the detention system, with a perforated pipe underdrain system to collect treated flows, and flows above the 2-year detained peak would be discharged directly to the nearby storm sewer system via an overflow pipe.

By placing the stormwater management facilities in underground pipes, significantly more parking spaces are available in comparison to the design assumed in the comparable 1993 case study (Herrera 1993). If the facilities were placed above ground there would be insufficient parking area available to justify the development.

The permanent BMP facilities, both with infiltration and without infiltration, are located so that they receive runoff from the entire site and maintain the natural drainage pattern of the site. The

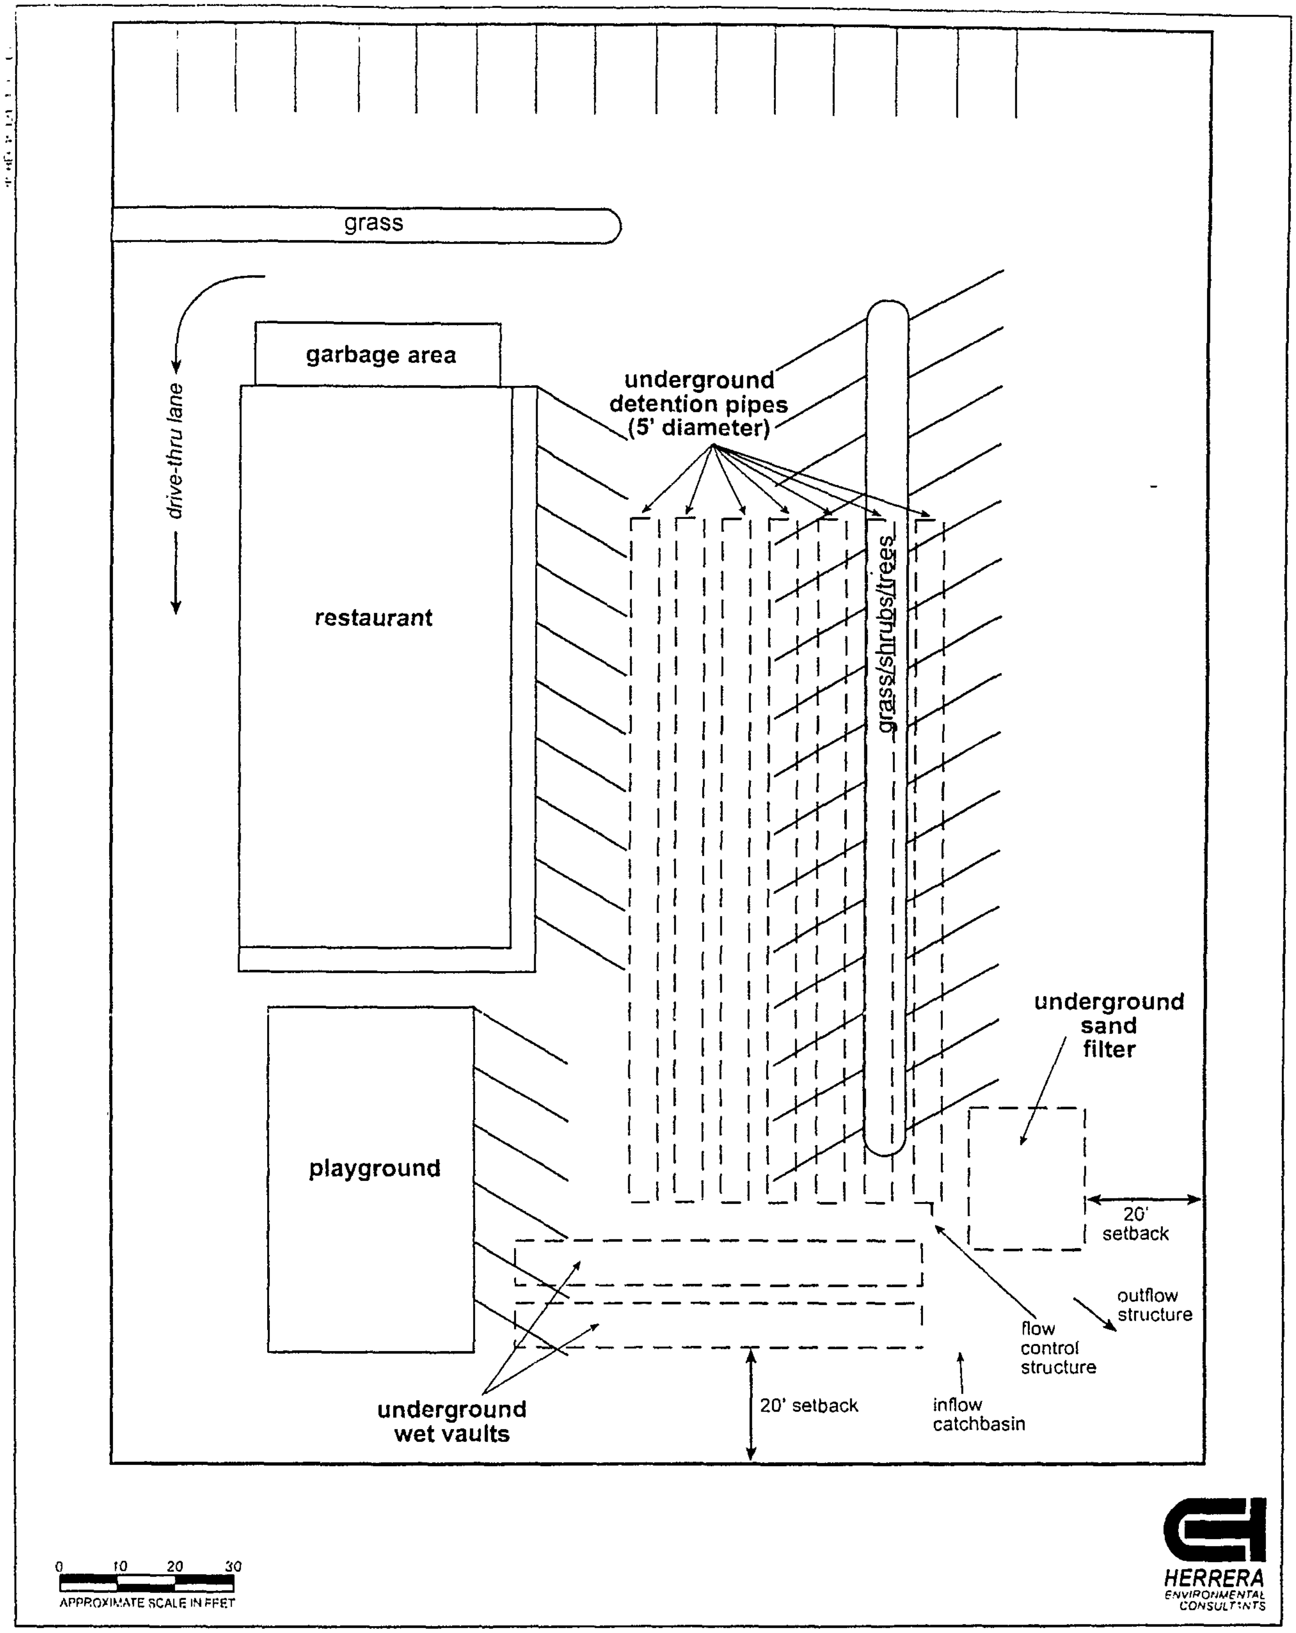

Figure 8. Permanent stormwater quality control BMPs for 1-acre commercial development without infiltration.

excavation site for the temporary sediment pond is partially used for burial of the permanent stormwater control vaults. Emergency overflow facilities are provided for each of the underground vaults. A catch basin is provided at the site discharge location; it is assumed that the catch basin outflow is piped into the storm sewer system adjacent to the site.

Site 2 Implementation Costs to Satisfy the Minimum Requirements

Costs With Infiltration

The total cost of planning, designing, and constructing the BMPs in the construction SWPPP and permanent stormwater site plans for the scenario with infiltration is estimated at approximately $280,000, including taxes and contingencies for unforeseen difficulties. The total cost for the scenario with the infiltration vaults also includes the cost of performing a hydrogeologic evaluation to confirm infiltration suitability and/or determine the site-specific infiltration rate. The cost of the permanent facilities in the stormwater site plan is approximately 95 percent of the total implementation cost.

Costs Without Infiltration

The total cost of planning, designing, and constructing the BMPs in the construction SWPPP and permanent stormwater site plans for the scenario without infiltration is estimated at approximately $570,000. The cost of the permanent stormwater facilities in the stormwater site plan under this scenario is approximately 97 percent of the total implementation cost.

Itemized costs for the components of the stormwater site plan are given for the two scenarios in Tables 10 and 13 of Appendix A. Appendix A also provides further details on assumptions used to estimate costs.

Comparison of Treatment and Detention Storage Volumes to 1993 Estimates

For the scenario where infiltration is feasible in type A soils and a wet vault is used for treatment of the runoff prior to infiltration, the storage volumes in both the wet vault and the infiltration tanks are now smaller in comparison to the sizes under the 1992 requirements. This is due to the requirement for onsite stormwater management (roof downspout infiltration). The volume of runoff assumed to reach the wet vault and infiltration tanks is significantly less in comparison to the calculations associated with the 1992 requirements. The storage volumes in the wet vault and detention pipes in type C soils analyzed in this case study are larger in size compared to the volumes estimated for this same site scenario in the 1993 report (Herrera 1993). This is because the wetpool storage volume has increased as a result of the design criteria for the 6-month storm precipitation depth and the detention storage volume has increased considerably as a result of the requirement to match flow durations in addition to controlling peak flow rates.

The comparison of these storage volumes in type A soils is as follows:

- 1993 analysis (re-analyzed as discussed in Appendix C) – wet vault treatment pool volume = 3,590 cubic feet: infiltration tank storage volume = 9,000 cubic feet

- Present analysis – wet vault treatment pool volume = 3,270 cubic feet; infiltration tank storage volume = 4,780 cubic feet

The comparison of these storage volumes in type C soils is as follows:

- 1993 analysis -- wetpond treatment pool volume = 3,660 cubic feet; detention storage volume = 7,200 cubic feet; total storage volume = 10,800 cubic feet

- Present analysis – wet vault treatment pool volume = 4,150 cubic feet; detention storage volume = 16,300 cubic feet; total storage volume = 20,500 cubic feet

The combination of greater storage volumes, the need for a sand filter to provide enhanced treatment, and placement of the facilities underground results in much greater stormwater management costs in the present analysis compared to the 1993 analysis.

Site 2 Operation and Maintenance Requirements and Costs

Operation and Maintenance Assumptions

Routine maintenance of the permanent stormwater facilities includes such tasks as annual inspections; frequent replacement of the catch basin inserts (assumed to be four times per year for each of four catch basins in the parking lot); tilling the bottom of the infiltration vaults periodically to restore maximum infiltration capacity (assumed to be once every two years); raking the sand filtration surface once the depth of accumulated silt and debris on the surface exceeds ¼ inch (assumed to be once every two years); removing accumulated sediments in the wet vault when the depth exceeds the sediment storage depth (assumed to be once every five years); replacing miscellaneous parts and materials as needed; and cleaning out connecting pipes. In addition, the parking lot should be swept frequently to limit the amount of sediments that enter the permanent stormwater control facilities, enabling them to function more effectively.

Operation and Maintenance Costs, With and Without Infiltration

The annual cost of routine operation and maintenance procedures for the scenario with the wet vault and infiltration tanks is estimated at approximately $4,000. The annual operation and maintenance cost for the scenario with a wet vault, detention pipes, and sand filter vault (without infiltration) is also estimated at approximately $4,000.

Further details on assumptions used to estimate maintenance costs are given in Appendix A. Tables 11 and 14 of Appendix A provide itemized costs of the individual maintenance tasks for each of the scenarios.

Site 3—Large Commercial Development

Site 3 is a 10-acre commercial development consisting of a retail shopping center and parking lot. Figure 9 shows the layout of the site as planned for development, without stormwater control facilities to satisfy the minimum requirements. The site has 85 percent impervious cover. The topography of this site in its undeveloped condition causes drainage to flow from the upper left to the lower right (as shown in Figure 9); there are several defined drainage courses that are not classified as streams or sensitive areas. This site would be graded extensively to construct the large building and parking lot. Stormwater runon and through-flow in the drainage courses would occur unless diversions are provided. It is assumed that the site would be ringed with diversion trenches on the upslope sides to convey runon and through-flow around the site to the downstream conveyance system.

The costs of providing diversion trenches and constructing retaining walls or similarly effective slope stabilization measures near the site border are not included in this analysis because their necessity is an arbitrary result of the hypothetical site layout.

Site 3 Construction Stormwater Pollution Prevention Plan

For all new development and redevelopment projects that add or replace 2,000 square feet or more of impervious surface or clear more than 7,000 square feet, such as site 3, the manual requires preparation of a SWPPP to guide selection and implementation of a variety of BMPs during construction. The 12 minimum requirements for stormwater pollution prevention during construction are listed above for site 1. It is assumed that construction would take one year to complete, and that clearing and grading activities would continue through the wet season.

Several BMPs are necessary to control site runoff and erosion during the construction phase. A combination of intercepting swales, a temporary sediment pond, a stabilized construction entrance and equipment parking areas, mulch application to bare areas, stabilization of disturbed slopes, storm drain inlet protection on surrounding streets, and silt fencing would be used to control transport of sediments off the site and protect downstream properties and waterways during construction. Figure 10 shows the locations of the erosion and sediment control BMPs selected for the large commercial development site. It is assumed that the large commercial building would also require excavation that results in a relatively steep slope, where erosion control blankets are needed for soil stabilization. These BMPs would be in place prior to construction activities to satisfy the minimum requirements.

The BMPs are almost all the same for type A soils (suitable for infiltration) and type C soils (unsuitable for infiltration). The differences assumed for BMP applications with type A soils include reduced size of the temporary sediment pond, reduced extent of street sweeping, reduced

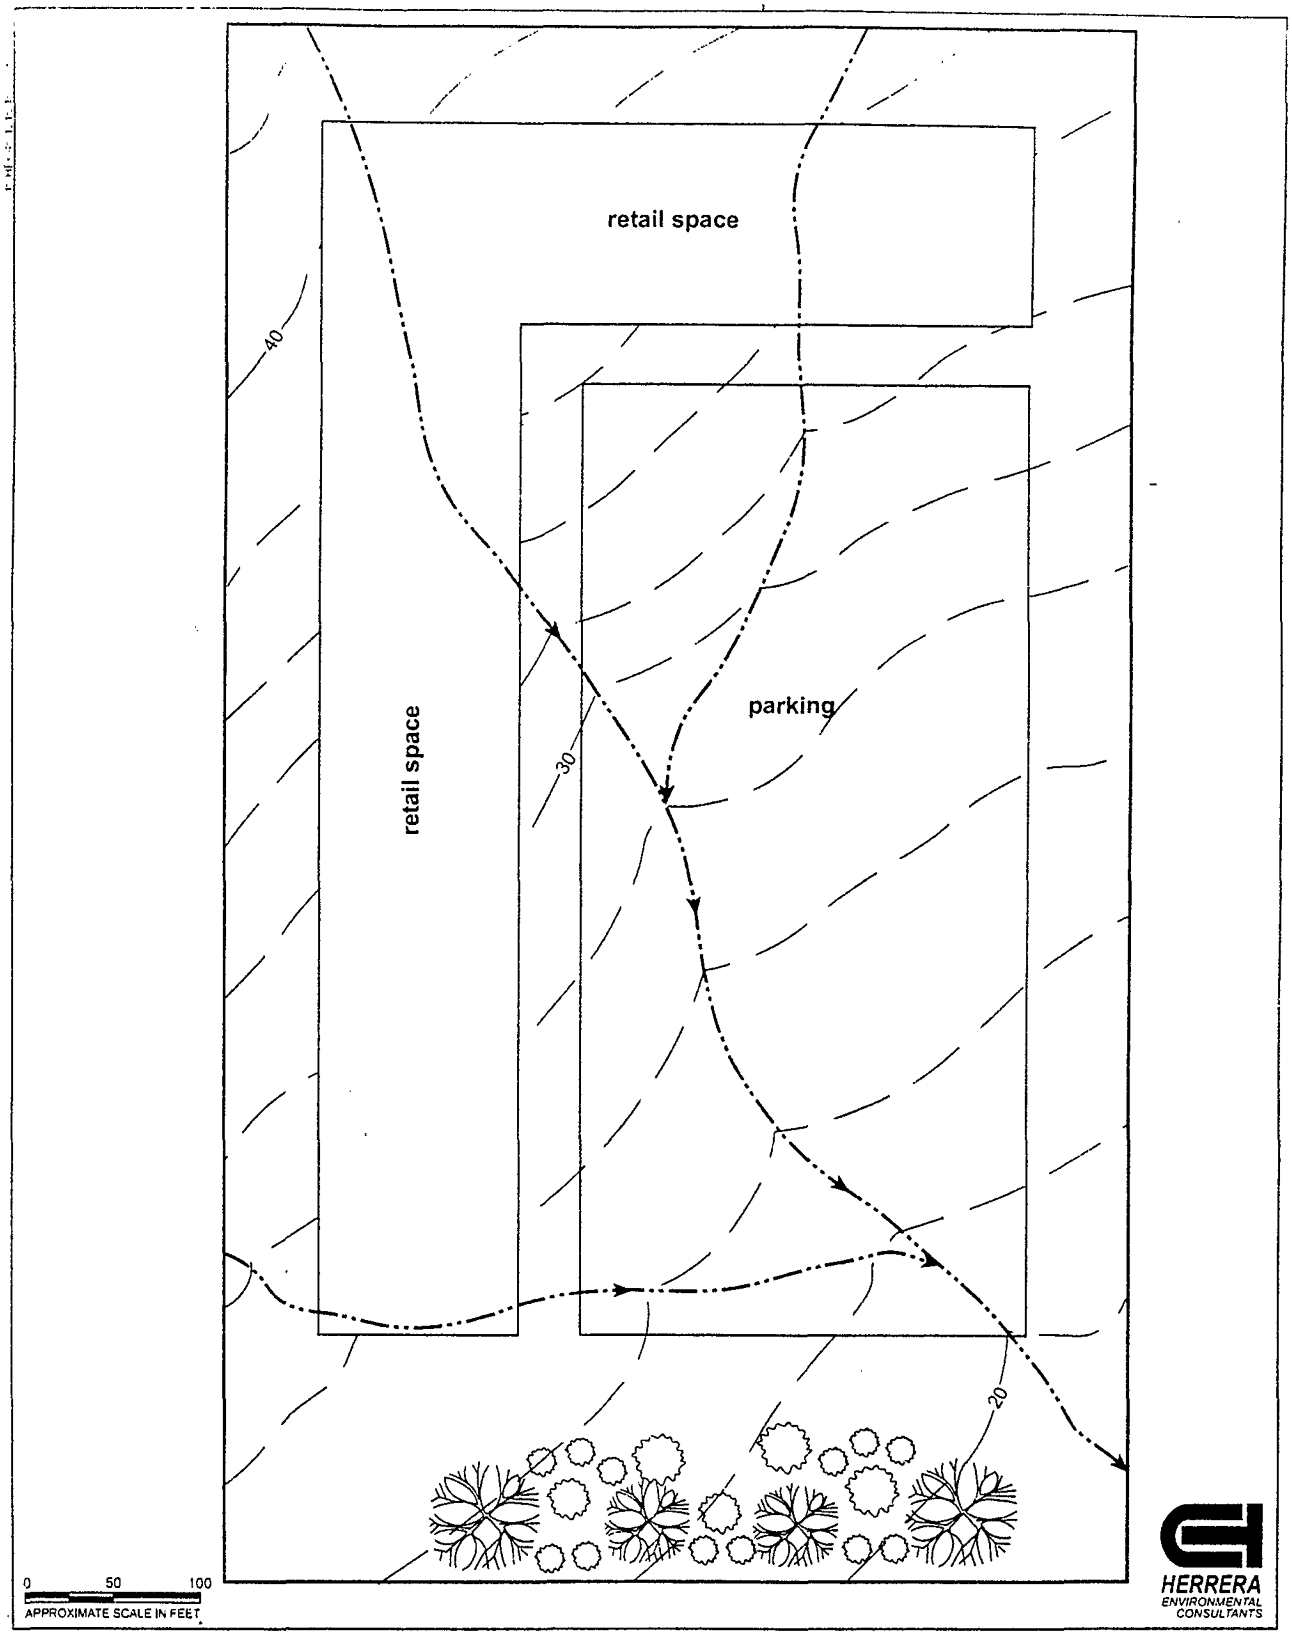

Figure 9. **Ten-acre commercial development plan, without stormwater facilities, superimposed on natural (pre-development) topography and drainage features.**

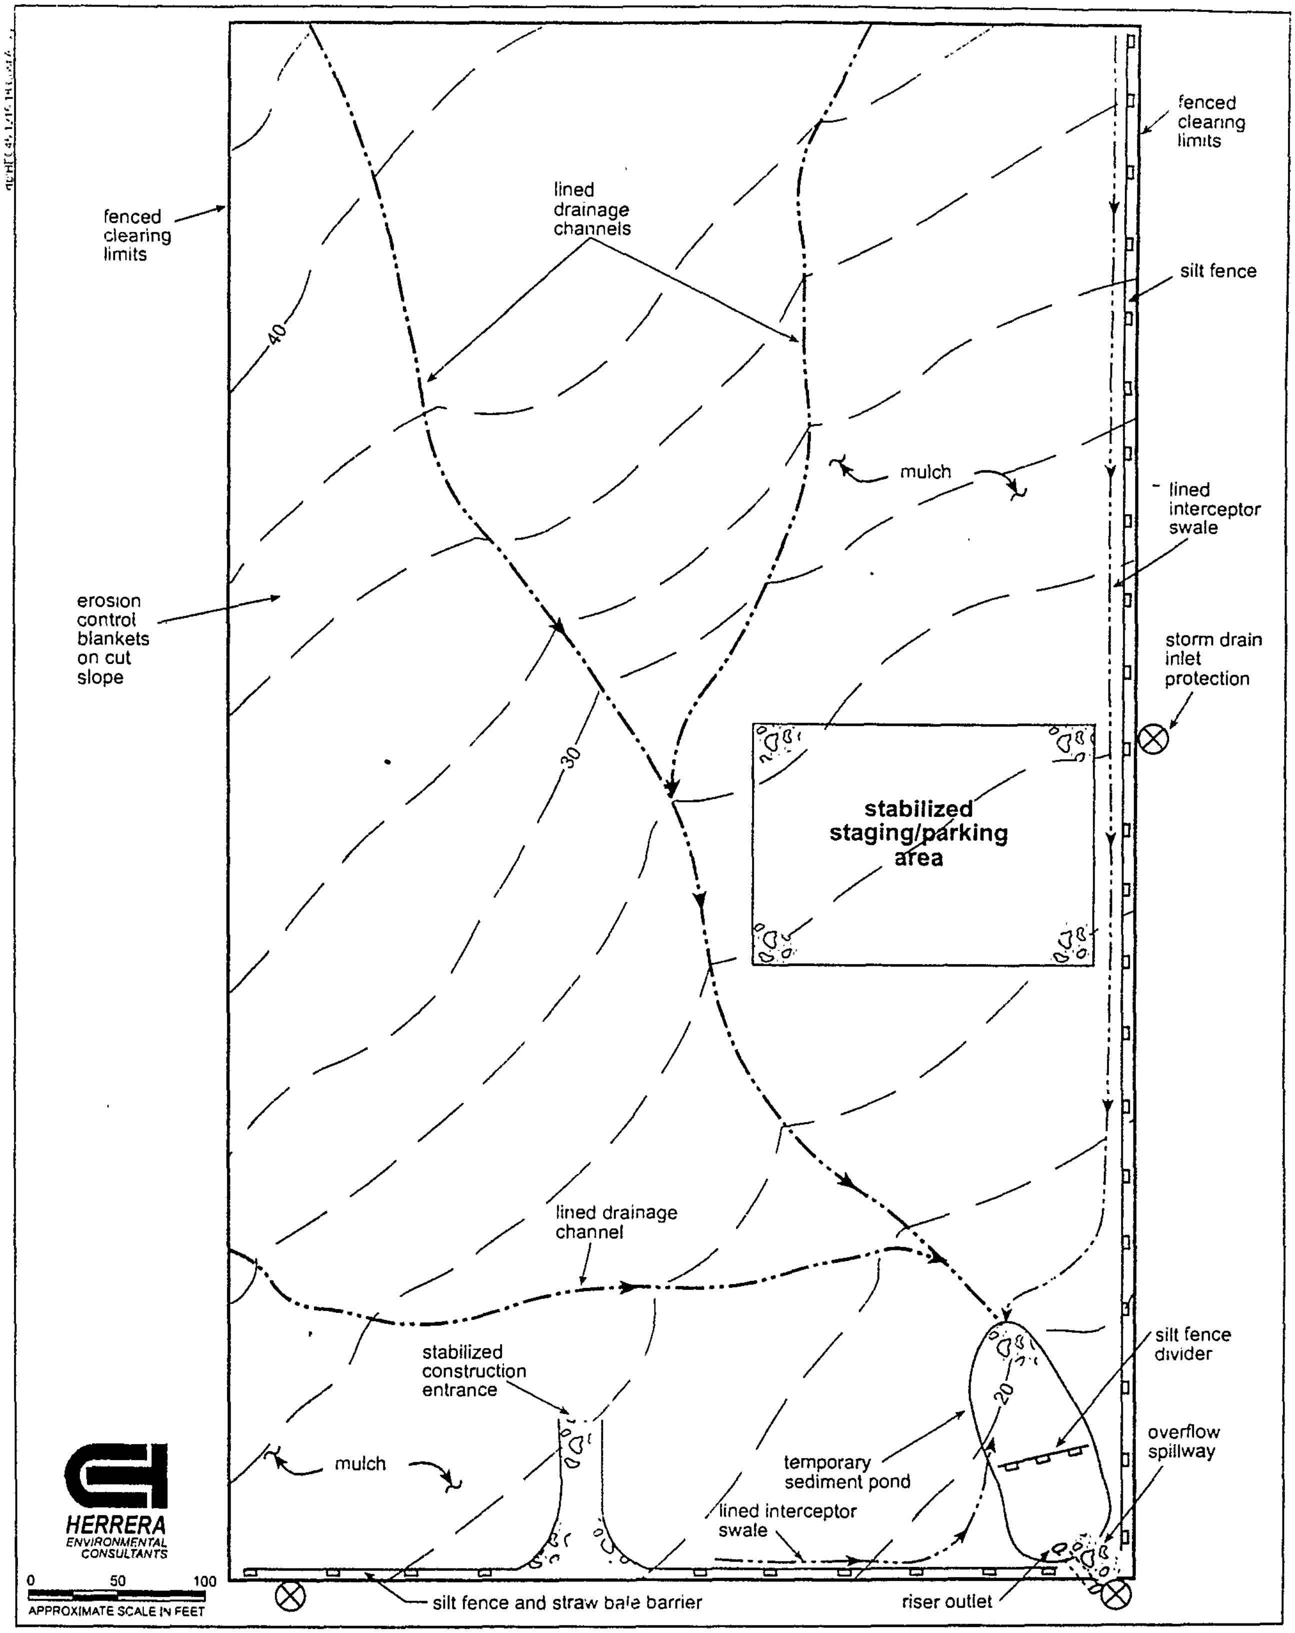

Figure 10. Erosion and sediment control BMPs for 10-acre commercial development.

extent of offsite catch basin cleaning, and elimination of a straw bale barrier along the lower left corner of the site as shown on Figure 10. Therefore, the cost estimate for the construction SWPPP associated with type A soils reflects slightly reduced BMP applications.

The intercepting swales would be used to convey site runoff to the sediment pond. These swales would be lined with suitable geotextiles or organic blankets, or stabilized with seed and mulch, to prevent erosion within the swale. Silt fencing would be used on downslope edges of the site boundary to prevent sediment discharge.

The manual specifies that sediment ponds be designed based on the 2-year, 24-hour storm peak runoff flow rate. The sediment pond size indicated on figure 10 is based on the 2-year peak runoff flow from the developed site with till soils (i.e., the larger sediment pond scenario for type C soils). Silt fencing would be used as a divider within the temporary sediment pond to enhance the removal of suspended sediments. The site entrance would be stabilized with quarry spalls, and all construction roads on the site and one main parking area would be stabilized with crushed rock. Mulch would be applied extensively to areas of exposed soil during staged construction. Silt fencing would be used to contain sediments on the site periphery that may be present in runoff that does not reach the interceptor swales. It is assumed that three catch basins on the adjacent street would require inlet protection. Other BMPs such as vehicle tire washing and spraying of dusty areas would be implemented during construction as needed.

Maintenance of the erosion and sediment control BMPs is a key component of the construction SWPPP. It is assumed that routine BMP maintenance checks would be performed once weekly and after runoff-producing storm events during the dry season, and daily during the wet season to ensure that BMPs continue to function effectively. Excess sediment accumulation must be removed from the pond and disposed of off the site or spread in a controlled location on the site. Silt fencing must be checked periodically, especially following storms, to determine if repairs or replacement fabric sections are needed. Mulch used to cover stripped site areas would be relocated and replaced as needed, as portions of the site are permanently stabilized. If sediment is tracked offsite onto neighboring streets, it must be swept and collected as necessary.

Costs for Construction Stormwater Pollution Prevention Plan

The construction cost for these SWPPP BMPs is estimated at approximately $54,000 for type A soils and $63,000 for type C soils. Tables 15 and 18 in Appendix A show itemized costs for the various BMP components and their associated construction procedures and materials. These costs do not include engineering planning and design fees, permit fees, performance bonding (or other appropriate financial instruments to ensure compliance with the approved SWPPP), and contingencies for unforeseen difficulties. Maintenance of the erosion control BMPs over the course of the 1-year construction period (included in the SWPPP BMP costs noted above) is estimated to cost approximately $10,000 for type A soils and $16,000 for type C soils (see Tables 17 and 21 in Appendix A, respectively). Appendix A provides further details on assumptions used to develop these costs.

Site 3 Permanent Stormwater Site Plan

The stormwater site plan must include provisions for maintaining natural drainage patterns, using source control BMPs to prevent pollutants from entering stormwater runoff, reducing hydrologic changes through onsite stormwater management techniques, treating runoff from smaller storm events, detaining runoff from larger storm events to prevent stream bank erosion due to high flows, and maintaining the BMPs that are chosen and implemented. Minimum requirement eight, pertaining to wetlands and minimum requirement nine, pertaining to basin planning, are assumed not to be applicable to this hypothetical site and this analysis.

In accordance with the manual, two preliminary considerations guided BMP selection for site 3. Oil control and special phosphorus control measures are not required for this site. The oil control requirement is assumed not applicable due to the traffic volume falling below the high use threshold. The standard western Washington peak flow control to match pre-development peak flow rates and durations is required because the site discharge is conveyed to a small stream (if site discharge is conveyed directly to a major water body, the standard does not apply).

Pollution Source Control BMPs

Pollution source control BMPs are important components of the stormwater site plan for this site to satisfy minimum requirement three. Several of the source control BMPs outlined in the manual are applicable to this development. The areas designated for garbage containers adjacent to the building should be covered or contained to prevent precipitation from contacting waste containers and to prevent the runoff from entering the nearby storm drainage system. The interior of this area must drain to the sanitary sewer if possible (BMP S1.50). Other materials and wastes that may introduce pollutants to stormwater should also be placed in the protected area. Cooking equipment such as vents and filters must not be cleaned outdoors unless a sanitary sewer drain is provided. In addition, storm drainage facilities must be maintained (BMP S2.00), and the parking lot should be swept frequently to collect and properly dispose of accumulated sediments and other materials that may contain pollutants (BMP S1.22).

Onsite Stormwater Management Measures

In addition to pollution source control BMPs, onsite stormwater management measures must also be implemented to infiltrate, disperse, and retain stormwater runoff onsite where practicable (minimum requirement five). Some examples of onsite stormwater management BMPs applicable to this commercial development include roof downspout infiltration, use of permeable/porous pavements in low traffic areas, and vegetated rooftops. For this site, the use of "typical" roof downspout infiltration trenches was assumed with infiltratable soils on site (type A). As with Site 2, the "alternative" infiltration design that is allowable in coarse soils was not assumed for this site because it is not likely that a grass strip would be provided between the building and the infiltration trenches in this type of development. Permanent stormwater facilities were sized, and the associated cost estimate developed, with roof downspout infiltration included. The contributing drainage area for the wetpond and infiltration basin is considerably reduced as a result (by approximately 25 percent).

For the scenario with type C soils, it was assumed that roof downspout dispersion systems would not be provided due to insufficient area for grass or other open space. The sizing of permanent stormwater treatment and flow control facilities accounted for all rooftop runoff because it was assumed that this runoff would reach the stormwater management pond quickly. Although it was assumed that porous pavements could be used for low traffic areas of the site, the sizing of the permanent stormwater treatment and flow control facilities conservatively assumed that all driveway and parking lot runoff would reach the pond quickly.

Permanent Stormwater Control Facilities by Soil Type

The permanent stormwater control facilities selected for the large commercial development site to satisfy the minimum requirements are dependent on soil type.

Type A Soils – With Infiltration

Infiltration is the preferred method of stormwater treatment and flow control, but infiltration requires suitable soils. For the scenario with type A soils, an infiltration basin preceded by a wetpond provides stormwater treatment. Figure 11 shows the layout of the site with the permanent stormwater control facilities for this condition. The infiltration basin would dispose of most runoff flows, but would have sufficient live storage capacity to detain and slowly release high flows to the nearby storm drainage system in this situation. Type A soils are suitable for infiltration disposal of runoff but are too porous to enable effective treatment of large volumes of water cost-effectively. Therefore, a wetpond (or other comparable treatment facility) is needed for pretreatment. The wetpond can also serve as a presettling facility to protect the infiltration soil surface from clogging.

The wetpond is designed to treat all runoff from the 6-month, 24-hour storm event and is divided into two separate cells. Both wetpond cells would be excavated approximately 4 feet deep, with an additional foot of depth in the first cell for sediment storage. The wetpond would overflow to the infiltration basin via a spillway. The infiltration basin would be excavated 4 feet below grade and is large enough to enable infiltration of most flow up to the 100-year event. An outlet control structure in the infiltration basin would enable limited flow to discharge to the nearby storm sewer system in extreme events, matching pre-developed site discharge rates and flow durations (the pre-developed site peak flows and volumes are very small in type A soils).

Type C Soils – Without Infiltration

For the scenario without infiltration, a combined wet detention pond with a permanent pool provides water quality treatment and excess storage capacity for peak flow control, and a sand filter provides enhanced treatment. Two options were evaluated for this sand filter. One option considered placement of the sand filter in an underground concrete vault. It was assumed that relatively frequent maintenance access requirements for the sand filter would lead to selection of a rectangular concrete vault structure as opposed to a large diameter pipe structure with less head room in the interior. The other option considered placement of the sand filter bed in an open-air configuration with steep (1H:1V) side slopes surrounded by safety fencing. A maintenance access roadway to the bottom of the sand filter bed would be required with this option. The

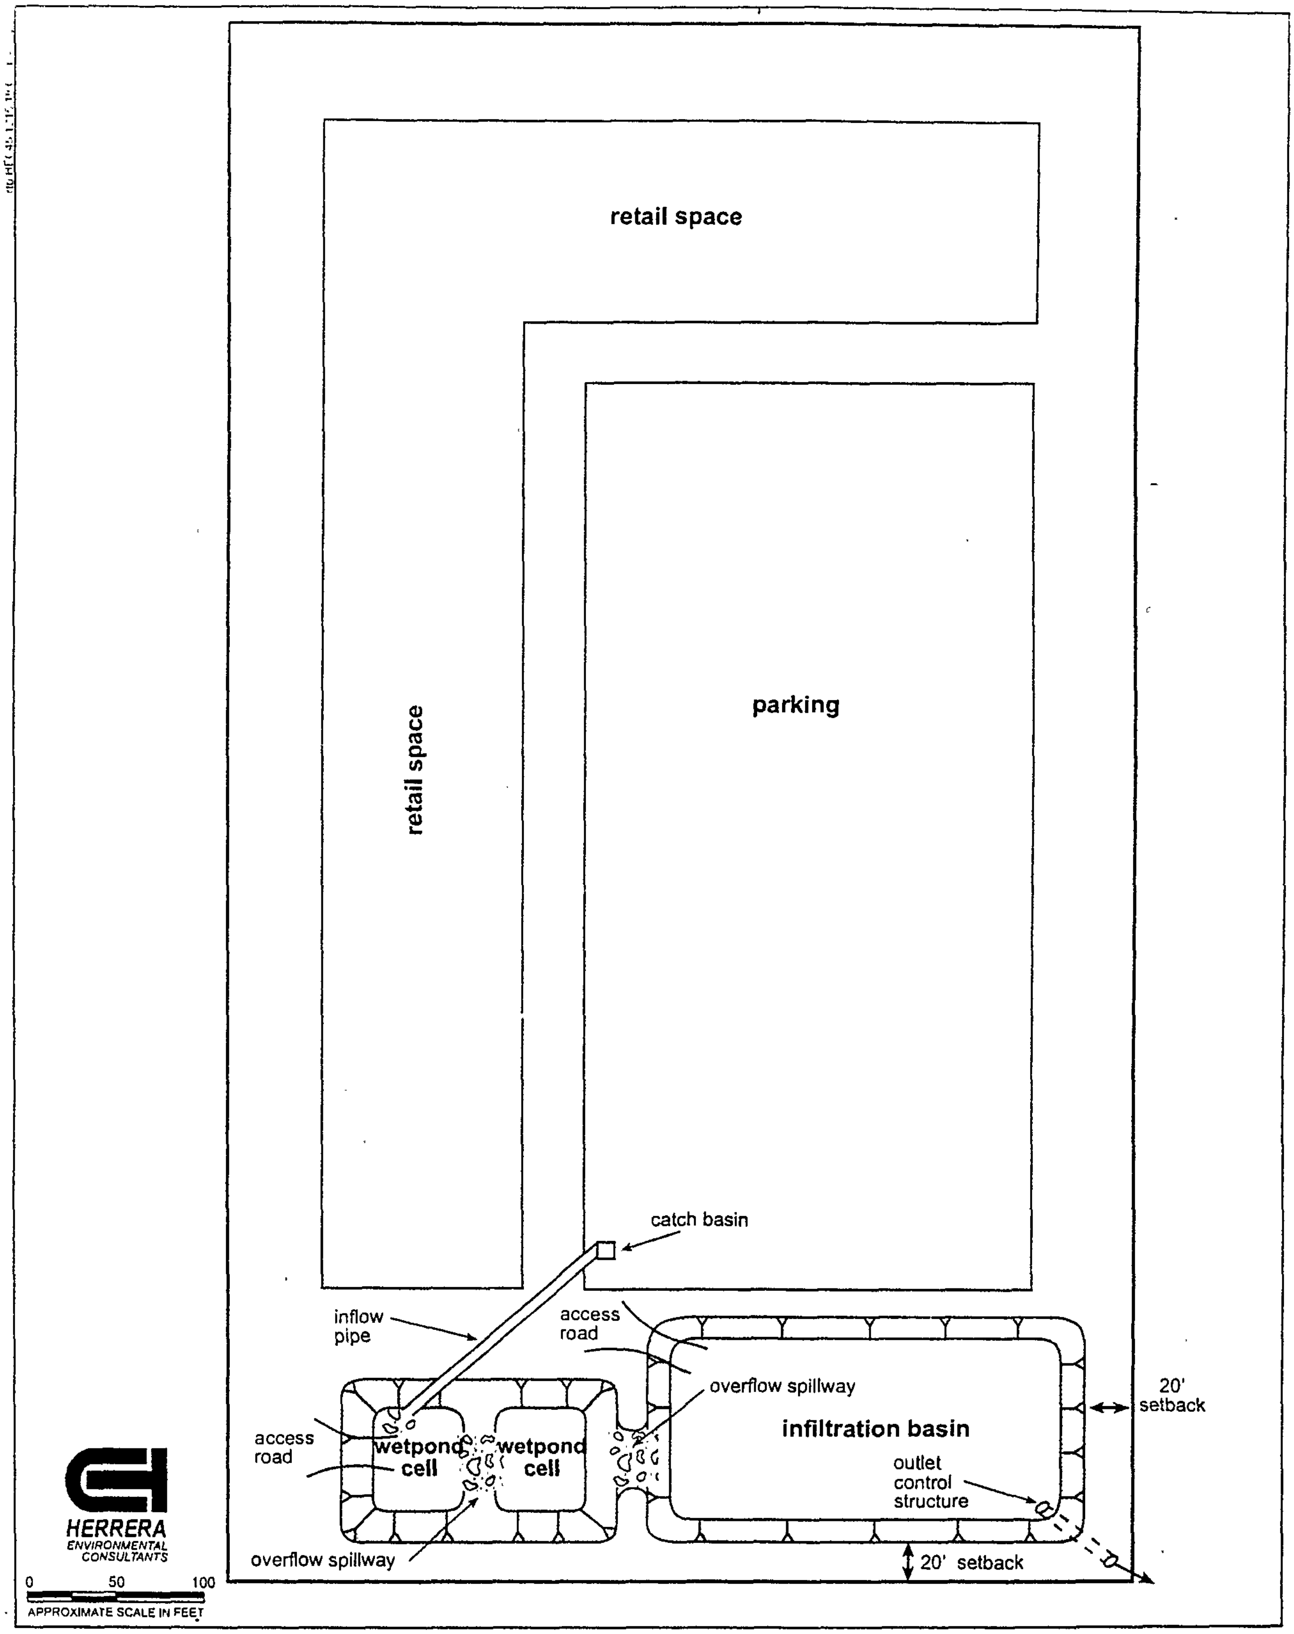

Figure 11. Permanent stormwater quality control BMPs for 10-acre commercial development with infiltration.

open-air configuration would reduce costs but would consume parking or roadway areas that may be valuable for the developer. Figure 12 shows the layout of the site with a combined wet/detention pond and the underground sand filter vault option. The treatment pool in the wet/detention pond and the subsequent sand filter constitute a two facility treatment train to perform the enhanced treatment that is required. The wetpond does not require special design features for enhanced phosphorus removal.

The wetpond has two cells separated by an earthen berm. The first cell is excavated approximately nine feet below existing grade, and the second cell is excavated eight feet below grade. Each cell provides four feet of water depth to create a permanent pool (during the wet months) for water quality treatment. The first cell has an additional foot of sediment storage capacity in the bottom. An additional 4 feet of storage space on top of the permanent pool provides detention capacity for the 100-year runoff event, including one foot of freeboard. This extra foot of storage allows for an emergency overflow spillway.

Because the detention storage volume needed is large in relation to the water quality treatment volume needed, the pond footprint area expands significantly in the upper detention zone. The pond has a multiple-orifice outflow restrictor above the permanent (treatment) pool level to maintain predevelopment site discharge rates. The detention outflow control structure directs flows into the sand filter. The bottom of the sand filter bed, whether in a vault or in an open-air configuration, is set approximately 8 feet below ground surface. The sand filter bed area was sized to treat the peak 2-year storm flow discharged from the detention outlet control structure, with a perforated pipe underdrain system to collect treated flows, and flows above the 2-year detained peak would be discharged directly to the nearby storm sewer system via an overflow pipe.

The permanent BMP facilities, both with infiltration and without infiltration, are located so that they receive runoff from the entire development and maintain the natural drainage pattern of the site. The excavation for the temporary sediment pond is expanded for the permanent stormwater control facilities. A catch basin is provided at the site discharge location; it is assumed that the catch basin outflow is piped into the storm drainage system adjacent to the site.

Site 3 Implementation Costs to Satisfy the Minimum Requirements

Costs With Infiltration

The total cost of planning, designing, and constructing the BMPs in the construction SWPPP and permanent stormwater site plan for the scenario with infiltration is estimated at approximately $320,000, including taxes and contingencies (see Table 16 in Appendix A). This total cost is higher than the cost estimated for the comparable 10-acre residential site. The size and cost of the wetpond and infiltration basin on site 3 would be significantly greater due to the greater amount of runoff generated on more impervious surfaces within the 10-acre development. The total cost for the scenario with the infiltration basin also includes the cost of performing a hydrogeologic evaluation to confirm infiltration suitability and/or determine the site-specific infiltration rate. The cost of the permanent stormwater facilities in the stormwater site plan is approximately 68 percent of the total implementation cost.

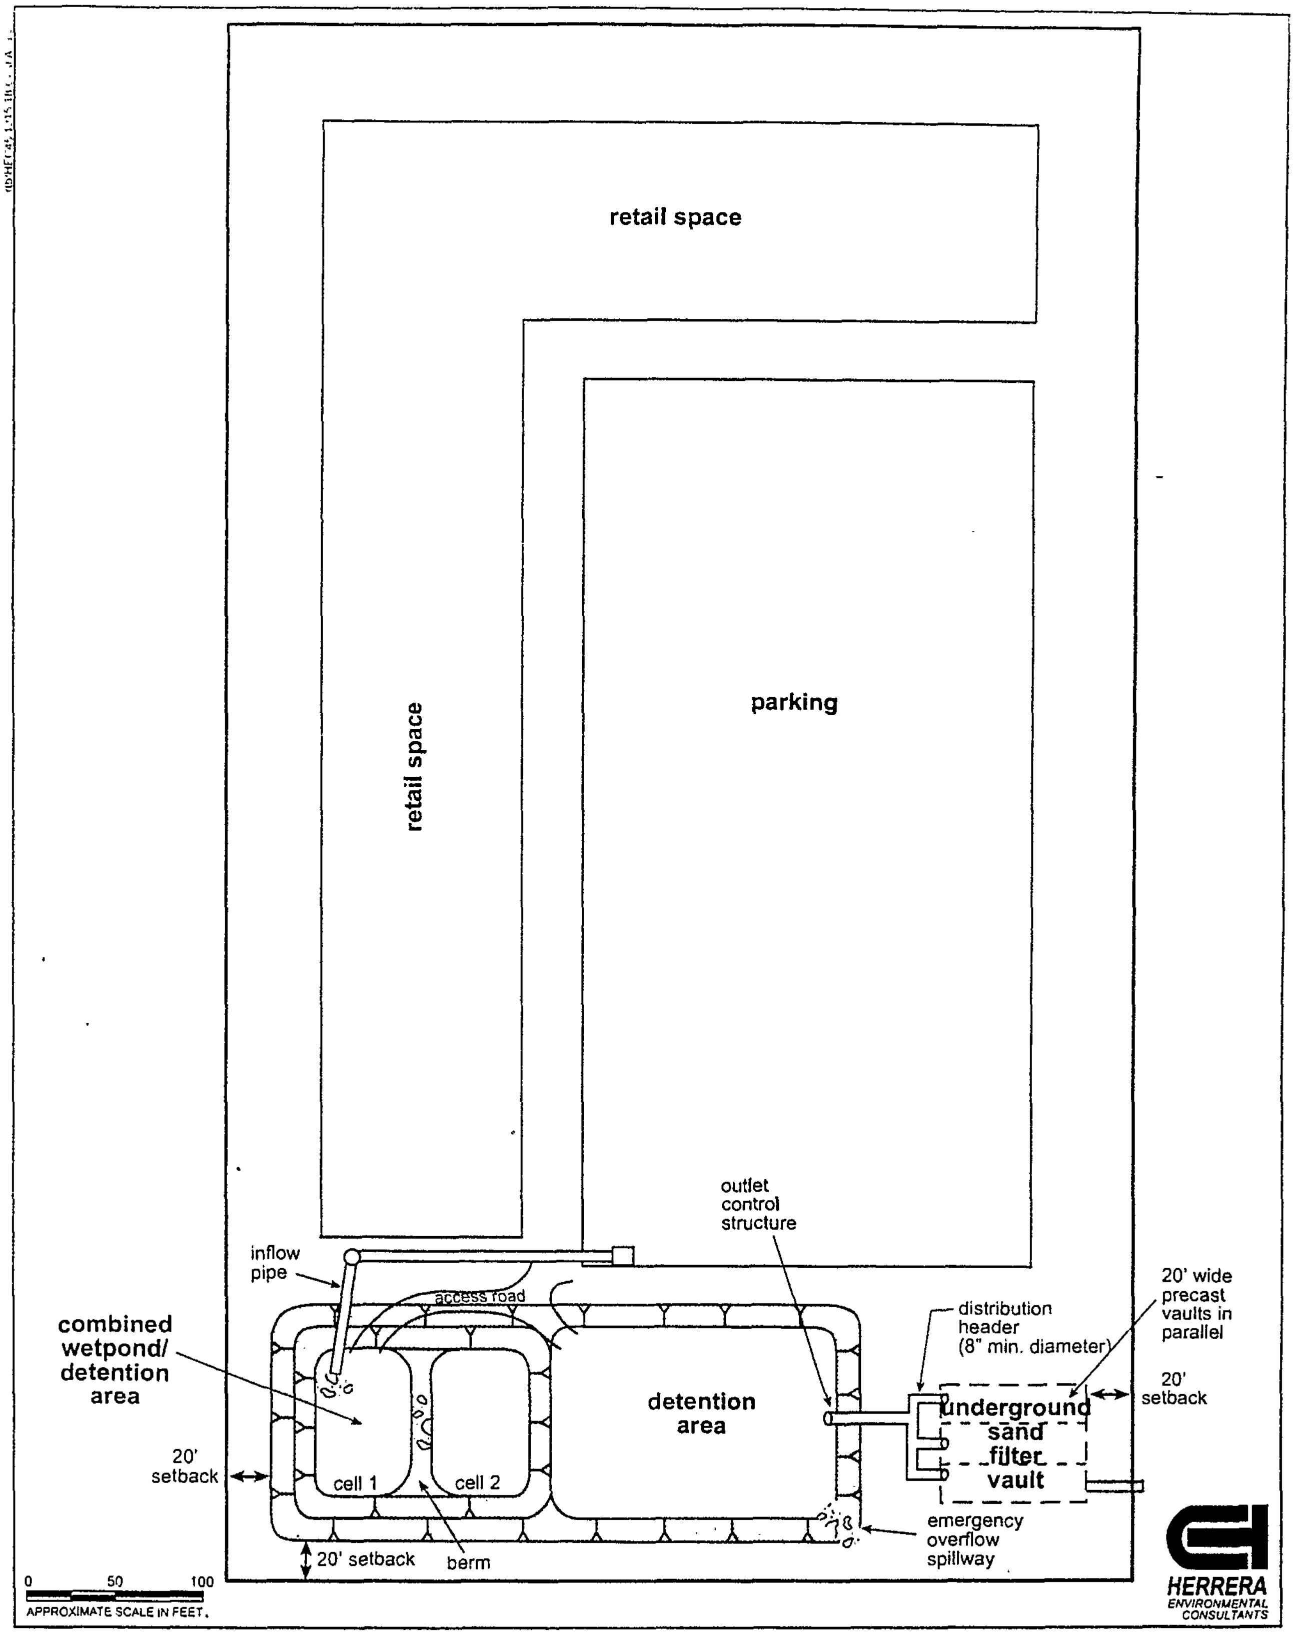

Figure 12. **Permanent stormwater quality control BMPs for 10-acre commercial development without infiltration.**

R0010822

Costs Without Infiltration

The total cost of planning, designing, and constructing the BMPs in the construction SWPPP and permanent stormwater site plan for the scenario without infiltration and with the underground sand filter vault option is estimated at approximately $860,000. The cost for this scenario is high because of the large size of the sand filter vault, and the assumed use of precast concrete to create the sand filter vault. If large diameter pipe or other creative means were used to construct the underground sand filter, the cost could be reduced considerably. The cost of this same scenario with the open-air sand filter option is estimated at approximately $490,000. While the open-air sand filter would reduce costs by $370,000 compared to placement of the sand filter in a buried vault, it would mean that approximately 0.25 acres of parking lot is unavailable for other use. The cost of the permanent stormwater facilities in the stormwater site plan with the underground sand filter vault option in this scenario is approximately 88 percent of the total implementation cost. That percentage is reduced if the sand filter is placed in an open-air configuration.

Itemized costs for the components of the stormwater site plan are given for the three scenarios in Tables 16, 19, and 20 in Appendix A. Appendix A also provides further details on assumptions used to estimate costs.

Comparison of Treatment and Detention Storage Volumes to 1993 Estimates

For the scenario where infiltration is feasible in type A soils and a wetpond is used for treatment of the runoff prior to infiltration, the storage volumes in both the wetpond and the infiltration basin are now smaller in comparison to the sizes under the 1992 requirements. This is due to the requirement for onsite stormwater management (roof downspout infiltration). The volume of runoff assumed to reach the wetpond and infiltration basin is significantly less in comparison to the calculations associated with the 1992 requirements. The storage volumes in the wet/detention pond in type C soils analyzed in this case study are larger in size compared to the volumes estimated for this same site scenario in the 1993 report (Herrera 1993). This is because the wetpond treatment storage volume has increased as a result of the design criteria for the 6-month storm precipitation depth and the detention storage volume has increased considerably as a result of the requirement to match flow durations in addition to controlling peak flow rates.

The comparison of these storage volumes in type A soils is as follows:

- 1993 analysis (re-analyzed as discussed in Appendix C) -- wetpond treatment volume = 34,600 cubic feet; infiltration basin storage volume = 69,300 cubic feet

- Present analysis – wetpond treatment volume = 27,700 cubic feet; infiltration basin storage volume = 56,200 cubic feet

The comparison of these storage volumes in type C soils is as follows:

R0010823

- 1993 analysis -- wetpond treatment volume = 35,600 cubic feet; detention storage volume = 69,400 cubic feet; total storage volume = 105,000 cubic feet

- Present analysis -- wetpond treatment volume = 40,000 cubic feet; detention storage volume = 162,000 cubic feet; total storage volume = 202,000 cubic feet

The combination of greater storage volumes, the need for a sand filter to provide enhanced treatment, and potential placement of the sand filter underground results in much greater stormwater management costs in the present analysis compared to the 1993 analysis.

Site 3 Operation and Maintenance Requirements and Costs

Operation and Maintenance Assumptions

Routine maintenance of the permanent stormwater facilities includes such tasks as conducting annual inspections; mowing the grass in the infiltration basin and wetpond, or combined wet/detention pond, at least twice per year; removing accumulations of debris and floating materials once per year; removing accumulated sediments in the wetpond once the sediment storage depth in the bottom is full (assumed to be once every five years); tilling the infiltration basin soil or otherwise re-establishing maximum infiltration capacity as needed (assumed to be once every two years); raking the sand filtration surface once the depth of accumulated silt and debris on the surface exceeds ¼ inch (assumed to be once every two years); seeding of grassed areas that turn bare at least once per year; adding gravel to overflow spillways and access driveways as needed; replacing miscellaneous parts and materials as needed; and cleaning out connecting pipes. In addition, the large parking lot should be swept frequently to limit the amount of sediments that enter the permanent stormwater control facilities, enabling them to function more effectively. All catch basins and storm drains in the development should be cleaned frequently to prevent clogging and to remove some of the pollutants that otherwise could be flushed into the treatment and detention facilities during large storm events.

Operation and Maintenance Costs, With and Without Infiltration

The annual cost of routine maintenance procedures is estimated at approximately $6,400 for the scenario with the wetpond and infiltration/detention basin. The annual maintenance cost for the scenario with a combined wet/detention pond and sand filter (without infiltration) is estimated at approximately $6,200. Much of the annual operation and maintenance cost is associated with conveyance system cleaning and street sweeping as opposed to pond and vault maintenance.

Further details on assumptions used to estimate maintenance costs are provided in Appendix A. Tables 17 and 21 in Appendix A provide itemized costs of the individual maintenance tasks for each of the scenarios.

3. Summary of Stormwater Site Plan Costs

This section presents a summary of the estimated costs for the three hypothetical development sites. The stormwater site plan features that greatly affect the total cost of satisfying the minimum requirements for stormwater controls in new developments are discussed. This section presents comparisons to the cost estimates developed in 1993 for the same case study development examples, based upon the minimum requirements in the 1992 *Stormwater Management Manual for the Puget Sound Basin*. The intent of this comparison is to illustrate the differences in costs between the 1992 and the 2001 requirements. Land costs are not included in the present analysis because there is considerable variability in land costs across western Washington that unnecessarily complicates this comparison. While land costs are not included in this analysis, they are an extremely important variable to be considered in accommodating the stormwater management requirements. Many project sites, for example those along transportation corridors, impose constraints on the ability to provide stormwater management facilities within the available space and therefore additional land must be purchased for those facilities. In many of the urban areas of western Washington that land can be very expensive.

Design Issues Affecting Cost

The permanent stormwater facilities for the three hypothetical development sites are sized according to what appears to be reasonable for the site conditions, but without a detailed assessment to optimize costs. Specifically, the 1-acre commercial development example has all of its stormwater management facilities underground because ground surface area is typically valuable at these types of sites, whereas the stormwater management facilities are mostly aboveground at the residential and large-scale commercial sites. The surface area of aboveground pond facilities could be minimized through the use of retaining walls or other steep slope stabilization techniques. However, the conceptual designs of wetponds and infiltration basins produced for this analysis assumed enough space is available to allow for more gradual side slopes. Surface ponds ideally have very gradual side slopes that consume greater area, and this analysis assumed 3H:1V side slopes, the maximum (steepest) allowed by the manual, to minimize cost. These assumptions affect the amount of land devoted to stormwater control facilities, which in turn affects total implementation cost.

For underground facilities, the assumptions regarding depth of water in the vault have a direct influence on cost. For instance, if a sand filter vault is assumed to have two feet of ponding depth above the sand bed rather than four feet, then the area of the filter bed is larger, resulting in vault excavation and material costs that are greater in comparison to a deeper vault with a smaller footprint area.

As illustrated for the 10-acre commercial development example (site 3) and type C soils where infiltration is not possible, placement of the sand filter in an underground vault results in far greater cost than if the sand filter is placed in an open-air configuration. The tradeoff of additional parking and driveway areas versus higher stormwater management costs on this site would constitute an important site planning decision.

Stormwater Control Components Having Greatest Cost Impact

The relatively expensive items in the construction SWPPP cost estimates are stabilization of construction site entrances, construction roads, equipment parking areas, and stripped areas on the sites with rock and mulch; excavation of temporary sediment ponds and interceptor swales; routine maintenance checks and upkeep of erosion and sediment control BMPs; and cleaning sediments off of streets adjacent to the sites. These BMPs are likely to be necessary on every developed site, so their cost cannot be avoided. The quarry spalls and crushed rock used for road stabilization may be used later in final site paving, so the cost of these materials cannot necessarily be categorized as strictly a construction SWPPP cost. The necessity of frequent street sweeping outside site entrances is uncertain and varies with site conditions.

The relatively expensive cost items for the permanent stormwater control BMPs are excavation of treatment and detention basins; liners for prevention of seepage in wetponds in porous type A soils (including topsoil backfill over the liner); inflow pipes, outflow pipes, and flow control structures; and downspout infiltration trenches. For the commercial site examples where it is assumed that some or all of the stormwater management facilities would be placed in underground vaults or tanks, the construction of those vaults and tanks is very expensive.

Additional costs that are not included in this analysis that may be incurred include compliance with local government requirements, such as fencing around permanent BMPs. Landscaping costs, which may be necessary to satisfy other local government requirements, may be reduced if the permanent BMPs can be incorporated into landscaping designs.

Total Stormwater Control Costs to Satisfy Minimum Requirements

The total estimated costs of compliance with the minimum requirements, not including land costs or foregone land use opportunity costs, are summarized on a per-acre basis in Table 1. A range of costs for each site is provided that incorporates the potential variation in soil condition, engineering planning and design costs, and construction costs. The range of costs per acre of site size are applicable only to the hypothetical sites discussed in this analysis. The cost to comply with the minimum requirements on other sites of various sizes and development plans can be estimated based on this information, with the understanding that each site has unique characteristics and development concerns that affect the actual cost of developing and implementing a stormwater site plan. Therefore, these cost figures should be considered only approximate indicators of the actual cost to be expected for a particular new residential or commercial development of comparable size. The costs listed in Table 1 include construction-phase SWPPP costs as well as permanent BMP costs.

Table 1. Summary of Costs to Comply with the Minimum Requirements for New Development

Type of Development	Low Cost Per Acre of Development	High Cost Per Acre of Development
10-acre single-family residential (5.5 dwelling units per acre)	$23,000	$24,000
1-acre commercial	$280,000	$570,000
10-acre commercial	$32,000	$86,000

Comparisons to Costs Associated With the Former Minimum Requirements

A similar cost analysis was performed for the 1992 *Stormwater Management Manual for the Puget Sound Basin.* Although the cost estimates for the current analysis include some items that were not incorporated in the 1993 analysis, those previous cost estimates provide a basis for a general evaluation of the effects of the updated stormwater management requirements on total implementation costs. The cost totals for the site examples with type C soils (i.e., no infiltration) in the 1993 report were updated to the year 2001 by using the same unit prices, as well as the same assumptions for engineering and permitting costs (30 percent) and taxes (8.8 percent), as applied in the present analysis. Thus, the 1993 cost analysis material quantities were used in combination with cost assumptions that parallel the present analysis as much as possible. Several minor cost items from the 1993 analysis were not incorporated in the cost tables for this report, and therefore a different approach was used to update those items to the year 2001. An adjustment factor of 30 percent was used to update these miscellaneous cost items, based on construction cost inflation observed in the Puget Sound area through the year 2000 and extrapolation to this year (ENR 2000).

The cost totals for the site examples with type B soils from the 1993 report were disregarded in the present analysis. Instead, new quantity and cost estimates were prepared for those site examples assuming type A soils, assuming the same types of permanent stormwater site plan BMPs as assumed in the present analysis, and incorporating the year 1992 design requirements to determine wetpond and infiltration basin sizes under the older requirements. The revised stormwater facility quantity estimates were then coupled with the year 2001 unit prices used for the present analysis to estimate comparable costs based on the previous design manual requirements. Appendix C presents a brief overview of the re-analysis performed for the 1993 cost examples with infiltration.

The updated cost totals for the 1993 examples, excluding land costs, are shown in Table 2 below in comparison to the cost totals from the present analysis.

This comparison illustrates some important points. If most or all of the site runoff can be infiltrated, and underground facilities are not needed in that process, the costs of managing stormwater are comparable or slightly lower in the present analysis. That is mostly due to the effect that rooftop downspout infiltration has on reduction of wetpond and infiltration basin sizes.

Table 2. Comparison of Implementation Costs Under the Year 1992 and Year 2001 Stormwater Management Requirements.

Development Scenario	Total Implementation Costs Based on 1992 Standards	Total Implementation Costs Based on 2001 Standards	Difference in Cost
10-acre residential with infiltration	$280,000	$240,000	- 14%
10-acre residential without infiltration	$214,000	$230,000	+ 7%
1-acre commercial with infiltration	$84,000[a]	$280,000	+ 233%
1-acre commercial without infiltration	$41,000[a]	$570,000	+ 1290%
10-acre commercial with infiltration	$340,000	$320,000	- 6%
10-acre commercial without infiltration	$260,000	$490,000[b]	+ 88%

[a] The 1993 study assumed that the stormwater management facilities would be placed above ground rather than in vaults, and that greatly affects implementation cost.

[b] Cost associated with open-air sand filter rather than more expensive option with buried sand filter vault

The new requirements for enhanced treatment of runoff (sites 2 and 3) and flow control to match pre-developed flow durations as well as peak rates (for the scenarios with type C soils on all three sites) result in significantly greater storage volumes in the stormwater management ponds and vaults compared to the 1992 requirements. If a site cannot use an infiltration system for flow disposal, the cost of managing the stormwater rises significantly because of the required detention volume and the required enhanced treatment system (at non-residential sites). The detention storage volumes needed to satisfy the new flow duration control requirements, in particular, are much higher, on the order of twice the detention volumes previously needed for peak flow control only. In addition, the wetpool treatment storage volumes needed have increased slightly compared to the 1992 requirements because of a greater design storm precipitation depth. The increase in storage volumes needed on all of the example sites has a direct effect on compliance costs. When these facilities are placed in buried vaults, that cost increase becomes more pronounced.

The new requirements for onsite stormwater management using downspout infiltration systems and flow dispersion systems (among other techniques) also have an effect on overall costs. In the 10-acre residential development example with type A soils these facilities are relatively inexpensive due to the ability to use the "alternative" infiltration trench design. However, in the 1- and 10-acre commercial site examples with type A soils these systems are relatively expensive due to the need for inlet catch basins, perforated pipe, and soil backfill. Even with the greater relative cost for downspout infiltration at the commercial sites, the savings in cost that result from smaller pretreatment systems and infiltration systems (roughly 20 percent lower cost) is well worth the investment in downspout infiltration. In type C soils it was assumed that downspout infiltration systems would not be provided at any of the sites (inexpensive downspout dispersion systems were assumed), resulting in a greater volume of runoff flowing to the stormwater treatment and detention facilities. This analysis did not attempt to incorporate creative design elements such as vegetated rooftops, porous pavements in selected areas, landscaping to promote infiltration and dispersion of runoff at the commercial sites, and other onsite runoff management techniques that can potentially result in significant cost savings due to smaller stormwater control ponds and vaults.

The overall trend that can be expected in stormwater management costs for sites where infiltration cannot be accomplished is a significant increase relative to the costs associated with satisfaction of the 1992 requirements. If infiltration can be accomplished, the overall stormwater management costs may be similar, and possibly lower, in comparison to the costs associated with the 1992 requirements. Some cost components, such as the costs for temporary erosion and sediment control, may not change significantly.

Preface

This document contains information on the cost of implementing the new minimum stormwater control requirements for new developments and redevelopments as set forth by the Washington Department of Ecology (Ecology) in its *Stormwater Management Manual for Western Washington* (Ecology 2001). The minimum requirements include provisions for controlling erosion and sediment transport during construction, as well as permanent facilities for treating and controlling peak runoff flows from developed sites. This cost analysis considers only the stormwater system components required for erosion and sediment control, stormwater treatment, and stormwater detention and/or infiltration that go beyond conventional stormwater systems. Thus, the costs of installing stormwater system components such as catch basins and conveyance pipes that are independent of the Ecology requirements are not addressed in this cost analysis.

The cost estimates for satisfying Ecology's new minimum requirements that are provided in this report should be considered as approximate, and should be viewed in the context of the hypothetical sites for which they were developed. Individual site conditions, selected components of stormwater control plans, costs of land, costs of engineering and construction services, and many other factors can vary considerably throughout western Washington and from project to project. Some projects will be faced with costs associated with construction of stormwater management facilities that are not captured in this analysis, such as traffic control costs, additional property costs, and mitigation costs for sensitive areas that are impacted by placement of stormwater management facilities. Therefore, for a particular development or redevelopment of comparable size to the hypothetical sites discussed in this report, the costs of satisfying Ecology's minimum requirements may differ from the costs given in this analysis. This analysis does not address the costs that stormwater design engineers, site designers, developers, and development reviewers may incur in learning the updated requirements and preparing the resultant technical documentation that will likely require greater detail.

1. Introduction

This report provides information on costs of stormwater control measures required for new single-family residential and commercial developments in western Washington based on the minimum requirements set forth by the Washington Department of Ecology (Ecology) in the *Stormwater Management Manual for Western Washington*, referred to hereafter as "the manual" (Ecology 2001, final version pending as of the date this report was completed). The manual describes the stormwater management requirements applicable to various development and redevelopment scenarios, including many types of development other than single-family residential and commercial land use. There are a multitude of development scenarios that could potentially be evaluated for stormwater management implementation costs but doing so would require extensive amounts of time and effort. This report discusses the range of stormwater management costs that could be expected for some representative examples, and the reader must necessarily use the information as a general guide to understand the cost implications for a specific project of interest.

Development Examples

This report addresses three hypothetical development examples and presents the associated costs for compliance with Ecology's new minimum requirements. These three hypothetical development sites include the following: a 10-acre single-family residential development (site 1), a 1-acre commercial development (site 2), and a 10-acre commercial development (site 3). These examples assume that new development is occurring on the hypothetical sites, that there is no existing development on the sites, that greater than 2,000 square feet of impervious surface is added, and that greater than 7,000 square feet of land area is cleared. Therefore, all of the minimum requirements set forth in the manual are applicable to these examples. Because the decisions regarding how to manage stormwater for a particular site are often directly tied to soil characteristics, this report addresses a range of control measures that may be used in differing soil conditions. For each of the three example sites, the costs to implement the minimum requirements were analyzed for two different soil conditions (soils that would promote infiltration of runoff [type A soils] and soils that are not suitable for infiltration [type C soils]).

This report may be viewed as an update to a similar report prepared in 1993 entitled *Cost Analysis, Minimum Requirements for Stormwater Management in New Developments and Redevelopments* (Herrera 1993), which contained an analysis based on requirements set forth in the *Stormwater Management Manual for the Puget Sound Basin* (Ecology 1992). The analysis in this report repeats the hypothetical development examples from the 1993 report, and the analysis is based on the minimum requirements, design guidelines, and stormwater facility sizing procedures in the updated 2001 Ecology manual. Where applicable, this report refers to the 1993 cost analysis report to enable comparison of the differences in stormwater management costs between the older and newer requirements for the same site conditions.

APPENDIX A

Cost Estimates and Related Assumptions

Cost Estimate Assumptions and Itemized Cost Estimates

This appendix provides detailed information on assumptions and references used in developing the cost estimates for implementing stormwater site plans at the three hypothetical development sites described in Section 2. Itemized cost tabulations are included at the end of the appendix for all of the BMPs associated with the construction SWPPP and permanent stormwater site plan for the three sites.

Costs of equipment, labor, materials, engineering services, and permitting fees are included in the estimates. Unit prices are derived from estimates on other stormwater projects, from the *Site Work and Landscape Cost Data* guide (Means 2000), from the Washington State Department of Transportation's "unit bid analysis" information posted on their web site, and from educated estimates on items for which cost information is not published. An additional 10 percent is added to the subtotal construction cost to cover mobilization and demobilization of equipment for construction and maintenance of BMPs. A contingency of 25 percent is subsequently added to cover unforeseen difficulties during construction and other miscellaneous items. Contingencies are necessary in planning level engineering cost estimates; the 25 percent used here is typical for the limited amount of site information available. An additional cost is listed for investigation of soil suitability for infiltration in the scenarios where infiltration is used for stormwater treatment. Tax (at 8.8 percent) is included on the total construction costs. Engineering services and permitting fees are added at a rate of 30 percent on the total construction cost for most of the development scenarios to obtain the total BMP implementation cost for each site. The assumed percentage of cost for engineering and permitting services was reduced to 15 percent for the 10-acre commercial site with buried sand filter vault because the capital construction costs are disproportionately high due to underground facilities.

The total BMP implementation costs listed in Tables 2, 6, 10, 13, 16, 19, and 20 are relatively conservative estimates. However, site conditions may dictate higher costs if steep slopes and erosive soils are present, or if extensive landscaping is used to make the BMPs aesthetically pleasing. The total implementation cost could also be considerably lower for some sites of comparable size. The total cost estimates should be considered as indicative of approximate average implementation costs. All costs listed in this analysis are in 2001 dollars.

Assumptions Used to Estimate Construction Costs

Assumptions used in developing construction costs for procedures and materials common to all three hypothetical development sites and many BMPs are outlined below. Assumptions used in developing construction costs for procedures and materials unique to either construction SWPPP BMPs or permanent stormwater site plan BMPs are briefly outlined separately in subsequent sections of this appendix.

Construction SWPPP Assumptions

- The cost of excavation for all three sites and all stormwater facilities assumes a short hauling distance of 150 feet (implying onsite relocation and reuse of excavated material). Grading of excavated areas is also included in the unit price of excavation, as shown in the itemized cost tables. The unit price includes equipment and labor.

- The cost of seeding for bare areas assumes hydroseeding with a common utility mix and includes equipment and labor.

- The cost of straw mulch assumes it is mechanically blown on the site rather than hand-cast.

- The cost of street sweeping assumes it is done for one hour, once per week for 6 months adjacent to the 10-acre development sites with type A soils; three times per week adjacent to the 10-acre development sites with type C soils; five times during the course of construction at the 1-acre commercial development site with type A soils; and 10 times during the course of construction at the 1-acre commercial development site with type C soils.

- Approximately 10 percent of the total silt fence length would need to be repaired at the 10-acre development sites with type A soils, and approximately 20 percent of the total silt fence length would need to be repaired at the 10-acre development sites with type C soils.

Permanent Stormwater Site Plan Assumptions

- Bottom liners were assumed necessary for wetponds in type A soils. The unit cost of the bottom liners is based on recent experience with a variety of lining systems at the Cedar Hills Landfill and recent contractor bids for a stormwater pond liner at a park-and-ride site in Puyallup. The backfill over basin liners is assumed to be compacted topsoil or sand, 18 inches thick.

- Access driveways and maintenance pads for all pond-type BMPs were assumed to be 15 feet wide, and the driveway portion extending into the pond bottom was assumed to be common borrow soil underlying a crushed gravel surfacing.

- Pond-type BMPs were assumed to be hydroseeded upon completion of grading rather than via hand-spread seeding.

- For downspout infiltration systems at Site 1 (residential, type A soils), it was assumed that each house (48 total) would have all of its downspouts draining into simple rock-filled trench systems without need for inlet catch basins and perforated pipe.

- It was assumed that the 1-acre commercial development building would have two separate downspout infiltration trench systems, and that the 10-acre commercial development building would have six separate trench systems. These systems would require inlet catch basins and perforated pipe. It was assumed that the catch basins used with these commercial downspout infiltration systems would be made of high density polyethylene rather than concrete to save on cost.

- Underground wet vaults were assumed to consist of 8-foot diameter corrugated steel pipe treated with asphalt coating.

- Underground infiltration tanks were assumed to consist of 5-foot diameter corrugated steel pipe with perforations in the bottom half of the barrel, laid on the drain rock.

- Underground detention systems were assumed to consist of 5-foot diameter corrugated aluminized steel pipe with prefabricated manifold connections, end caps and access risers.

- Underground sand filter vaults were assumed to consist of pre-cast concrete vault sections 20 feet in width, with lateral connecting pipes.

Operation and Maintenance Cost Assumptions

Operation and maintenance (O&M) costs are estimated for the temporary erosion and sediment control and permanent stormwater site plan BMPs. The total duration of construction for Sites 1 and 3 is assumed to be 12 months. The total duration of construction for Site 2 is assumed to be 2 months. The estimates of O&M costs for the construction SWPPPs are applicable only during the construction phase, that is, they are one-time costs. These O&M costs for construction SWPPP measures are factored into the total SWPPP costs listed in Tables 2, 6, 10, 13, 16, 19 and 20. The estimates of O&M costs for permanent stormwater control facilities are applicable as annual requirements. These O&M cost estimates are approximate. A contingency of 20 percent is added to all O&M cost estimates to account for miscellaneous maintenance requirements and variable site conditions. The following discussion details the assumptions used to develop the O&M cost estimates, which are found in Tables 3, 7, 8,11, 14, 17, and 21.

Erosion and Sediment Control BMP Maintenance

- It is assumed that erosion and sediment control BMPs are checked daily in the wet season, and once per week for the remainder of the year. In the dry season it was assumed that several other checks would be needed following infrequent storm events.

- Sediment accumulations in temporary sediment ponds would be cleaned out once during construction on the 10-acre sites with type A soils, and twice during construction on the 10-acre sites with type C soils.

- Offsite catch basins adjacent to the site would be cleaned out for the 10-acre sites with type C soils, but such cleaning would not be needed on the 1-acre commercial site due to the short duration of construction, nor on the 10-acre sites with type A soils because offsite sediment transport would not be problematic in outwash soils.

- Laborers involved in all aspects of operation and maintenance of BMPs are paid at a rate of $30 per hour.

Permanent Stormwater Control BMP Maintenance

Permanent stormwater facilities must be routinely maintained on a scheduled basis for the life of the facilities. Assumptions used to develop O&M costs for permanent stormwater facilities are as follows:

- Infiltration and detention basins, which are normally dry, must be mowed twice per year to promote thick grass cover that enhances sediment settling and infiltration It is assumed that 4 hours of labor would be required to mow the infiltration basins at Sites 1 and 3, twice per year.

- The bottom and side slopes of infiltration basins and the bottoms of the infiltration tanks should be tilled periodically to loosen sediments that may clog the soil surface. It is assumed that tilling is conducted once every 2 years, requiring two laborers for one 8-hour work day on the 10-acre sites (Sites 1 and 3) and two laborers for 4 hours on the 1-acre site (Site 2). In addition to the labor cost, it is assumed that a lump cost of $300 covers mobilization, equipment, and sediment disposal (if necessary) associated with this activity.

- It is assumed that tilling, conditioning, and/or removal of sediment accumulations is conducted once every 2 years in the sand filters for Sites 2 and 3, requiring two laborers for 4 hours on the 1-acre site (Site 2) and two laborers for 8 hours on the 10-acre site (Site 3). In addition to the labor cost, it is assumed that a lump cost of $300 covers mobilization, equipment, and sediment disposal (if necessary) associated with this activity.

- It is assumed that sediment deposits are cleaned out once every 5 years in wetponds and wet vaults. The wetponds at Sites 1 and 3 take approximately 16 hours to clean with a crew of two laborers, and the wet vault at Site 2 takes approximately 12 hours to clean with a crew of two laborers. It is assumed that mobilization, equipment, and sediment disposal associated with this activity costs $500 for Sites 1 and 3, and $300 for Site 2, in addition to the above labor costs.

- Catch basins and storm drains must also be cleaned out periodically to remove accumulated sediments and debris. It is assumed that some of the catch basins in the residential development are cleaned every year, that half of the catch basins in the parking lot at the 1-acre commercial site are cleaned once per year, and that roughly half of the catch basins in the parking lot for the 10-acre commercial site are cleaned each year. It is assumed that the cost is $200 per catch basin or storm drain segment.

- It is assumed that the catch basin inserts in each of four catch basins in the parking lot at Site 2 are replaced four times per year, for a total of 16 inserts per year.

- It is assumed that street or parking lot sweeping will be conducted at each of the sites. At the residential site (Site 1) it is assumed that a sweeper will operate 4 hours per month, for each of 7 months during the year. At the 1-acre commercial site (Site 2), it is assumed that a sweeper will operate 1 hour per month, for each of 7 months during the year. At the 10-acre commercial site (Site 3), it is assumed that a sweeper will operate 3 hours per month for a total of 7 months during the year.

Table 1. Cost estimate for construction stormwater pollution prevention plan -- 10-acre residential development with infiltration.

Item	Unit	Quantity	Unit Cost	Cost
Stabilized construction entrance - quarry spalls	CY	60	$35	$2,100
Stabilized construction entrance - geotextile	SY	170	$1.25	$213
Stabilized staging/parking area - crushed gravel	CY	700	$20	$14,000
Tire wash	LS	1	$500	$500
Interceptor swale excavation	CY	90	$15	$1,350
Interceptor swale seeding	AC	0.6	$1,000	$600
Interceptor swale bonded fiber matrix	AC	0.6	$200	$120
Check dams - quarry spalls	CY	10	$35	$350
Dewatering bag	EA	1	$300	$300
Storm drain inlet protection	EA	2	$200	$400
Straw mulch	AC	9	$800	$7,200
Silt fence	LF	340	$5	$1,700
Water spray for dust control	LS	1	$300	$300
Temporary sediment pond excavation	CY	160	$10	$1,600
Quarry spalls for spillway, inlet dissipation	CY	7	$35	$245
Compacted earth fill berm	CY	55	$4	$220
8" CMP riser pipe for outflow (incl. conc. base)	EA	1	$400	$400
Corrugated polyethylene dewatering device	EA	1	$200	$200
Subtotal				$31,800
Maintenance of erosion and sediment control BMPs (see Table 3 for details)				$8,400
Total SWPPP cost				$ 40,200

Table 2. Cost estimate for permanent stormwater site plan -- 10-acre residential development with infiltration.

Item	Unit	Quantity	Unit Cost	Cost
Onsite stormwater management measures				
Downspout infiltration trench excavation	CY	430	$10	$4,300
Downspout infiltration trench drain rock	CY	320	$30	$9,600
Geotextile for material separation	SY	1,600	$1.25	$2,000
Wet pond				
Excavation	CY	1,300	$10	$13,000
Bottom liner	SY	720	$10	$7,200
Liner backfill (soil or sand)	CY	270	$15	$4,050
Common borrow and gravel for access driveways	CY	40	$20	$800
Outflow structure (catch basin with debris barrier)	EA	1	$3,000	$3,000
Discharge pipe, 12" diam.	LF	50	$40	$2,000
Infiltration basin				
Hydrogeologic evaluation for soil suitability	LS	1	$10,000	$10,000
Basin excavation	CY	2,600	$10	$26,000
Basin liner - nonwoven geotextile	SY	1,870	$1.25	$2,338
Quarry spalls for overflow spillway	CY	7	$35	$245
Seeding	AC	0.39	$1,000	$390
Gravel for access driveway, maintenance pad	CY	41	$20	$820
Observation wells	EA	2	$200	$400
Subtotal				$86,100
Construction SWPPP cost (see Table 1 for detailed TESC costs)				$40,200
Subtotal construction cost				$126,300
Mobilization and demobilization (10%)				$12,630
Subtotal stormwater control BMP cost				$138,930
Contingencies (25%)				$34,733
Total construction cost				$173,700
Taxes (8.8%)				$15,300
Engineering and permitting fees for stormwater facilities (30%) (excluding basic site drainage infrastructure)				$52,100
Total cost for stormwater BMP construction				$240,000

Table 3. **Cost estimate for stormwater BMP operation and maintenance -- 10-acre residential development with infiltration.**

Item	Unit	Quantity	Unit Cost	Cost
Construction SWPPP BMPs				
Regular maintenance checks on BMPs	EA	190	$20	$3,800
Clean out sediment buildup in pond	EA	1	$300	$300
Repair damaged sections of silt fencing	LF	30	$5	$150
Sediment removal in offsite catch basins	EA	0	$200	$0
Street sweeping	HR	26	$100	$2,600
Removal of BMPs at conclusion of construction	LS	1	$1,500	$1,500
Total SWPPP O&M cost (for 1 year only)				$8,400
Permanent stormwater site plan BMPs				
Annual inspection	EA	1	$100	$100
Misc. cleanup	EA	1	$50	$50
Drain and remove sediments from wetpond	EA	0.2	$1,460	$292
Mow infiltration basin	EA	2	$120	$240
Till/remove sediments from infiltration basin	EA	0.5	$780	$390
Spot seeding/repair of bare areas	LS	1	$100	$100
Clean catch basins and storm drains	EA	10	$200	$2,000
Street sweeping	HR	28	$100	$2,800
Subtotal permanent stormwater BMP annual O&M cost				$6,000
Contingencies (20%)				$1,200
Total annual O&M cost				$7,200

Table 4. Cost estimate for construction stormwater pollution prevention plan -- 10-acre residential development without infiltration and without wet season shutdown

Item	Unit	Quantity	Unit Cost	Cost
Stabilized construction entrance - quarry spalls	CY	60	$35	$2,100
Stabilized construction entrance - geotextile	SY	170	$1.25	$213
Stabilized staging/parking area - crushed gravel	CY	700	$20	$14,000
Tire wash	LS	1	$500	$500
Interceptor swale excavation	CY	90	$15	$1,350
Interceptor swale seeding	AC	0.6	$1,000	$600
Interceptor swale bonded fiber matrix	AC	0.6	$200	$120
Check dams - quarry spalls	CY	10	$35	$350
Dewatering bag	EA	1	$300	$300
Storm drain inlet protection	EA	8	$200	$1,600
Straw mulch	AC	9	$800	$7,200
Silt fence	LF	340	$5	$1,700
Water spray for dust control	LS	1	$300	$300
Temporary sediment pond excavation	CY	290	$10	$2,900
Quarry spalls for spillway, inlet dissipation	CY	7	$35	$245
Compacted earth fill berm	CY	65	$4	$260
8" CMP riser pipe for outflow (incl. conc. base)	EA	1	$400	$400
Corrugated polyethylene dewatering device	EA	1	$200	$200
Subtotal				$34,300
Maintenance of erosion and sediment control BMPs (see Table 7 for details)				$14,500
Total SWPPP cost				$48,800

Table 5. **Cost estimate for construction stormwater pollution prevention plan -- 10-acre residential development without infiltration and with wet season shutdown**

Item	Unit	Quantity	Unit Cost	Cost
Stabilized construction entrance - quarry spalls	CY	60	$35	$2,100
Stabilized construction entrance - geotextile	SY	170	$1.25	$213
Stabilized staging/parking area - crushed gravel	CY	700	$20	$14,000
Tire wash	LS	1	$500	$500
Interceptor swale excavation	CY	90	$15	$1,350
Interceptor swale seeding	AC	0.6	$1,000	$600
Interceptor swale bonded fiber matrix	AC	0.6	$200	$120
Check dams - quarry spalls	CY	10	$35	$350
Dewatering bag	EA	1	$300	$300
Storm drain inlet protection	EA	4	$200	$800
Straw mulch	AC	5	$800	$4,000
Soil stabilization with polyacrylamide for winter	AC	9	$200	$1,800
Silt fence	LF	340	$5	$1,700
Water spray for dust control	LS	1	$500	$500
Temporary sediment pond excavation	CY	290	$10	$2,900
Quarry spalls for spillway, inlet dissipation	CY	7	$35	$245
Compacted earth fill berm	CY	65	$4	$260
8" CMP riser pipe for outflow (incl. conc. base)	EA	1	$400	$400
Corrugated polyethylene dewatering device	EA	1	$200	$200
Subtotal				$32,300
Maintenance of erosion and sediment control BMPs (see Table 8 for details)				$9,100
Total SWPPP cost				$41,400

Table 6. Cost estimate for permanent stormwater site plan -- 10-acre residential development without infiltration.

Item	Unit	Quantity	Unit Cost	Cost
Onsite stormwater management measures				
Downspout dispersion splash blocks	EA	96	$20	$1,920
Wet/detention pond				
Excavation	CY	6,200	$10	$62,000
Common borrow and gravel for access driveways	CY	65	$20	$1,300
Quarry spalls for inlet dissipation, overflow spillway	CY	7	$35	$245
Seeding	AC	0.45	$1,000	$450
Outlet piping	LF	60	$40	$2,400
Outlet control structure	EA	1	$3,500	$3,500
Subtotal				$71,800
Construction SWPPP cost (see Table 4 for detailed TESC costs)				$48,800
Subtotal construction cost				$120,600
Mobilization and demobilization (10%)				$12,100
Subtotal stormwater control BMP cost				$132,700
Contingencies (25%)				$33,200
Total construction cost				$165,900
Taxes (8.8%)				$14,600
Engineering and permitting fees for stormwater facilities (30%) (excluding basic site drainage infrastructure)				$49,800
Total cost for stormwater BMP construction				$230,000

Table 7. Cost estimate for stormwater BMP operation and maintenance -- 10-acre residential development without infiltration and without wet season shutdown.

Item	Unit	Quantity	Unit Cost	Cost
Construction SWPPP BMPs				
Regular maintenance checks on BMPs	EA	190	$20	$3,800
Clean out sediment buildup in pond	EA	2	$300	$600
Repair damaged sections of silt fencing	LF	70	$5	$350
Sediment removal in offsite catch basins	EA	2	$200	$400
Street sweeping	HR	78	$100	$7,800
Removal of BMPs at conclusion of construction	LS	1	$1,500	$1,500
Total SWPPP O&M cost (for 1 year only)				$14,500
Permanent stormwater site plan BMPs				
Annual inspection	EA	1	$100	$100
Misc. cleanup	EA	1	$50	$50
Drain and remove sediments from wet pond	EA	0.2	$1,460	$292
Mow wet/detention pond slopes	EA	2	$120	$240
Spot seeding/repair of bare areas	LS	1	$50	$50
Clean catch basins and storm drains	EA	20	$200	$4,000
Street sweeping	HR	28	$100	$2,800
Subtotal permanent stormwater BMP annual O&M cost				$7,500
Contingencies (20%)				$1,500
Total annual O&M cost				$9,000

Table 8. Cost estimate for stormwater BMP operation and maintenance --
10-acre residential development without infiltration and with wet season shutdown.

Item	Unit	Quantity	Unit Cost	Cost
Construction SWPPP BMPs				
Regular maintenance checks on BMPs	EA	60	$20	$1,200
Clean out sediment buildup in pond	EA	2	$300	$600
Repair damaged sections of silt fencing	LF	70	$5	$350
Sediment removal in offsite catch basins	EA	1	$200	$200
Street sweeping	HR	52	$100	$5,200
Removal of BMPs at conclusion of construction	LS	1	$1,500	$1,500
Total SWPPP O&M cost (for 1 year only)				$9,100
Permanent stormwater site plan BMPs				
Annual inspection	EA	1	$100	$100
Misc. cleanup	EA	1	$50	$50
Drain and remove sediments from wet pond	EA	0.2	$1,460	$292
Mow wet/detention pond slopes	EA	2	$120	$240
Spot seeding/repair of bare areas	LS	1	$50	$50
Clean catch basins and storm drains	EA	20	$200	$4,000
Street sweeping	HR	28	$100	$2,800

Contingencies (20%)				$1,500
Total annual O&M cost				$9,000

Table 9. **Cost estimate for construction stormwater pollution prevention plan -- 1-acre commercial development with infiltration.**

Item	Unit	Quantity	Unit Cost	Cost
Stabilized construction entrance - quarry spalls	CY	60	$35	$2,100
Stabilized construction entrance - geotextile	SY	170	$1.25	$213
Storm drain inlet protection	EA	2	$200	$400
Straw mulch	AC	0.8	$800	$640
Silt fence	LF	390	$5	$1,950
Temporary sediment pond excavation	CY	17	$10	$170
Quarry spalls for spillway, inlet dissipation	CY	2	$35	$70
Rock and washed gravel spillway	CY	2	$40	$80
Subtotal				$5,600
Maintenance of erosion and sediment control BMPs (see Table 11 for details)				$1,300
Total SWPPP cost				$6,900

Table 10. Cost estimate for permanent stormwater site plan -- 1-acre commercial development with infiltration.

Item	Unit	Quantity	Unit Cost	Cost
Onsite stormwater management measures				
Downspout infiltration trench excavation	CY	40	$10	$400
Downspout infiltration trench drain rock	CY	30	$30	$900
Compacted backfill	CY	10	$4	$40
Geotextile for material separation	SY	200	$1.25	$250
Type 1 catch basin with sump	EA	2	$400	$800
4" perforated drain pipe	LF	250	$2	$500
Extension of downspouts into trenches	LF	25	$2	$50
Wet vaults				
Excavation	CY	540	$15	$8,100
Vault structures (8' diameter steel pipe)	LF	110	$95	$10,450
Vault installation and connections	LF	110	$80	$8,800
Pipe bedding gravel	CY	100	$20	$2,000
Vault backfill	CY	235	$4	$940
Hauling and disposal of excess material	CY	305	$20	$6,100
Discharge pipe, 12" diam.	LF	40	$40	$1,600
Infiltration tanks				
Hydrogeologic evaluation for soil suitability	LS	1	$10,000	$10,000
Tank excavation	CY	1,000	$15	$15,000
Tank structures (5' diameter perforated steel pipe)	LF	405	$80	$32,400
Tank installation and connections	LF	405	$50	$20,250
Pipe bedding gravel	CY	260	$20	$5,200
Tank backfill	CY	460	$4	$1,840
Hauling and disposal of excess material	CY	540	$20	$10,800
Observation wells	EA	4	$200	$800
Catch basin inserts	EA	4	$100	$400
Subtotal				$137,600
Construction SWPPP cost (see Table 9 for detailed TESC costs)				$6,900
Subtotal construction cost				$144,500
Mobilization and demobilization (10%)				$14,450
Subtotal stormwater control BMP cost				$158,950
Contingencies (25%)				$39,700
Total construction cost				$198,700
Taxes (8.8%)				$17,500
Engineering and permitting fees for stormwater facilities (30%) (excluding basic site drainage infrastructure)				$59,600
Total cost for stormwater BMP construction				$280,000

Table 11. Cost estimate for stormwater BMP operation and maintenance -- 1-acre commercial development with infiltration.

Item	Unit	Quantity	Unit Cost	Cost
Construction SWPPP BMPs				
Regular maintenance checks on BMPs	EA	10	$20	$200
Water spray for dust suppression	LS	1	$100	$100
Repair damaged sections of silt fencing	LF	20	$5	$100
Street sweeping	HR	5	$100	$500
Removal of BMPs at conclusion of construction	LS	1	$400	$400

Total annual O&M cost				$6,200

APPENDIX B

Technical Assumptions Used in Analysis of Stormwater Best Management Practices

Technical Assumptions Used in Analysis of Stormwater Best Management Practices

The technical assumptions, runoff modeling methods, and design parameters used in the analysis of stormwater BMPs for each of the three hypothetical development sites are outlined below.

Two methods were used to estimate runoff from the sites and size stormwater facilities. StormShed, which employs the Santa Barbara Urban Hydrograph (SBUH) method, was used to determine water quality treatment volumes for permanent pretreatment and water quality treatment ponds. The King County Run Time Series (KCRTS) model was used to estimate runoff peak flows for pre- and post-developed conditions, and to determine the size of stormwater detention facilities. KCRTS is a continuous simulation model that functions similarly to the Ecology Hydrologic Model, which, when released, will be WSDOE's preferred tool for stormwater analysis. The water quality sand filtration systems were sized based on treatment of the post-detention 2-year peak flow derived with KCRTS.

Rainfall data used in StormShed for analyzing stormwater runoff volumes are from SeaTac Airport (estimated from isopluvial maps). The 6-month, 24-hour precipitation depth was used to calculate water quality treatment volume, and was estimated to be 1.44 inches, or 72 percent of the 2-year precipitation depth at SeaTac Airport (2.0 inches). The cost analyses for these same site examples for the 1992 storm water manual requirements (Herrera 1993) assumed 1.28 inches for the 6-month storm depth.

The SCS curve numbers (CN) used in the StormShed runoff modeling are:

- Type A soil, residential site, pervious areas in the post-development condition CN = 80 ("good" grass cover)
- Type A soil, commercial sites, pervious areas in the post-development condition CN = 85 ("fair" grass cover)
- Type C soil, residential site, pervious areas in the post-development condition CN = 86 ("good" grass cover)
- Type C soil, commercial sites, pervious areas in the post-development condition CN = 90 ("fair" grass cover)
- Impervious surfaces on all sites CN = 98.

Curve number values listed above for Type A soils are slightly conservative. This resulted in more conservative runoff volume estimates for water quality treatment, pretreatment and infiltration pond designs.

The infiltration rate assumed for the sites with suitable soils is 1 inch per hour.

Depth to ground water is assumed to be 20 feet (below the bottom of an infiltration basin) for all sites.

Rainfall data from the SeaTac rain gauge was used in the KCRTS runoff modeling with a 1.0 scaling factor. The predevelopment ground cover for all of the sites is assumed to be 100 percent forest.

The land use categories and areas used in the KCRTS runoff modeling are:

- Type A soil, 10-acre residential site, predeveloped condition – 10-acres outwash forest.
- Type A soil, 1-acre commercial site, predeveloped condition – 1-acre outwash forest.
- Type A soil, 10-acre commercial site, predeveloped condition – 10-acres outwash forest.
- Type A soil, 10-acre residential site, during construction – 90 percent (9.0 acres) outwash grass, 10 percent (1.0 acre) impervious
- Type A soil, 10-acre residential site, developed condition with on-site storm water management BMPs – 3.3–acres drain to downspout infiltration systems, 2.1-acres impervious, 4.6-acres outwash grass.
- Type A soil, 1-acre commercial site, developed condition with on-site storm water management BMPs – 0.2-acres drain to downspout infiltration systems, 0.1-acres outwash grass, 0.7-acres impervious.
- Type A soil, 10-acre commercial site, developed condition with on-site storm water management BMPs – 2.5-acres drain to downspout infiltration systems, 6.0-acres impervious, 1.5-acres outwash grass.
- Type C soil, 10-acre residential site, predeveloped condition – 10-acres till forest.
- Type C soil, 1-acre commercial site, predeveloped condition – 1-acre till forest.
- Type C soil, 10-acre commercial site, predeveloped condition – 10-acres till forest.

- Type C soil, 10-acre residential site, during construction – 90 percent (9.0 acres) till grass, 10 percent (1.0 acre) impervious
- Type C soil, 10-acre residential site, developed condition – 1.65-acres till grass (rooftops to downspout dispersion), 1.65-acres rooftop impervious, 2.1-acres other impervious, 4.6-acres till grass (lawns).
- Type C soil, 1-acre commercial site, developed condition – 0.9-acres impervious, 0.1-acres till grass.
- Type C soil, 10-acre commercial site, developed condition – 8.5-acres impervious, 1.5-acres till grass.

Re-Analysis of 1993 Cost Examples with Infiltration Systems

This appendix provides information on the methods and results of a re-analysis of stormwater management costs for the site examples from the 1993 cost analysis report (Herrera 1993) that included runoff infiltration. That report assumed type B soils for the infiltration scenarios, whereas the present report assumes type A soils for the infiltration scenarios. To make the cost estimates as comparable as possible, the soil type must be consistent. Therefore, a decision was made to re-analyze the 1993 infiltration examples assuming type A soils. The 1992 design requirements set forth in the *Stormwater Management Manual for the Puget Sound Basin* (Ecology 1992) were applied to the three case study sites with type A soils.

This re-analysis essentially maintains consistency with all aspects of the 2001 cost analysis examples for type A soils, except the sizing of the treatment and flow control facilities is based on the 1992 requirements. The 1993 cost analysis examples for type C soils were not included in this re-analysis, as there was no need to revise the sizes and types of stormwater facilities for those examples to enable a fair cost comparison. The methods used to adjust the cost estimates for those examples to year 2001 dollars are described in the main body of this report.

Permanent Stormwater Site Plan Assumptions

It was assumed that a wetpond and infiltration basin would be used in combination to accomplish treatment and flow disposal at each of the three case study sites for the scenario with type A soils. As discussed in the present report, type A soils enable disposal of large quantities of runoff but pretreatment must be provided. The 1992 Ecology manual required full 6-month design storm treatment prior to discharge to an infiltration system using one of several options, among them a wetpond. Wetponds were assumed for all three sites to closely match the assumptions used in the 2001 cost analysis examples.

As was done in the 1993 report, it was assumed that the stormwater control facilities for the 1-acre commercial development site (Site 2) would be placed aboveground. Likewise, the wetpond and infiltration basin for each of the 10-acre site examples were assumed to be aboveground. The wetponds were sized based on the runoff volume associated with 64 percent of the 2-year 24-hour storm rainfall depth.

The infiltration basins were sized to infiltrate all site runoff up to the 100-year event, with drawdown criteria as stipulated in the 1992 manual (these criteria have not changed in the 2001 manual). The native soil infiltration rate for each of these examples was assumed to be 4 inches per hour, which is on the low end of what is typically observed in type A soils. The 1992 manual required application of a factor of safety of 2, and therefore the design infiltration rate applied in this re-analysis was 2 inches per hour for each infiltration basin. As described in Appendix B, the 2001 analyses of the infiltration examples assumed a design infiltration rate of 1 inch per hour, incorporating a factor of safety of 4 (as if the native soil infiltration rate were measured as 4 inches per hour).

Whereas the 2001 case study examples assumed that rooftop runoff would be disposed of via infiltration trenches, the re-analysis of the 1993 infiltration examples assumed that rooftop runoff would reach the wetponds and infiltration basins.

Results of the Re-analysis of Costs for Sites with Infiltration Capacity Under the 1992 Requirements

Tables C-1 through C-9 present the cost estimates for the permanent stormwater control facilities, temporary erosion and sediment control facilities, and operations and maintenance of temporary and permanent facilities for each of the three case studies in type A soils. These cost tables incorporate unit prices, contingencies, taxes, and engineering and permitting fees that are consistent with the tables for the 2001 cost analysis examples (see Tables 1 through 21 in Appendix A). Thus, the cost estimates presented in Tables C-1 through C-9 are in year 2001 dollars.

Table C-1. Cost estimate for permanent stormwater quality control facilities -- 10-acre residential development with infiltration (1992 design standards).

Item	Unit	Quantity	Unit Cost	Cost
Wet pond				
Excavation	CY	2,000	$10	$20,000
Bottom liner	SY	1,400	$10	$14,000

Contingencies (25%)				$47,369
Total construction cost				$236,840
Soils investigation for infiltration suitability (cost range $6,800 to $8,500)				$6,800
Taxes (8.8%)				$21,440
Additional engineering and permitting fees (30%)				$71,050
Total cost for stormwater BMP implementation (see Table C-9 for annual operation and maintenance costs)				$340,000

Table C-8. Cost estimate for erosion and sediment control measures -- 10-acre commercial development with infiltration (1992 design standards).

Item	Unit	Quantity	Unit Cost	Cost
Stabilized construction roads and entrances				
4"-8" quarry spalls	CY	180	$35.00	$6,300
2"-4" crushed rock	CY	900	$20.00	$18,000
Interceptor swales				
Excavation	CY	830	$15.00	$12,450
Temporary seeding	AC	0.55	$1,000.00	$550
Check dams (pea gravel filled sandbags)	CY	4.2	$35.00	$147
Sediment pond				
Excavation	CY	350	$10.00	$3,500
2"-4" gravel fill for inlet protection	CY	3	$35.00	$105
Compacted earth fill berm	CY	575	$4.00	$2,300
Baffles (4'x8'x1/2" plywood, 6' posts 8' o.c.)	LS	1	$360.00	$360
12" riser pipe for outflow (incl. conc. base)	EA	1	$400.00	$400
2" perforated drain pipe on bottom	LF	35	$1.00	$35
0.5" gravel backfill for drain pipe	CY	0.6	$30.00	$18
Filter fabric wrapping around drain pipe	SY	11	$1.25	$14
12" outflow pipe	LF	45	$10.00	$450
4" gravel outflow protection	CY	11	$35.00	$385
Filter fabric fencing	LF	50	$5.00	$250
Miscellaneous				
Mulch for bare site areas	AC	2	$800.00	$1,600
4" gravel protection for offsite diversions	CY	7	$35.00	$245
Removal of sediment BMPs	LS	1	$1,500.00	$1,500
Subtotal				$48,609
Maintenance of erosion and sediment control BMPs (see Table C-9 for details)				$8,840
Total ESC plan cost				$57,450

Table C-9. Cost estimate for stormwater BMP annual operation and maintenance -- 10-acre commercial development with infiltration (1992 design standards).

Item	Unit	Quantity	Unit Cost	Cost
Erosion and sediment control plan BMPs				
Regular maintenance checks on BMPs (2/week)	EA	104	$20.00	$2,080
Rotate mulch cover on areas exposed	AC	2	$800.00	$1,600
Clean out sediment buildup in traps and ponds	EA	6	$60.00	$360
Repair damaged sections of filter fabric fencing	LF	25	$5.00	$125
Collect and dispose of sediments tracked offsite	LS	1	$3,200.00	$3,200
Subtotal erosion and sediment control BMP maintenance cost				$7,365
Contingencies (20%)				$1,473
Total ESC O&M cost (for 1 year only)				$8,840
Permanent stormwater quality control BMPs				
Mow infiltration and presettling basins	EA	2	$120.00	$240
Rake infiltration and presettling basins	EA	0.5	$780.00	$390
Clean out sediment buildup in presettling basin	EA	1	$300.00	$300
Periodically replace materials and equipment	LS	1	$250.00	$250
Clean catch basins and storm drains	EA	10	$200.00	$2,000
Parking lot sweeping	LS	1	$2,100.00	$2,100
			subtotal	*$1,180*
Subtotal permanent stormwater control annual O&M cost				$5,280
Contingencies (20%)				$1,056
Total annual O&M cost				$6,340

1.0 Introduction

In 1989, the economic importance of the Chesapeake Bay was estimated to be $678 billion per year to the economies of Virginia and Maryland through commercial fishing, marine trade, tourism, port activities, and land values (MDEED, 1989). While it is often difficult to calculate the "true" value of a waterbody or watershed, the above statistic shows that society often measures the value of these resources in terms of factors such as income from water-related activities, property values, and construction costs.

The irony of placing an economic value on water and other natural resources is that, for the most part, the services of these resources are freely available to those who wish to use it. However, human activity that has a negative impact on water resources such as dumping of toxic waste into rivers and streams, or sediment pollution downstream due to extensive land clearing upstream, also has a negative economic impact on the value of these water resources to others who wish to use them. In this case, the person creating the negative impact is transferring the cost of carrying out these activities responsibly to the general public, who will end up paying the consequences. To illustrate this externality, EPA estimated that because of urban runoff pollution, hundreds of millions of dollars are lost each year through added government expenditures, illness, or loss of economic output (USEPA, 1998). The intent of this report is to document these economic costs related to poor environmental regulation or lack thereof, as well as to document the economic benefits of implementing environmental regulations.

The Center for Watershed Protection has conducted a literature search and synthesis of potential economic benefits associated with environmental protection regulations such as stream buffer establishment, wetland protection, erosion and sediment control, floodplain protection, zoning restrictions, stormwater management (quantity and quality), forest conservation, and source water protection. This study identifies sources that illustrate land value and other benefits associated with environmental protection programs as well as possible negative economic consequences of ineffective or non-existent programs. This research is provided in support of Virginia's coastal nonpoint source stormwater management program. Therefore, sources that reference Virginia economic considerations were given preference over others. A list of references is included with this report.

2.0 Economic Benefits of Watershed Protection

The Center for Watershed Protection previously developed an approach to watershed protection that applies eight tools to protect or restore aquatic resources. These eight tools of watershed protection are: watershed planning, land conservation, aquatic buffers, better site design, erosion and sediment control, stormwater treatment practices, non-stormwater discharges, and watershed stewardship programs (see Figure 1). This report reviews the economic benefits of environmental regulations within the framework of these eight tools.

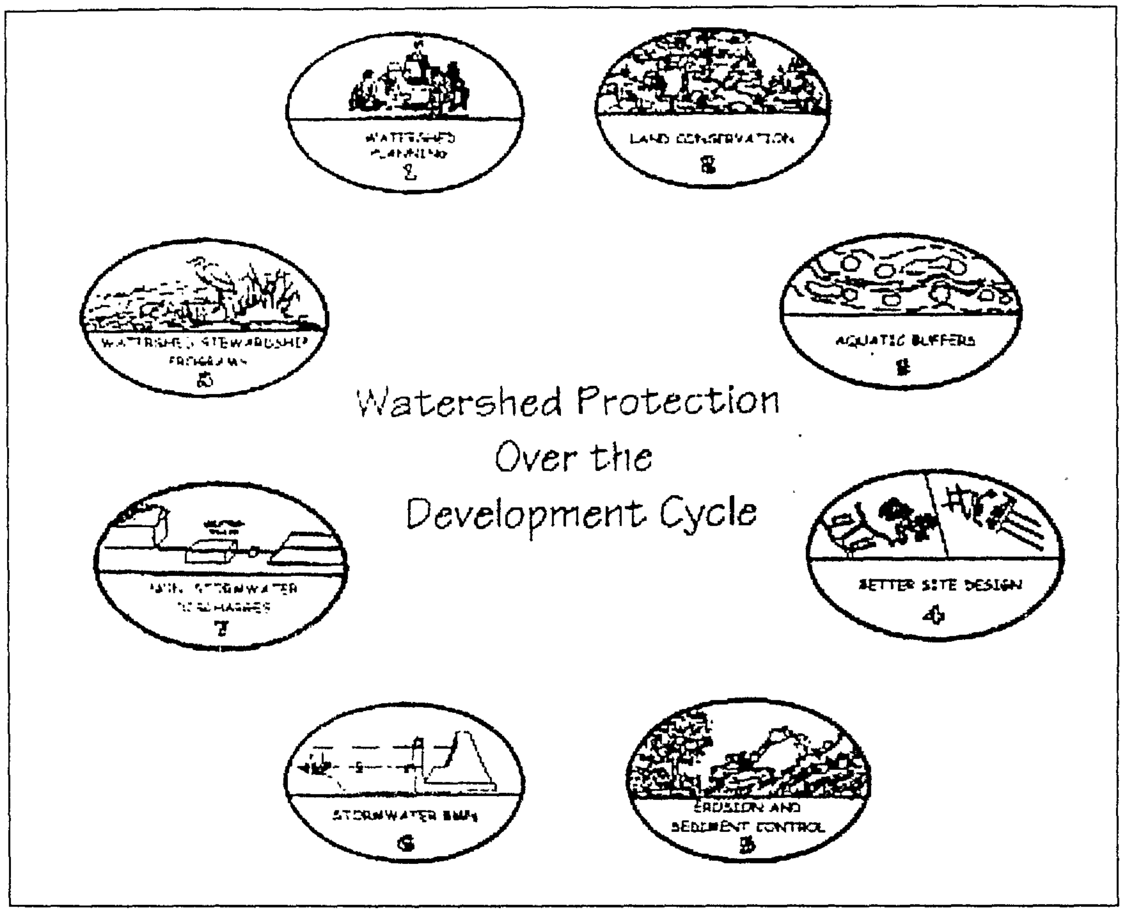

Figure 1 - The Eight Tools of Watershed Protection

The eight tools correspond roughly to the stages of the development cycle from land use planning, site design, construction and ownership. Communities can apply these tools to guide where and how new development occurs, and to design development to have the smallest possible impact on streams, lakes, wetlands and estuaries. While economic research on some of the tools is rather sparse, much of the evidence indicates that these tools can have a positive or at least neutral economic effect, when applied properly. Each tool is described in more detail in this report.

There are two types of economic benefits of implementing environmental protection regulations: income generated by economic activities which rely on water or other natural resources, and a reduction in or avoidance of costs which may result from environmental degradation and consumption of natural resources. These benefits are listed in Table 1 by the eight watershed protection tools. Environmental regulations that correspond to the watershed protection tools are listed next to each tool.

Table 1 – The Economic Benefits of Watershed Protection

Watershed Protection Tool	Economic Benefit
Watershed Planning – zoning tools, urban growth boundaries, source water protection	• Income from fisheries, agriculture, industry, and recreation and tourism • Reduction of drinking water treatment costs, health care costs, and restoration costs
Land Conservation – forest conservation, wetland protection, preservation of parks and open space	• Income from recreation and tourism and increased property values • Reduction of energy costs, health care costs, flood control and stormwater quality and quantity treatment costs
Aquatic Buffers – resource protection areas, stream buffers	• Income from fishing and increased property values • Reduction of flood control and stormwater quality and quantity treatment costs, and restoration costs
Better Site Design – cluster development, impervious cover limits	• Income from increased property values • Reduction of construction, maintenance, and infrastructure costs, as well as stormwater and flood control costs
Erosion and Sediment Control – channel protection, clearing and grading, construction site erosion and sediment control	• Income from marine and port activities and increased property values • Reduction of drinking water treatment costs, construction costs, restoration costs, and dredging costs
Stormwater Treatment Practices – **stormwater regulations, floodplain protection**	• Income from increased property values • Reduction of flood damage costs, reduction of cost of structural stormwater and flood controls
Non-Stormwater Discharges – ***point source controls, septic system regulations***	• Reduction of pollution-related health costs and restoration costs
Watershed Stewardship Programs – ***watershed education and management, monitoring, and residential, industrial and commercial pollution prevention programs***	• Income from stewardship programs • Reduction of restoration costs

The benefits listed above may be direct benefits, indirect benefits, or diversionary benefits. Direct benefits of water quality improvement include enhanced recreational water activities and reduced exposure to contaminants (USEPA, 1999). Indirect benefits include enhancement of near-stream recreational activities, or the quality of residing, working, or traveling near water (USEPA, 1999). Diversionary benefits include avoided water storage replacement costs and water treatment costs (USEPA, 1999). The remainder of this report provides a more comprehensive review of each of the above benefits and cost reductions associated with environmental regulations within the framework of the eight tools of watershed protection.

2.1 Watershed Planning

Watershed planning is perhaps the most important watershed protection tool because it involves decisions on the amount and location of development and impervious cover, and choices about appropriate land use management techniques. Land use planning techniques include overlay zoning, urban growth boundaries, down zoning, transfer of development rights, and many others. The benefit of these tools is improved water quality due to a reduced pollutant load; however, there are often costs associated with many of these land use planning techniques, such as reduced tax revenue and less economic activity. Down zoning in particular can be costly to developers, landowners, and the community because a reduction in density deprives landowners of the potential value of development. Transfer of development rights may help to offset these costs by transferring development potential from sensitive watershed areas to areas designated for growth without taking away the benefits of potential development value. The benefits of watershed planning are difficult to quantify, but are usually measured in terms of the economic benefits of improved water quality.

Stream quality is directly related to land use and consequently impervious cover. Because many land use planning elements also fall under at least one of the other watershed protection tools, this section will focus on the economic benefits of watershed planning regulations that specifically protect water quality. Good water quality has important economic benefits because it is essential for productive fisheries and water-related recreation. Improvements in water quality can also reduce drinking water treatment costs, dredging costs, pollution-related medical costs (e.g., water-bourne illness), and stream and lake restoration costs.

The U.S. economy also depends on clean water. Water used for irrigating crops and raising livestock helps American farmers produce and sell $197 billion worth of food and fiber (USEPA, 2000c). Water is equally important to industry. Manufacturers use about nine trillion gallons of fresh water every year (USEPA, 2000c). The soft drink manufacturing industry alone uses more than 12 billion gallons of water annually to produce products valued at almost $58 billion (USEPA, 2000c).

The fisheries industry is important in the U.S., and especially in the Chesapeake Bay region. The total economic value of commercial fishing in the Chesapeake Bay was estimated to be $520 million per year in 1987 dollars (MDEED, 1989). In 1999, 460 million lbs of fish valued at $108 million were landed in Virginia (NMFS, 2001). Particularly important in Virginia are oysters and blue crabs. In 1999, blue crabs brought in $21 million while the eastern oyster generated $967,000 (NMFS, 2001).

This income from fisheries can quickly decline when water quality declines. Pollutants can contaminate or suffocate fish, as well as degrade fish habitat. The EPA estimated that stormwater runoff costs the commercial fish and shellfish industries approximately $17 million to $31 million per year (USEPA, 1999). Nitrogen and phosphorus are often associated with stormwater runoff, and high levels of these nutrients have been linked to fish kills caused by the toxic dinoflagellete *pfiesteria piscicda*. According to Douglas W. Lipton, coordinator of the Maryland Sea Grant Extension Program, *pfiesteria* cost the Chesapeake Bay seafood industry $43 million in 1997, and the recreational fishing industry $4.3 million.

Water quality is just as important for recreational fishing and other water-related recreational activities such as rafting, swimming, and boating. The average estimated value of freshwater for recreational fishing and wildlife habitat in the U.S. was $48 per acre foot (Frederick, et al., *1996), while freshwater wetlands were valued at $200 per acre for recreational use (Thibodeau and Ostro, 1981). The following statistics illustrate the contribution of recreational fishing and water-related recreation to the economy.*

- A third of all Americans visit coastal areas each year, making a total of 901 million trips while spending about $44 billion (USEPA, 2000c).

- In 1996, total expenditures related to recreational salt and freshwater fishing in Virginia were $821,318 (USFWS, 1997).

- On North Carolina's Nantahala River, raft trip participants increased 700% between 1972 and 1981, and generated $1.8 million in expenditures in 1982 (Swain County Board of Commissioners, 1982).

- *A national survey determined that people were willing to pay more for a higher quality outdoor recreation opportunity (Walsh,* ét al., *1986).*

Medical costs associated with the treatment of illnesses related to water pollution may be reduced when water quality is improved. Pollution-related illness commonly occurs from direct contact with polluted water or from eating contaminated fish or seafood. The USEPA (1994) estimated the economic benefits of the Clean Water Act related to human health effects to be $40 million to $320 million in 1993 dollars. Pollution-related illness can also occur from drinking contaminated water. Currently, EPA estimates that at least half a million cases of illness annually can be attributed to microbial contamination in drinking water (USEPA, 2000c).

The costs associated with source water protection are relatively small when compared to the costs of installing a drinking water treatment plant, locating new drinking water sources, constructing new systems, and cleaning up contamination sites. Other potential costs that go along with cleaning up after a contamination incident include decreased property values, loss of tax base, loss of citizens confidence in their drinking water, public utilities, and community leaders (USEPA, 2001).

Examples of capital costs for drinking water treatment plants are $660 million for the Croton reservoir in New York and $150 million for Portland-Bull Run (cost information was obtained from the respective treatment plants). Operation and maintenance costs for these reservoirs are $11 million and $4 million per year, respectively. These reservoirs are currently unfiltered, therefore treatment costs are lower than for filtered water supplies. The estimated cost of the proposed filtration of New York City's Catskill/Delaware water supply is $4.57 billion (Aponte Clarke and Stoner, 2001).

On average, protecting water quality is less costly than restoring or treating water after it has been polluted. The average annual federal cost of reducing nonpoint source inputs of nitrogen, phosphorus, and sediment to Highland Silver Lake in southwest Illinois was estimated to be $3,000 to $9,000 per percentage point reduction in pollutant loading for non-structural practices. Compare this to the cost for structural treatment practices such as impoundments, which can be greater than $59,000 per percentage point (Setia and Magelby, 1988). Lake restoration costs can be even greater than the water quality protection practices, and will vary depending on the technique used as well as the characteristics of the lake. For example, alum addition can cost $14,000 per 100 tons, shading and sediment covers can range from $1,375 to $65,475 per acre, and plant harvesting costs on average $140 to $310 per acre (USEPA, 1990). Often, more than one technique is used to restore a body of water, which may raise these costs significantly.

2.2 Land Conservation

The second tool, land conservation, involves choices about the types of land that should be conserved to protect a watershed. Conserving forests and open space, and protecting sensitive areas such as wetlands can be accomplished through techniques such as land acquisition and conservation easements, and has an important economic value. While land conservation regulations may have associated costs related to the loss of marketable land, the benefits can greatly outweigh these costs. The conservation of trees has value for keeping energy costs down and reducing air pollution, while wetland protection can reduce flood damage and stormwater management costs. Forest and open space that is preserved as park or greenbelt can also be used for multiple types of recreation.

Properties located near these natural areas have higher real estate values, may appreciate at a faster rate, or have higher than normal resident retention rates. Studies show that people are often willing to pay more to live or work near parks or open space, and lots with trees or near a park tend to sell at a faster rate than typical lots. On average, property values have been found to increase by 5 to 33% when located near a park or greenbelt. The following studies document these findings.

- *The results of a Maryland survey show almost half the respondents said they would be inclined to move if existing open space in their commun[illegible] lost (CBP, 1998).*
- *According to a Bank of America survey, [illegible] agents say that homes with treed lots are 20% more saleable (CBP, 1998).*
- *A land developer donated a 50 foot wide [illegible] easement to provide a critical link for the Big Blue Trail in Front Royal, Virginia. Th[illegible] along the perimeter of a subdivision, and the developer advertised that the trail would [illegible] parcels, all of which sold within four months (American Hiking Society, 1990).*

- *1294-acre Pennypack Park in Philadelphia was found to account for 33% of the land value of properties located 40 feet from the park, compared to 9% of properties located 1000 feet away (CBF, 1996b; Hammer,* et al., *1974).*

- *In Boulder, Colorado, the average value of property adjacent to a greenbelt was 32% greater than properties 3200 feet away (Correll,* et al., *1978).*

- *In Salem, Oregon, urban land adjacent to a greenbelt was worth $1200 more per acre than urban land 1000 feet away (Nelson, 1986).*

- *An analysis of property surrounding four parks in Worcester, Massachusetts found that homes located 20 feet away sold for $2,675 more than similar homes located 2000 feet away from the park. This study also found that if residents were willing to pay $1 per visit to the park, the annual income of $425,000 would be greater than the annual cost to maintain the park of $125,000 (More,* et al., *1982).*

- *In the Whetstone Park area of Columbus, Ohio, a nearby park and river accounted for 7.5% of the selling prices of residential homes (Kimmel, 1985).*

- *Two regional economic surveys document that conserving forests on residential and commercial sites can enhance property values by an average of 6 to 15% and increases the rate at which units are sold or leased (Morales, 1980; Weyerhaeuser, 1989).*

Because many of these conservation areas are preserved as parks, there may be a significant amount of income generated through recreation activities such as biking, hiking, wildlife-viewing, and hunting. The following statistics illustrate the contribution of these activities to local economies.

- *The economic value of tourist activities in the Chesapeake Bay region was estimated to be $8.4 billion per year in 1987 dollars (MDEED, 1989).*

- *In 1996, total expenditures related to wildlife-watching in Virginia were $698,245 (USFWS, 1997).*

- *In 1996, total expenditures related to hunting in Virginia were $518,891 (USFWS, 1997).*

- *A survey by the U.S. Fish and Wildlife Service found that 60% of suburban residents actively engage in wildlife watching, and are willing to pay premiums for locations in settings that attract wildlife (USFWS, 1993).*

- *A national survey determined that people were willing to pay more for higher quality outdoor recreation opportunities (Walsh,* et al., *1986).*

Recreation activities involving exercise can also reduce health care costs. People who exercise regularly have 14 percent lower claims against their medical insurance, spend 30 percent fewer days in the hospital, and have 41 percent fewer claims greater than $5,000. These figures were taken from a Corporate Wellness Study for the city of San Jose, Department of Recreation in 1988 (cited in NPS, 1995). The creation of greenways and trails also reduces employees commuting costs because they provide the opportunity to commute by foot or bicycle (NPS, 1995). People are also more likely to exercise if they have convenient access to a park or greenway with trails or other type of recreation area.

Another type of cost savings that can result from tree conservation and forest preservation is reduced home heating and cooling costs. Energy savings of 10% can result by adding as little as 10% tree cover to buffers near buildings (CBP, 1998). This is because a single mature tree releases about 100 gallons of clean water per day into the atmosphere, and provides the cooling equivalent of nine room air conditioners operating at 8000 btus per hour for twelve hours a day (CBP, 1998). Studies by the American Forest Association have shown that homes and businesses that retain trees save 20% to 25% in their energy bills for heating and cooling. In some cases, trees can reduce winter heating costs by up to 40% (Newsweek, 1979).

Wetland and forest preservation is important not only to protect the diversity of wildlife and habitat there, but also because of the capacity of wetlands and forests to hold floodwaters and filter sediment and nutrients, as well as other toxicants. The cost of preserving or protecting a wetland is therefore less than the benefits gained when taking into account the cost of floodwater storage and water treatment that would otherwise be necessary if the wetland were lost. Forested areas also store floodwaters and filter sediment and nutrients, because the vegetation slows down runoff and promotes infiltration. The following studies document the economic value of wetlands and forest for flood control and water treatment.

- *The Minnesota DNR computed the average cost to replace an acre-foot of floodwater storage to be $300. Therefore, if development eliminates 1 acre of wetland that naturally stores 1 foot of water during a storm, the public replacement cost is $300. The cost to replace 5000 acres of wetlands lost annually in Minnesota would be $1.5 million (FMA, 1994)*

- The wetlands of Congaree Bottom Swamp in South Carolina provide sediment, toxicant, and excess nutrient removal. The least cost substitute for comparable water quality services provided would be a $5 million water treatment plant (FMA, 1994).

- American Forests found that from 1972 to 1996, areas with high vegetation and tree canopy coverage declined by 37% in the Puget Sound area. It is estimated that replacing this lost stormwater retention capacity with reservoirs and other engineering structures would cost $2.4 billion or $2 per cubic foot (American Forests, 1998).

- In Atlanta, Georgia, it was found that a 20% loss in trees and other vegetation in the metropolitan region provided a 4.4 billion cubic foot increase in stormwater runoff; officials estimated that at least $2 billion would be required to build containment facilities capable of storing the excess water (American Forests, as cited in US Water News, 1997).

- The estimated value of freshwater wetlands for water treatment plant function is $10,578 per acre (Thibodeau and Ostro, 1981).

2.3 Aquatic Buffers

The third watershed protection tool, aquatic buffers, involves choices on how to maintain the integrity of streams, shorelines and wetlands, and provide protection from disturbance. Stream and shoreline buffers perform a variety of functions that promote infiltration, slow runoff, store floodwaters, stabilize stream banks, provide stream surface shading, provide habitat, and filter nutrients and sediment. Unfortunately, many development projects will clear right up to the stream edge and remove protective streamside vegetation. Buffer programs preserve existing buffers and create new ones along a stream at a designated distance from the stream edge. Economic benefits resulting from establishing aquatic buffers include: increased property values, reduced flood damage and restoration costs, improved fisheries, and reduced drinking water treatment costs. The following studies document these economic benefits by category.

Property Values

- The Maryland Conservation Act encourages conservation of trees and buffers. Developers in Maryland say they are receiving 10 to 15% premiums for lots adjacent to forest and buffers (CBP, 1998).

- In one Maine case study, increased water clarity (increased visibility depth of 3 feet) due to the addition of lake buffers increased property values by $11 to $200 more per foot of shoreline property (Michael, *et al.*, 1996).

- An economic study in California showed that home prices increased on average 17% because of trees and buffers (CBP, 1998).

- Homes near seven California stream restoration projects had 3 to 13% higher property values than homes on unrestored streams. Most of the perceived value was due to enhanced buffers, habitat, and recreation afforded by the restoration (Streiner and Loomis, 1996).

- Fawn Lake, a 200 acre golf course/lake community in Spotsylvania County, Virgina, received premiums of at least $10,000 per lot for property adjacent to buffer zones or open space compared to interior lots. The total preservation area of the development was 464 acres in buffer zones and open space and these areas were successfully incorporated into the marketing strategy (Melton, 1997).

Fish Habitat

- Land clearing for development can reduce stream surface shading. Studies have shown that when stream surface shade is reduced to 35%, trout populations can drop by as much as 85% (CBP, 1998; Galli, 1991). Stream and shoreline buffers also contribute to better water quality, which means better fish habitat and therefore more productive fisheries.

Flooding

- *Retaining forest area and buffers has reduced stormwater costs in Fairfax County, VA by $57 million (CBP, 1998).*

- Observations of flood damage after major flooding in Virginia in 1994-95 showed that where forest and trees were retained in the floodplain or along streams, the damage was less extensive than in grassy or farmed areas (CBP, 1998).

Water Quality

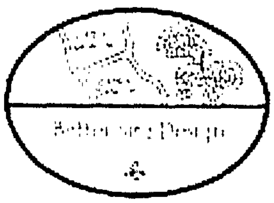
- Riparian forest buffers remove an estimated 21 lbs of nitrogen per acre per year for $0.30 per pound, compared to $3 to $5 per pound for Washington, D.C. area wastewater treatment facilities (CBP, 1998).

Stream Restoration

- *In Fairfax County, Virginia, a local bond issue provided nearly $1.5 million to restore two miles of degraded stream and riparian area (CBP, 1998). Retaining stream buffers is a much more cost-effective way to preserve the integrity of the stream and protect it from erosion and habitat degradation.*

- A summary of 15 stream restoration projects in Maryland and Illinois ranging from 500 feet to 13,200 feet in length showed costs ranging from $12,000 to $2.2 million per project (CWP, 2000b).

- Streambank restoration projects can cost up to $100,000 per linear foot for concrete channelization, compared to $100 per linear foot for vegetative methods such as reforesting the buffer area (Firehock and Doherty, 1995).



2.4 Better Site Design

Better site design is an alternative to conventional sprawl-like development that focuses on clustering development in order to preserve open space, treating stormwater for quantity and quality, and minimizing impervious cover in order to reduce impacts to local streams. Cluster developments, particularly those that permanently protect open space, are often more desirable to live in, and consequently have higher property values. Additionally, there are various cost savings associated with environmentally sensitive development, most of which are related to infrastructure, maintenance, and stormwater costs.

The proximity to a forested area, park or open space often increases property values and real estate premiums; therefore, it is to a developers' advantage to conserve trees and open space within a subdivision. Cluster developments, which use better site design techniques such as tree conservation, reduction of impervious cover, increased common open space, and minimal clearing and grading, typically keep 40 to 80% of a site in permanent community open space and yield lots that bring a higher selling price. In addition, urban forests boost property values by reducing irritating noise levels and screening adjacent land uses. These costs savings are documented with the following examples.

- Clustered homes with permanently protected open space in a development in Amherst, Massachusetts appreciated at an average annual rate of 22% compared with 19.5% for a conventional subdivision. This translated into an average difference in selling price of $17,100 in 1989, even though the conventional subdivision had larger lot sizes (Lacy, 1991).

- In Howard County, MD a cluster development with an average lot size of one acre had the same market value as a conventional subdivision with one to five acre lots (Legg Mason, 1990).

- *The Maryland Critical Areas Act and the New Jersey Pinelands land use regulations improved the tax base because the value of developed land increased by 5% to 17%, and the value of vacant land increased by 5% to 25% (Beaton, 1988; Beaton, 1991). Similar land use restrictions designed to protect the Chesapeake Bay increased property values by 14% to 27% (Fausold and Lillieholm, 1996).*

- *It was projected in 1970 that for a 760 square mile area in Maryland, uncontrolled development would yield $33.5 million in land sales and development profits by 1980. Open space development would yield $40.5 million, yielding $2300 more per acre (Caputo, 1979).*

What many developers do not realize is that using better site techniques can actually cost less than conventional design. However, in cases where the use of better site design techniques creates additional construction costs, these costs are usually offset by increased revenues and higher than normal resident retention rates (CBP, 1998). The following studies document the decrease in infrastructure and maintenance costs associated with better site design.

- *For a medium density residential site in Stafford County, Virginia, using better site design techniques saved $300,547 compared to a conventional design due to reduced infrastructure and stormwater costs (CWP, 1998).*

- *An assessment of better site design techniques in Virginia found that for three residential case studies, better site design cost from 14.5 to 49% less than conventional development, due to reduced infrastructure costs (CWP, 2000).*

- *A Prince William County, Virginia report in 1998 estimated that each new sprawl-designed home costs that locality $1600 more than is returned in taxes and other revenues (CBF, 2000).*

- *Suffolk, Virginia estimates that each new single-family home costs the increasingly spread-out city $7000 in capital for infrastructure and services (CBF, 2000).*

- *A 1986 American Farmland Trust study determined that school transportation costs for a 1,000 unit development at 1 dwelling unit per acre in Virginia's Loudon County would be over 5.5 times greater than the same number of units at 4.5 dwelling units per acre (American Farmland Trust, 1986).*

- *Case studies of developments in New York [illegible] and North Carolina showed that corporate land owners can save $270 to $640 per acre in [illegible] mowing and maintenance costs when open lands are managed as a natural buffer area rather [illegible] WHEC, 1992).*

- *The 1988 public costs for maintaining op[illegible] Boulder, Colorado were $2425 to $3125 less than maintaining developed land (Crain, 198[illegible]*

- *Tax revenue spent on county services in [illegible] County, Virginia in 1987 was 6.6 times greater for residential land uses than for industrial, commercial, farm, forest, or open lands. The same study showed that the average new residential unit in Culpeper County can be expected to produce a deficit* *in the county budget of $1242 (1988 dollars) because the public service costs exceed the revenue (Vance and Larson, 1988).*

- *A study by the Chesapeake Bay Foundation (1996a) derived cost estimates for two development scenarios for Remlick Farm Hall that result in equivalent yield to the developer. In the conventional scenario, the farm is subdivided into 84 large-lot units, whereas in the open space scenario, 52 higher-end units are located on smaller lots in three clusters. Over 85% of the site is retained in open space, as farmland, forest or wetland. The authors compute net development savings of over $600,000 for this 490-acre cluster development (50% lower than the conventional scenario). Most of the savings are attributed to lower infrastructure costs (CBF, 1996a).*

- *Cluster development can reduce the capital cost of subdivision development by 10 to 33%, primarily by reducing the length of the infrastructure needed to serve the development (NAHB, 1986; Maryland Office of Planning, 1989; Schueler, 1995).*

- *Better site design can also reduce the need to clear and grade 35% to 60% of total site area. Since the total cost to clear, grade, and install erosion control practices can range up to $5,000 per acre, reduced clearing can be a significant cost savings to builders (Schueler, 1995).*

Much of the reduction in capital costs can be attributed to a reduction in impervious cover. According to Schueler (1997), potential savings related to impervious cover reduction include:

- *$150 for each linear foot of road that is shortened*

- *$25 to $50 for each linear foot of roadway that is narrowed*

- *$10 for each linear foot of sidewalk that is eliminated*

- *$1,100 of construction cost per space that is eliminated in a commercial parking lot, with a lifetime savings in the range of $5,000 to $7,000 per space when future parking lot maintenance is considered*

Better site design can reduce site impervious cover from 10% to 50% (depending on the original lot size and layout), thereby also lowering the cost for both stormwater conveyance and treatment (Schueler, 1997). This cost savings can be considerable, as the cost to treat the quality and quantity of stormwater from a single impervious acre can range from $30,000 to $50,000 (CWP, 1997). Additionally, the use of non-structural methods of stormwater conveyance and treatment such as grass channels, swales, bioretention areas, and site grading, is typically less expensive than conventional stormwater techniques. Some examples are cited below:

- *Liptan and Brown (1996) documented two commercial/industrial case studies in Oregon where the use of bioretention and swales reduced the size and cost of conventional storm drains for stormwater requirements. Total savings per project ranged from $10,000 to $78,000 (Liptan and Brown, 1996).*

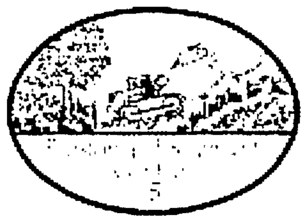
- *In the same study, Liptan and Brown (1996) found that the use of open space design techniques at a residential develoment in Davis, California provided an estimated infrastructure construction cost savings of $800 per home (Liptan and Davis, 1996).*

- *The Oregon Museum of Science and Industry in Portland saved $78,000 by using vegetated swales instead of conventional stormwater management to convey and treat runoff (Lehner,* et al., *1999).*

- *Developers of Prairie Crossing in Grayslake, Illinois saved $2.7 million by using swales, prairie, and wetlands for stormwater conveyance and treatment, and eliminating curb and gutter (Lehner,* et al., *1999).*

- *Curb and gutter costs $40 to $50 per running foot, which is 2-3 times more than an engineered swale (SMBIA, 1990; CWP, 1998).*

2.5 Erosion and Sediment Control



Erosion and sediment control deals primarily with the clearing and grading stage in the development cycle when runoff can carry high quantities of sediment into nearby waterways. Sediment is the most common pollutant affecting U.S. waters (USEPA, 2000b). Sediment pollution and deposition impacts navigable waterways and raises drinking water treatment costs, while shoreline and bank erosion can erode property and destroy fish habitat. Therefore, the control of erosion at its source through construction site erosion and sediment controls, channel protection, and clearing and grading restrictions can increase property values, as well as reduce drinking water treatment costs, stream and lake restoration costs, and dredging costs.

A 1998 analysis of the Phase II Stormwater Rule showed that the annual estimated gross federal benefits for construction site erosion and sediment controls as well as post-construction controls were comparable to the costs of these erosion and sediment controls (USEPA, 1999). However, the benefits to the developer may be even greater. For example, reducing the amount of clearing and grading on a site can save money (as well as trees) in the long run, since the cost to clear, grade, and install erosion control devices can range up to $5,000 per acre (DEDNREC, 1997).

Water resources are essential to the operation of the marine industry. Erosion and sediment control may ultimately decrease the amount of dredging needed to keep these waterways cleared for boat traffic. It costs $10 to $11.5 million annually to dredge and dispose sediments deposited into Baltimore Harbor to keep it navigable (CBP, 1998). Listed below are some facts documenting the economic benefits of marine and port activities on local economies:

- The economic impact of port activity in the Chesapeake Bay (from 3 major ports, Baltimore, Norfolk, and Newport News) was estimated to be $5.3 billion per year in 1987 (MDEED, 1989).

- The economic impact of the shipbuilding and repair industry in the Chesapeake Bay region was estimated to be $17.3 billion per year in 1987 dollars (MDEED, 1989).

- Frederick, *et al.* (1996) estimated the average value of freshwater for navigation to be $146 per acre foot for the entire U.S.

Dredging is necessary not only in navigable waterways, but also in drinking water reservoirs that lose capacity with excess sediment deposition. Because a major function of drinking water treatment plants is to remove sediment, it stands to reason that the more sediment in the intake water, the more effort will have to be expended to remove the sediment and ultimately dispose of it. Therefore erosion and sediment control regulations can prevent an increase in drinking water treatment costs.

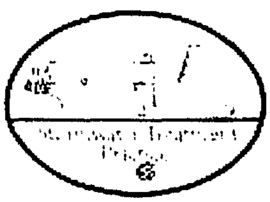
To illustrate the costs of sediment pollution, the following example computes the sediment loading to a downstream reservoir during one year from active construction on a 100 acre mixed use site. The Simple Method (Schueler, 1987) was used to calculate the sediment load in pounds per year from the construction site, assuming 40 inches of annual rainfall, 0.9 effective precipitation value, a runoff coefficient of 0.5 for the construction site, and an event mean concentration (EMC) of 15,000 mg/L (taken from Owens, *et al.*, 2000). Using 100 pounds per cubic foot as the dry density of the sediment, the volume of sediment entering the reservoir during one year was determined to be 2,267 cubic yards. Assuming a cost of $20 per cubic yard for dredging, transport, and disposal of the material, the annual cost would be $45,340 to remove the sediment generated from one source alone. When other sources of sediment to the reservoir are accounted for, this cost will rise significantly.

Shoreline and bank erosion eats away at property values as well as the shoreline. The economic benefits of erosion and sediment control are illustrated with the following studies.

- A study in the Lake Erie, Ohio area used the hedonic price method[1] to predict that an erosion control device lasting 8 years would raise property values by $5,500, and one lasting 20 years would raise property values $11,000 (Kreisel, *et al.*, 1993).

- Using hedonic price indices, Van deVerg and Lent determined that property values for Chesapeake Bay shoreline homes in Maryland would decline on average $3,474 per annual foot of erosion (Van deVerg and Lent, 1994).

2.6 Stormwater Treatment Practices



The sixth tool, stormwater treatment practices, involves choices about how, when, and where to provide stormwater management within a watershed, and which combination of management practices can best meet watershed objectives. Stormwater regulations that are designed to prevent flooding or reduce damages from flooding have measurable economic benefits. Not only are the costs of flood damage reduced or in some cases eliminated, but non-structural controls such as floodplain protection also reduce the need for structural stormwater controls of these larger storms. Effective stormwater management that reduces flood risk may also increase the property values of nearby homes. Stormwater treatment practices also improve water quality, and these benefits are discussed under the first watershed protection tool, watershed planning.

[1] The hedonic price index is a statistical method for determining the prices of the individual attributes of properties. .

Flood damages can be extensive, particularly in areas where there are no regulations regarding development in the floodplain. From 1990-1999, flooding was the most frequently reported disaster in the U.S., and according to FEMA more than $7.3 billion was committed by FEMA for flood damages (FEMA, 2001). Conversely, FEMA placed a value of $800 million on the amount communities are collectively saving on an annual basis through the National Flood Insurance Program by adopting and enforcing responsible floodplain management and regulating new development in flood hazard areas (FEMA, 1999). The following studies document the economic impacts of flooding and flood control.

- *The so-called 'Grandfather' of water resources management, Gilbert White estimated in 1958 that for every six dollars in potential damages reduced each year by new flood protection measures, at least five dollars in additional damage resulted from development in floodplains. Flooding accounts for larger annual property losses than any other single geophysical hazard (Riley, 1985).*

- *At a cost of $27 million, Baltimore County acquired 100 homes and cleared the 100 year floodplain in eight of its most critical watersheds, saving $85 million in local storm damage assistance costs over 5 years (Caputo, 1979).*

- *A national study of ten programs that diverted development away from flood-prone areas found that land next to protected floodplains increased in value by an average of $10,427 per acre (Burby, 1988).*

The total gross benefits of the Phase II Stormwater Rule were estimated to be between $671.5 million and $1.10 billion per year, compared to total annual costs of $847.6 million to 981.3 million (USEPA, 1999). The benefits included reduced damages from flooding, as well as increased property values. Property values can increase from reduced flood risk as well as residents desire to live near water features such as stormwater ponds. The following studies document residents' preference to live near urban runoff controls as well as the real estate premiums paid for this privilege.

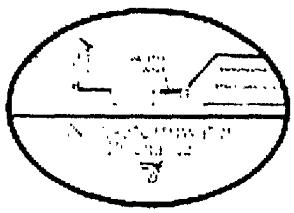
- *A survey of 143 residents in Champaign-Urbana, Illinois found 82.3% of residents were willing to pay a premium to be located next to a wet pond. Overall, the respondents believed lots adjacent to wet ponds were worth on average 21.9% more than non-adjacent lots in the same subdivision (Emmerling-DiNovo, 1995).*

- *In 1982 the National Institute for Urban Wildlife surveyed 600 homeowners in Columbia, Maryland. 75% of homeowners expressed a preference for lots near wet basins, and felt the pond presence increased property values. 73% of respondents were willing to pay more to live in an area with a detention basin designed to enhance fish and wildlife use. The same survey found that developments with wet ponds have higher initial costs, but these costs are recovered by a faster sales rate (Adams,* et al., *1986).*

- *An EPA study of several developments in Virginia showed that real estate premiums for property fronting urban runoff controls averaged up to $7,500 per unit for condominiums, up to $10,000 per unit for townhomes, up to $49,000 per unit for single family homes, up to $10 per month per apartment rental, and up to $1 per square foot for commercial rentals (USEPA, 1995).*

- *Chancery on the Lake, a condominium development in Alexandria, Virginia is a residential project with an attractive 14-acre urban runoff detention area. The wet pond is the focal point of the* *development, and is surrounded by a walking trail and will be used for fishing. Condominiums that front the lake are selling at a $7,500 premium (Harden, 1995).*

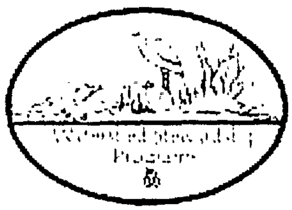
- *In Fairfax County, Virginia, the townhouse community of Pinewood Lakes has been selling waterfront townhomes at a premium for 23 years. The average sales price of a waterfront townhome is $6,117 more than a similar home without a view of the constructed pond (Wade, 1995).*
- *A townhouse community in Tysons Corner, Virginia called Evans Mills is built around an existing pond. In 1994, the waterfront homes sold for an average $17,467 premium above the average price of homes not facing the pond (Wade, 1995).*
- *Franklin Farms, a single family home residential neighborhood in northern Virginia has a 5-acre urban runoff detention area surrounded by a walking path. Waterfront homes in this development sold for 10 to 20 % more initially and again at resale than land with no water view (Downham, 1995).*



2.7 Non-Stormwater Discharges

The seventh tool, non-stormwater discharges, involves choices on how to control discharges from wastewater disposal systems, illicit connections to stormwater systems, discharges from failing septic systems, and reducing pollution from household and industrial products. The EPA estimated the annual benefits of current water quality levels relative to what they would have been without water pollution control programs, particularly the Clean Water Act. This benefit was estimated to be $11 billion annually (USEPA, 2000).

One type of non-stormwater discharge is septic system effluent. In areas outside water and sewer service areas, septic systems are used to treat wastewater. In order to be effective, septic systems must have appropriate drainage area and soils as well as be maintained regularly. There are costs associated with failing septic systems. A failed or failing septic system can decrease property values, delay the issuance of building permits, or hold up the purchase settlement (NSFC, 1995). In the event a septic system fails, homeowners can expect to pay from $3,000 to $10,000 for replacement (Schueler, 1997).



2.8 Watershed Stewardship

The final tool, watershed stewardship programs, involves careful choices about how to promote private and public stewardship to sustain watershed management. Many communities now invest in programs of watershed education, public participation in watershed management, monitoring, inspection of treatment systems, low input lawn care, household hazardous waste collection, or industrial and commercial pollution prevention programs. The common theme running through each program is education, and although this is somewhat difficult to put a price on, some examples are listed below.

- The Chesapeake Bay Restoration fund reports revenues of $341,811 in the year 2000 from donations, while sales of bay plates have climbed to $1 million per year.

- The Mattaponi and Pamunkey Rivers Association in Virginia reports they receive over 3,000 volunteer hours annually for water quality monitoring, trash cleanup, and community education. Assuming public works employees were paid $15/hour for the same work, this results in a savings of over $45,000 per year just from one organization's efforts. There are currently over 300 watershed organizations in the Chesapeake Bay watershed alone.

- The Alliance for the Chesapeake Bay reports they currently have 145 volunteers who perform weekly water quality monitoring, which allows the paid staff to address other critical issues.

- The Chesapeake Bay Foundation reports an estimated 300,000 volunteer hours per year bay-wide for projects such as bay restoration and cleanup. They estimate this benefit to be worth $3 million annually based on a rate of $10 per hour of work.

- Education about lawn care practices has an associated cost reduction. In 1981 the city of Plano, Texas, instituted a program that encouraged residents to leave clippings on home lawns to provide nutrients and moisture. Knopp and Whitney (1989) reported that the city saved $60,000 in disposal costs the first year, even though the number of households served increased 12% over the same period. Residents participating in the program saved $22,000 in leaf/lawn bag purchases (Knopp and Whitney, 1989).

- In Seattle, an education program encouraged urban citizens to compost yard and food wastes. About 5,300 tons of yard waste were removed from disposal annually, for a net savings of $378,000 (EPA, 1991).

- Raup and Smith (1986) reported that integrated pest management (IPM) reduced community pest management costs by 22%, even though more pests were controlled under the new program. The use of expensive chemicals to control weeds can also be substantially reduced.

- Conserving native vegetation results in significant costs savings for maintenance. Americans spend over $7.5 billion each year on lawn care products to maintain turf lawns (CWP, 1998). Native vegetation is usually low-maintenance and is better adapted to climatic changes and pests, therefore does not require the use of fertilizer or constant watering that is characteristic of the turf lawn (CWP, 1998).

3.0 Conclusions

Environmental regulations cost money to implement. However, the related benefits and savings can be equal to or greater than the costs. This report documents the economic benefits of specific environmental regulations including: floodplain, water quality, conservation area protection, buffers, erosion and sediment control, and zoning regulations. The numerous sources of references in this report identify several types of economic benefits resulting from these regulations. These benefits include increased property values, income from fisheries, recreation, tourism, and the marine industry, as well as savings or avoidance of costs related to flood damage, stormwater treatment, construction, infrastructure and maintenance, drinking water treatment, home heating and cooling, medical treatment, and stream/lake restoration. These economic benefits, combined with the other, immeasurable benefits of preserving forests, and protecting habitat, biodiversity and natural resources, makes the decision to establish environmental regulations a justifiable and responsible approach to protecting water resources and the environment in general.

Many Virginia communities are currently struggling with the issue of balancing economic growth with protection of their natural resources and water quality. The rise in impervious cover associated with new development affects local water resources by reducing the infiltration of rainfall and increasing the volumes of stormwater runoff that eventually enter local waterbodies. One strategy for minimizing the effects of this additional runoff is through a variety of development strategies collectively known as "better site design".

Better site design is a process by which local governments review and modify their zoning codes and ordinances to permit new site development practices that preserve more pervious areas and lessen environmental impacts. These better site design practices allow communities to continue to realize the economic benefits of new development while improving their ability to protect the local environment . At the heart of the better site design process is a set of Model Development Principles that focus on the design of streets, parking lots, and site lots in new developments. Recently, 16 Model Development Principles were reviewed and endorsed by the Virginia Chesapeake Bay Local Assistance Department as conducive to addressing the general performance criteria of the Chesapeake Bay Preservation Act. Table 1 provides a summary of the sixteen principles applicable to the Chesapeake Bay Preservation Act.

The application of the better site design principles can help developers and local governments recognize increased economic benefits through reduced infrastructure requirements, decreased need for clearing and grading of sites, and less expenditure to meet stormwater management requirements due to reduced runoff volumes and nutrient export from a site. The following are examples of the economic benefits that Virginia communities can gain through the encouragement of better site design practices:

- For a 45 acre medium density residential site in Stafford County, Virginia, using better site design techniques would have saved $300,547 compared to a more conventional design due to reduced infrastructure and stormwater costs (CWP, 1998b).
- Studies have found that construction savings can be as much as 66% by using the open space designs encouraged by better site design (CWP, 1998a).
- Better site design can also reduce the need to clear and grade 35% to 60% of total site area. Since the total cost to clear, grade, and install erosion control practices can range up to $5,000 per acre, reduced clearing can be a significant cost savings to builders (Schueler, 1995).
- A summary of 40 years of fiscal impact studies showed that smart growth consumes 45% less land, costs 25% less for roads, 15% less for utilities 5% less for housing, and costs 2% less for other fiscal impacts than current trends of sprawl development. (Burchell and Listokin, 1995).

A 1990 study for the city of Virginia Beach compared the costs and benefits of conventional and smart growth development patterns. The study found that the smart growth pattern resulted in 45% more land preserved, 45% less in infrastructure costs to the city, and a 50% reduction in impervious surface due to roads (Siemon, Larsen and Purdy, et al., 1990).

Table 1. Virginia Model Development Principles

Conservation of Natural Areas

1. Conserve trees and other vegetation at each site by planting additional vegetation, clustering tree areas, and promoting the use of native plants. Wherever practical, manage community open space, street rights-of-way, parking lot islands, and other landscaped areas to promote natural vegetation.
2. Clearing and grading of forests and native vegetation at a site should be limited to the minimum amount needed to build lots, allow access, and provide fire protection. A fixed portion of any community open space should be managed as protected green space in a consolidated manner.

Lot Development

3. Promote open space development that incorporates smaller lot sizes to minimize total impervious area, reduce total construction costs, conserve natural areas, provide community recreational space, and promote watershed protection.
4. Relax side yard setbacks and allow narrower frontages to reduce total road length in the community and overall site imperviousness. Relax front setback requirements to minimize driveway lengths and reduce overall lot imperviousness.
5. Promote more flexible design standards for residential subdivision sidewalks. Where practical, consider locating sidewalks on only one side of the street and providing common walkways linking pedestrian areas.
6. Reduce overall lot imperviousness by promoting alternative driveway surfaces and shared driveways that connect two or more homes together.

Residential Streets and Parking Lots

7. Design residential streets for the minimum required pavement width needed to support travel lanes; on-street parking; and emergency, maintenance, and service vehicle access. These widths should be based on traffic volume.
8. Reduce the total length of residential streets by examining alternative street layouts to determine the best option for increasing the number of homes per unit length.
9. Residential street right-of-way widths should reflect the minimum required to accommodate the travel-way, the sidewalk, and vegetated open channels. Utilities and storm drains should be located within the pavement section of the right-of-way wherever feasible.
10. Minimize the number of residential street cul-de-sacs and incorporate landscaped areas to reduce their impervious cover. The radius of cul-de-sacs should be the minimum required to accommodate emergency and maintenance vehicles. Alternative turnarounds should be considered.
11. Where density, topography, soils, and slope permit, vegetated open channels should be used in the street right-of-way to convey and treat stormwater runoff.
12. The required parking ratio governing a particular land use or activity should be enforced as both a maximum and a minimum in order to curb excess parking space construction. Existing parking ratios should be reviewed for conformance taking into account local and national experience to see if lower ratios are warranted and feasible.
13. Parking codes should be revised to lower parking requirements where mass transit is available or enforceable shared parking arrangements are made.
14. Reduce the overall imperviousness associated with parking lots by providing compact car spaces, minimizing stall dimensions, incorporating efficient parking lanes, and using pervious materials in the spillover parking areas where possible.
15. Provide meaningful incentives to encourage structured and shared parking to make it more economically viable.
16. Wherever possible, provide stormwater treatment for parking lot runoff using bioretention areas, filter strips, and/or other practices that can be integrated into required landscaping areas and traffic islands.

To illustrate the economic advantages of better site design, a comparison of four development projects in Virginia that have applied a number of the Model Development Principles was recently conducted. Table 2 provides a short summary of the environmental cost benefits realized for the four projects reviewed. For a more complete description of each case study, consult the publication "Better Site Design: An Assessment of the Better Site Design Principles for Communities Implementing the Chesapeake Bay Preservation Act" available from the Center for Watershed Protection or from the Virginia Chesapeake Bay Local Assistance Department.

The assessment of Model Development Principle application in Virginia found that for the three residential case studies, the use of better site design could save up to 49% in total infrastructure costs compared to conventional development (CWP, 2000). Estimated total infrastructure costs include the costs of roads, gutters, sidewalks, landscaping, and stormwater management best management practices. In all three cases, the designs incorporating the Model Development Principles saved the developers more than $200,000 in infrastructure costs, while producing the same number of housing units. In addition, other more intangible economic benefits that may be derived from the use of better site design practices are not included in the case studies. These may include reduced heating and cooling costs for homeowners from tree preservation, decreases in flooding incidence and associated damage, and improved pollutant removal from the filtering action of forest and stream buffer areas. For a more detailed summary, consult "The Economic Benefits of Protecting Virginia's Streams, Lakes, and Wetlands" prepared for the Virginia Department of Conservation and Recreation by the Center for Watershed Protection.

Table 2. Benefits of Better Site Design vs. Conventional Development - 4 Virginia Studies

Case Study	Percent of Natural Areas Conserved	Percent Reduction in Impervious Cover	Percent Reduction in Stormwater Impacts			Percent Reduction in Total Infrastructure Costs
			Runoff	N Load	P Load	
Fields at Cold Harbor Hanover County	80.4	25.3	12.2	6.4	6.4	47.2
Governor's Land, James City County	49.3	21.7	14.3	17.5	17.3	14.5

The Arboretum III, Chesterfield County	5.1	12	19.7	36	37.1	N/C

* - Open space area is maintained as landscaped parkland.
N/C - Not Calculated.

R0010913

Conclusion

Better site design is an alternative to conventional development that focuses on preserving open space as natural areas and minimizing impervious cover in order to reduce the impacts of stormwater runoff on local streams. Studies have found that developments that permanently protect open space are often more desirable to live in, and consequently have higher property values (CWP, 1998a). Table 3 illustrates the cost savings for both local governments and developers associated with using better site design, most of which are related to infrastructure, maintenance, and stormwater costs.

As the case studies show, using better site design not only saves money, but provides significant reductions in nutrient export, especially at higher densities. Adoption of the Model Development Principles by Virginia communities will help protect local water quality while permitting the new development necessary for local governments to fund community services and protect watersheds.

Table 3. Burchell (1992-1997) Savings Due to Compact Growth Patterns

Area of Impact	Lexington, KY and Delaware Estuary	Michigan	South Carolina	New Jersey
Infrastructure Roads	14.8-19.7	12.4	12	26
Utilities	6.7-8.2	13.7	13	8
Developable Land Preservation	20.5-24.2	15.5	15	6
Agricultural Land Preservation	18-29	17.4	18	39

IMMEDIATE RELEASE
July 10, 2001

Conference of Mayors President Launches Nationwide "Competitive Cities Tour"

Releases New Report Showing Many U.S. Metro Areas Outpace States, Even Nations, in Economic Output

Washington, DC -- Today, delivering the keynote address at a National Press Club luncheon, Conference President and New Orleans Mayor Marc H. Morial announced a nationwide "Competitive Cities" tour dramatizing the renaissance of America's cities during the 1990s. To set the stage for the tour, Morial released data from a new report showing that America's cities drive the national economy, and outpace states, and even nations, in economic output.

Download the Full Transcript of the Speech

Download the Full Report and Charts

Metro Economies: A Decade of Prosperity

"The new data we are releasing today makes it clear that metropolitan economies are the engines of America's growth and driving America's economy," Morial said in releasing the report. "Metro regions are growing, producing more, and creating unprecedented levels of employment."

The data is part of the fourth annual report, entitled "U.S. Metro Economies: A Decade of Prosperity." Compiled by Standard & Poor's DRI, the report documents the Gross Metropolitan Product (GMP) of the nation's 319 largest metro areas, and shows improved economic vitality for the nation's metro regions. (Gross Metropolitan Product is a concept analogous to Gross Domestic Product, the commonly accepted measure nations use to calculate the total annual value of goods and services they have produced.)

This report describes the scope of metro areas, their vital contribution to the nation's economy, the level of income creation by metro areas, generation of new industries by metro areas, and the relationship between metro areas and the nation's overall economic growth. The report also ranks U. S. metro areas relative to themselves, states and national economies around the world. Among the key findings of the 2001 report:

International

- In 2000, U.S. Metro areas retained their leadership status in the world economy—if treated as nations, U.S. metro areas would comprise 47 of the world's largest economies.

- New York now ranks as the 14^{th} largest economy in the world, compared to last year's ranking of 16^{th}; Los Angles moved from 17^{th} to 16^{th}; and Chicago moved from 19^{th} to 18^{th} in world ranking; Boston moved from 24^{th} to 23^{rd}. The New York metro area had more economic output than Australia; Los Angeles more than the Netherlands; Chicago more than Taiwan, Argentina, Russia, or Switzerland; Boston more than Belgium, Sweden or Turkey; Philadelphia and Houston more than Hong Kong.

- If the five largest U.S. metro areas were treated as a single country, it would rank as the fourth largest economy in the world ($1.59 trillion), trailing only the U.S., Japan and Germany.

National

- The combined gross economic output of the top ten U.S. metro areas in 2000 was $2.43 trillion—an amount greater than the combined economic output of 31 states ($2.39 trillion).
- In 2000, U.S. metro areas contributed to the U.S. economy 84 percent of employment (111 million jobs); 85 percent of Gross Domestic Product ($8.476 trillion); and 88 percent of labor income ($4.22 trillion).
- Over the past decade, the majority of new jobs in the financial services and transportation and utilities sectors were created within cities: 88 percent, or 804,000 jobs in financial services, and 90 percent, or 1.116 million jobs in transportation and utilities.

The 1990s

- U.S. metro areas' contribution to Gross Domestic Product grew from 84.3 percent in 1990 to 84.7 percent in 2000 and is forecast to increase steadily over the next 25 years, reaching 86.9 percent in 2025.
- U.S. metro areas contributed an astounding 86 percent, or $3.66 trillion, of economic growth to the U.S. economy during the 1990s—an amount larger than the 2000 gross domestic product of Germany and the United Kingdom combined.
- Las Vegas (10.3%), Austin (9.8%), Boise (9.4%), Laredo (9.4%) and Phoenix (9.2%) had the fastest average annual growth rate for gross metropolitan product in the 1990s.

Mayors believe national and international economic policies must focus on the needs of the 319 economically potent metropolitan regions surveyed in the report. "We believe that the data we've seen sustain our call to the Congress and the Administration to support local and metropolitan economic growth by investing in transportation, distressed communities, and education and training," Morial said.

__Nationwide Competitive Cities Tour__

Mayor Morial also announced a nationwide "Competitive Cities Tour" to promote America's metro areas as competitive powerhouses in the national and international economic arenas.

The tour, scheduled to begin in September, will highlight the best practices and strategies employed by Mayors across the country to foster what Mayor Morial calls the *six keys to keeping cities competitive:*

- Safe streets and communities;
- A skilled workforce;
- The arts, as both a cultural/educational and economic force in communities;
- Strong infrastructure;
- Good, affordable housing; and
- Strong economies.

"America's cities are cultural destinations for people around the world," Morial said in his address. "Cities are economic powerhouses. You may not see it, but every day, in cities across the nation, Mayors are working to forge partnerships on the national and international economic stages. What does it mean when the City of Denver opens trade offices in London and China, or negotiates with airlines for international non-stop flights bringing tourism and business travel into the city? Or when the Mayor of Akron brokers an agreement which locates a German business in that city, bringing with it 70 new jobs and millions of dollars annually in economic output?

"It might mean, if you really think about it, that there are a number of Mayors in this country who are taking their rightful places as world economic leaders. Because of their economic clout, in the coming years you will see mayors leading trade delegations as much if not more so than governors. Institutions involved in promoting trade, such as the Commerce Department, will have to reinvent themselves to think metro economies, not states." Morial continued." If this nationwide tour of America's Competitive Cities accomplishes one goal, I hope that it's to secure our cities' rightful place in the dialogue on national and international economic issues and development."

Copies of the report, charts, graphs and accompanying data and information, as well as the full text of Mayor Morial's address, will be posted on the Conference's website, www.usmayors.org, as of 2:00pm EST on Tuesday, July 10.

PRESS RELEASES HOMEPAGE

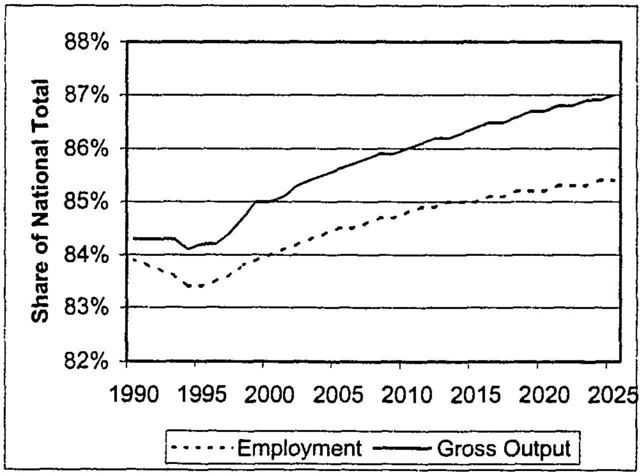
The Role of Metropolitan Areas in the National Economy

As the focal points of economic activity, metropolitan areas are vital to the nation's economic development. While states are defined by geographic and political boundaries, metro areas are shaped by economic activity, sometimes across state or national borders. The concentration of people and business in metro areas creates unique economic conditions that give rise to new industries, speed the diffusion of knowledge, spur technological innovation, and increase productivity. The economic dynamism and creativity found in metro areas enables American industries to thrive in global competition. Historically, most of the largest U.S. industries began in cities, where access to labor, capital, and customers fostered business development. Today, metro areas generate more than 80% of the nation's employment, income, and production of goods and services.

1 The Recent Performance of Metropolitan Area Economies

The contribution of metro areas to the national economy has increased over the last decade, a trend that is expected to continue over the next twenty-five years. Metro area employment increased from 92.1 million in 1990 to 110.8 million in 2000, growing at a 1.9% annual rate over the decade. In 2000, metro area employment posted a solid 2.6% gain. The share of employment in metro areas fell slightly in the first half of the 1990s before rebounding to a new high of 84.0% last year.

Figure 1 - The Contribution of Metro Areas to the National Economy Will Continue to Grow



Gross metropolitan product, the value of goods and services produced in metro areas, increased from $4.812 trillion in 1990 to $8.476 trillion in 2000, an average gain of 5.8%

R0010921

annually. After adjusting for inflation, this represented an annual growth rate of 3.5%. The share of the nation's output produced in metro areas advanced from 84.3% at the beginning of the decade to 84.7% in 2000. DRI-WEFA projects that the contribution of metro areas to U.S. gross domestic product will increase steadily over the next 25 years, reaching 86.9% by 2025.

Metro area economies now compare even more favorably with international economies than they did a decade ago. The ranking of New York City's gross metro product among international economies rose from 21st in 1990 to 14th last year; its economy is now ranked ahead of Australia's. The economy of the Washington, D.C. metro area ranks 27th, up from 35th in 1990, and ahead of Austria and Hong Kong; the gross product of the Dallas metro area surpassed Denmark, Saudi Arabia, and Thailand on its rise from 47th to 35th. Denver's ranking increased from 77th to 60th, as it's GDP grew to exceed those of Malaysia and the Philippines.

Many other key indicators of the contribution of metro areas to the national economy have also increased steadily. Metro area employment in the financial services and transportation, communications, and utilities sectors, which are two of the nation's highest value-added industries, grew 1.3% and 2.0% annually, respectively, from 1990 to 2000. Metro area business services payrolls rose 6.8% annually. Following the national pattern, high-tech employment in metro areas declined from 1990 to 1993 in response to defense spending reductions. In the second half of the 1990s, high-tech employment surged 5.4% annually, lifting its ten-year growth rate to 2.6%. Metro area per capita income increased by 4.4% over the last decade, a gain of over $3,100. After accounting for inflation, this represented a real gain of 2.1% annually.

2 The Contribution of Metropolitan Areas to the National Economy

2.1 The Scope of Metro Area Economies

The size of metro area economies illustrates their importance to the nation. If they were counted as a single country, the gross product of the five largest U.S. metropolitan areas ($1.59 trillion) would rank fourth among the world's economies, trailing only the U.S. ($9.96 trillion), Japan ($4.6 trillion) and Germany ($1.87 trillion). The importance of metro area economies can also be illustrated by their size relative to the output of U.S. states. The gross product of the 10 largest U.S. metro areas exceeds the combined output of the 31 smallest states. Last year, the five largest metro areas produced more goods and services than California; $1.59 trillion compared with $1.3 trillion.

Within a particular state, a single metropolitan area often dominates the state's economy. For example, the Atlanta metro area provides 55% of Georgia's employment and 56% of gross state product. In Minnesota, the Minneapolis-St. Paul metro area produces 66% of the state's output and employs 65% of the work force. In highly urbanized states, almost all economic activity occurs in metro areas. In Pennsylvania, 97% of employment and 98% of output is generated within metro areas.

2.2 Employment and Output

As previously noted, most of the economic activity in the United States occurs within metro area cities and counties. A total of 110.8 million workers were employed in metro areas in 2000, or 84.0% of national employment. The total value of goods and services produced in metro areas last year was $8.476 trillion, 85% of U.S. gross domestic product. Metro areas, though geographically smaller, contribute much more to the national economy than non-metro areas. The metro area percentages of national employment and gross domestic product both exceed metro area shares of population and land area, highlighting the geographic concentration of economic activity within urban and suburban areas.

This geographic concentration of companies and people is one of the main reasons metro areas are able to make a disproportionately large contribution to the national economy. Close proximity between producers and consumers reduces the costs of business operations, allowing more goods and services to be produced per person and per acre of land.

Table 1 - Most Economic Activity Occurs in Metro Areas

Shares of U.S. Economy (2000)		Metro Areas	Rest of United States	United States
Size	Population (Millions)	226	55	281
	Percentage	80%	20%	
	Land Area (Square Miles, 000s)	719	2,873	3,592
	Percentage	20%	80%	
Jobs & Output	Employment (Millions)	111	21	131
	Percentage	84%	16%	
	Gross Domestic Product (Billions)	$8,476	$1,501	$9,977
	Percentage	85%	15%	
High Value Added Employment Sectors	Financial Services (Thousands)	6,882	720	7,602
	Percentage	91%	9%	
	Transportation & Utilities (Thousands)	6,096	928	7,024
	Percentage	87%	13%	

The clustering of two of the nation's highest value added sectors in urban locations also magnifies the metro area contribution to the national economy. In 2000, 91% of financial services employment and 87% of transportation, communications, and utilities sector employment was located within metropolitan areas. The financial services sector had the highest level of output per employee last year, $257,000. Financial services companies choose to locate in metro areas for proximity to major securities and commodity markets and access to highly skilled workers. Companies maximize the efficiency of their transportation and communications networks by locating hubs and distribution centers in metro areas, taking advantage of extensive road, rail, shipping, and communications infrastructure.

From 1990 to 2000, most of the economic gains made in the United States were generated within cities and counties in metro areas. Of the 22.2 million jobs created in the U.S. over that period, 18.7 million, or 84%, were created in metropolitan areas. The contribution of metro areas to gross domestic product, meanwhile, increased by nearly $3.7 trillion in the last decade, representing 86% of the national gain.

Table 2 - Most Economic Gains Were Made in Metro Areas

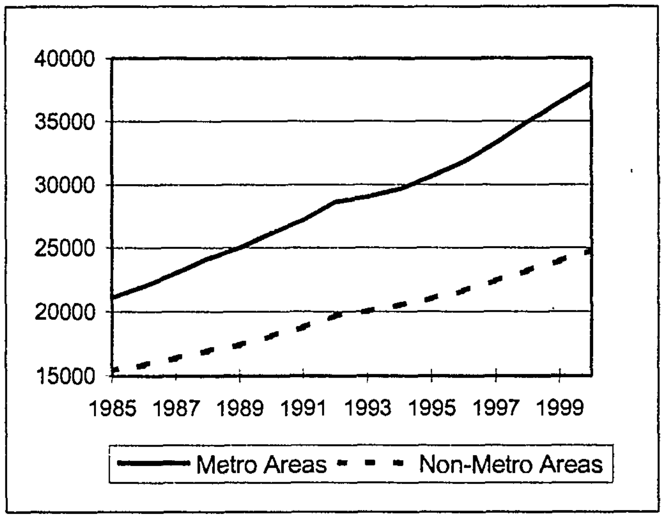
Additions to U.S. Economy (1990 to 2000)		Metro Areas	Rest of United States	United States
Size	Population (Millions)	28	5	33
	Percentage	84%	16%	
Jobs & Output	Employment (Millions)	18.7	3.5	22.2
	Percentage	84%	16%	
	Gross Domestic Product	$3,664	$606	$4,270
	Percentage	86%	14%	
High Value Added Employment Sectors	Financial Services (Thousands)	804	106	910
	Percentage	88%	12%	
	Transportation & Utilities (Thousands)	1,116	124	1,240
	Percentage	90%	10%	

2.3 Income Creation

Most of the nation's labor income is also generated by metro area economies. In 2000, metro area workers earned $4.22 trillion in wages and salaries, while non-metro area workers earned $554 billion. Metro area economies also create more income per person than non-metro areas. Last year, the average metro area worker collected $38,000 in wages and benefits, while the average non-metro area worker earned $24,800, a difference of $13,200 per worker. The gap between metro and non-metro area workers has grown consistently since 1985, when the difference between metro area and non-metro area earnings was only $4,600.

In most labor markets, earnings are directly related to labor productivity--workers that are more productive receive higher wages and benefits. Figure 2, therefore, provides an indirect measure of the higher labor productivity in cities and counties within metro areas. Metro area workers are able to produce more goods and services than non-metro area workers because of the clustering of specialized industries within urban areas, access to superior training and educational facilities, and a greater degree of knowledge-transfer and interaction between companies.

Figure 2 - Metro Area Workers Earn More Than Non-Metro Area Workers



2.4 Generating New Industries

With few exceptions[1], most major industries in the United States started in cities, including automobile manufacturing (Detroit), television broadcasting (New York), and personal computer manufacturing (San Jose). Metro areas provide new industries with crucial amenities--a diverse and ample supply of labor, financial and physical capital, access to national and international markets, a local base of technical knowledge--that are essential for their initial development and eventual success. As an industry matures, technological advances often allow companies within that industry to move to non-urban locations. As a consequence, newer, faster-growing industries tend to cluster within metro areas, while older, slower-growing industries are less tied to urban locations.

Table 3 shows that two of the fastest-growing segments of the U.S. economy, high-tech and business services, are almost entirely concentrated within metro areas. These two sectors of the economy contain some of the nation's newest and most innovative industries, including computer hardware, computer software, telecommunications equipment, optical instruments, Internet publishing, and management consulting. From

[1] The major exceptions are resource-extraction industries (e.g., forestry, coal mining, oil drilling) which are tied to the geographic location of a particular natural resource.

1990 to 2000, employment in high-tech industries grew 2.6% per year, while employment in the business services sector increased by a remarkable 6.8% per year.

Table 3 - Most High-Tech and Business Services Employment is Located in Metro Areas

Shares of U.S. Employment (2000)		Metro Areas	Rest of United States	United States
High Growth Employment Sectors	High-Tech (Thousands)	7,345	524	7,869
	Percentage	93%	7%	
	Business Services (Thousands)	9,140	642	9,783
	Percentage	93%	7%	

Over the past ten years, the majority of these new jobs in the high-tech and business services segments have been created in metro areas. Metro area business services employment increased by close to 4.4 million from 1990 to 2000, compared with an increase of only 312,000 outside of metro areas. Over the same period, almost 1.66 million jobs were created by high-tech companies in metro areas, while only 52,500 jobs were added outside of metro areas.

In the future, metro areas will play a larger and larger role in the national economy. The movement of people from rural to urban areas will continue unabated, providing a steady stream of labor, knowledge, and capital to the businesses located there.

Table 4 - Gross Product of Metro Areas

Nominal Gross Product (Billions, $Current)					
Metro Area	**1997**	**1998**	**1999**	**2000**	**Rank**
New York, NY	363.19	383.60	407.60	437.80	1
Los Angeles-L Beach, CA	303.09	321.03	339.45	363.70	2

City of Los Angeles
1998 Economic and Demographic Information

The City of Los Angeles is the second most populous City in the United States with an estimated 1998 population in excess of 3.7 million. Los Angeles is the principal city of a metropolitan region stretching from the city of San Buenaventura to the north, the City of San Clemente to the south, and the City of San Bernardino to the east.

Founded in 1781, Los Angeles was for its first century a provincial outpost under a succession of Spanish, Mexican, and American rule. It experienced a population boom following its linkage by rail with San Francisco in 1876. Los Angeles was selected as the Southern California rail terminus because its natural harbor, unlike San Diego's, seemed to offer little challenge to San Francisco, home of the railroad barons. But what the region lacked in commerce and industry, it made up in temperate climate and unspoiled real estate, and soon tens and then hundreds of thousands of people living in the northeastern and midwestern United States migrated to new homes in the region. Its population climbed to 50,000 in 1890, and then swelled to 1.5 million by 1940. Agricultural and oil production, followed by the creation of a deep water port, the opening of the Panama Canal, and the completion of the City-financed Owens Valley Aqueduct to provide additional water, all contributed to an expanding economic base. During this same period, the motor car became the principal mode of American transportation, and Los Angeles developed as the first major city of the automotive age. Following World War II, Los Angeles became the focus of a new wave of migration, with its population reaching 2.4 million by 1960.

Both the City and its surrounding metropolitan region have continued to experience growth in population and in economic diversity. Services, wholesale and retail trade, manufacturing, government, financial service industries, transportation, utilities, and construction contribute significantly to local employment. The City's 470 square miles contain 11.5% of the area and 38.8% of the population of the County of Los Angeles (the "County). The County is the top ranked county in manufacturing in the United States, producing more than 10% of the nation's production of such diverse items as aircraft, aircraft equipment, aluminum, dental equipment, games and toys, gas transmissions and distribution equipment, guided missiles, space vehicles and propulsion units, and women's apparel. Fueled by trade with the Pacific Rim countries, the Port of Los Angeles/Long Beach ranks first in the nation in volume. As home to the film, television and recording industries, as well as important cultural facilities, Los Angeles serves as a principal global cultural center. With Los Angeles International Airport serving as the new "Ellis Island" for foreign immigration to this country, the metropolitan region has achieved a new ethnic and cultural diversity.

ECONOMIC AND DEMOGRAPHIC INFORMATION

Introduction

The economic and demographic information provided below has been collected from sources which the City deems to be reliable. Because it is difficult to obtain timely regional economic and demographic information, the impact on the City of the recent recession and the City's recovery from the recession may not be fully apparent in all of the publicly available regional economic statistics provided herein.

Population

The City's population expanded by 4.8% during the 1970's and by more than 17.4% from 1980 to 1990. This latter expansion compares to an 18.5% growth rate for the County and a 25.1% growth rate for the State of California (the "State") during the same period. Table 1 summarizes City, County, and State population estimated at January 1 of each year.

Table 1
CITY, COUNTY AND STATE POPULATION STATISTICS

	City of Los Angeles	County of Los Angeles	State of California
1980	2,968,579	7,477,517	23,780,000

Industry and Employment

Table 4 summarizes the State Department of Employment Development's estimated average annual employment of nonagricultural wage and salary workers in the County between 1996 and March 1998. Percentages indicate the percentage of the total employment for each type of employment for the given year. For purposes of comparison, employment for the United States is also summarized for 1996 through 1998.

The services sector has been the major employment sector in the County through April 1998, employing 32.9% of the nonagricultural wage and salary workers in the County. (Separate figures for the City are not maintained). Wholesale and retail trade, at 21.9%, is the second highest employment sector in the County, followed closely by manufacturing, which employs 17.2% of the nonagricultural wage and salary workers in the County. From 1996 to April 1998, total employment for nonagricultural wage and salary workers increased by 3.9%

Major Employers

The economic base of Los Angeles is diverse, with no one sector being dominant. Some of the leading activities include business/professional management services (including engineering), health services (including training and cutting-edge research), tourism, distribution, and entertainment. The job loss in the technology sector has ended, while major new investments are being made in entertainment and tourism. The ten leading employers in the Los Angeles Five County Area, as reported in March 1996, are listed in Table 6. A five-year history is not available.

Table 6
TEN LEADING EMPLOYERS IN THE LOS ANGELES FIVE COUNTY AREA(1)
March 1996

Company/Organization	Product	Number of Employees(2)
Los Angeles County	Government	84,616
U.S. Government	Government	64,404
City of Los Angeles	Government	55,964
Los Angeles Unified School District	Public Schools	55,727
Bank of America	Financial Services	26,563
Hughes Electronics Corporation	Aerospace	26,000
Kaiser Permanente	Health Services	24,163
American Stores	Retail	23,525
UCLA	Higher Education	23,492
Sears, Roebuck & Company	Retail	21,370

(1) Los Angeles, Orange, Riverside, San Bernardino and Ventura Counties.
(2) Approximately two-thirds of the total number of employees for each company work in Los Angeles County except for the County of Los Angeles, the Los Angeles Unified School District and the City of Los Angeles. For these employers, virtually one hundred percent of the employees work in Los Angeles County.

Effective Buying Income

"Effective Buying Income" ("EBI"), also referred to as "disposable" or "after tax" income, consists of personal income less personal tax and certain non-tax payments. Personal income includes wages and salaries, other labor-related income (such as employer contributions to private pension funds), and certain other income (e.g. proprietor's income; rental income; dividends and interest; pensions; and welfare assistance). Deducted from this total are personal taxes (federal, state and local) certain non-tax payments (e.g. fines, fees and penalties), and personal contributions to a retirement program.

Table 7 shows the top ten metropolitan areas in total EBI for 1996.

Retail Sales

As the largest city in the County, the City accounted for $24,906,839,000 (or 30.2%) of the total $82,620,919,000 in County taxable sales for 1996. Table 8 sets forth a history of taxable sales for the City from 1992 through 1996. Total City taxable sales in 1996 increased 3.9% as compared to the total City taxable sales in 1995.

Construction Activity

The total valuation of building permits issued in the City exceeded $1.8 billion in 1997, which represents a 5% increase from 1996. Residential valuation as a percentage of total valuation was 47.5% in 1997. Table 9 provides a summary of building permit valuations and number of new dwelling units in the City for the years 1992 through April 1998.

In May 1988 the City Council passed an interim ordinance that limited, with certain exceptions, the issuance of building permits within the City for certain projects that would discharge sewage into the Hyperion Treatment System. Applications for building permits are below the maximum limitations under the sewer limitation ordinance, due to economic conditions.

Commercial Real Estate Markets in Los Angeles

The largest commercial real estate concentrations in the City are located in the Central Business District ("CBD") and western Los Angeles areas. For the quarter ended December 31, 1997, the vacancy rate in the CBD was 22.9% down from 23.4% for the 3rd quarter, 1997. No new office space has been added to the CBD since 1992.

Table 10 shows vacancy rates and rents for office space in the central business district of the City.

Table 10

Education

The Los Angeles Unified School District ("LAUSD"), administers public instruction for grades K-12, adult, and occupational schools in the City and all or significant portions of a number of the smaller cities and unincorporated territory. The LAUSD, which encompasses approximately 708 square miles, was formed in 1854 as the Common Schools for the City of Los Angeles, and became a unified school district in 1960.

During fiscal year 1998, the LAUSD will operate 419 elementary schools, 71 middle/junior high schools, 49 high schools, five multi-level schools, 44 continuing education, 132 magnet schools and centers, 18 special education schools, 8 opportunity schools and centers, 106 children's and infant's centers, 1 adult program facility, four primary school centers and two orientation or newcomers centers. The LAUSD is governed by a seven-member Board of Education, elected by district to serve alternating four-year terms. As of September 1996, the LAUSD employed 36,521 certificated employees and 27,728 classified employees. Although the LAUSD employs part-time and temporary employees, it does not track these numbers.

Table 11 provides a summary of the Enrollment and Average Daily Attendance of Students ("ADA") of the LAUSD for the fiscal years 1988-89 through 1996-97.

Table 11
LOS ANGELES UNIFIED SCHOOL DISTRICT
TOTAL AVERAGE DAILY ATTENDANCE

(2) Includes the equivalent ADA of summer school hours of attendance.

Source: Los Angeles Unified School District.

There are many public and private colleges and universities located in the City. Major universities located within the City include the University of California at Los Angeles, the University of Southern California, California State University at Los Angeles, California State University at Northridge, Occidental College and Loyola Marymount University. There are seven community colleges located within the City.

MUNICIPAL GOVERNMENT

Under the State Constitution, charter cities are generally independent of the state legislature in matters relating to municipal affairs, and in their ability to raise revenues. The City is a charter city originally incorporated in 1850. The present City charter was adopted in 1925 and has since been amended from time to time.

Los Angeles is governed by the Mayor and the Council. The Mayor is elected at large for a 4-year term. As executive officer of the City, the Mayor has the overall responsibility of administration.. The Mayor recommends and submits the annual budget to the Council and passes upon subsequent appropriations and transfers, approves or vetoes ordinances, and appoints certain City officials and commissioners. He supervises the administrative process of the local government and works with the Council in matters relating to legislation, budget, and finance. As prescribed by the Charter and City ordinances, the Mayor operates an executive department, of which he is the ex-officio head. Richard Riordan has been Mayor since July 1, 1993.

The Council, the governing body of the City, is a full time council and enacts ordinances subject to the approval or veto of the Mayor. The Council may override the veto of the Mayor by a two-thirds vote. It orders elections, levies taxes, authorizes public improvements, approves contracts, adopts zoning and other land use controls, and adopts traffic regulations. The Council adopts or modifies the budget proposed by the Mayor. It creates positions, fixes salaries, and authorizes the number of employees in budgetary departments. The Council consists of 15 members elected by district for 4-year terms.

The other two elective offices of the City are the Controller and the City Attorney, both elected for 4-year terms. The Controller is the chief accounting officer for the City. The current Controller, Rick Tuttle, was elected to his fourth term at the April 1997 election. The City Attorney is attorney and legal advisor to the Council and all officers, boards, and departments of the City, and prosecutes misdemeanors. The current City Attorney, James K. Hahn, was elected to his fourth term at the April 1997 election.

The City Administrative Officer ("CAO"), appointed by the Mayor and confirmed by the Council, is the chief financial advisor to the Mayor and Council and reports directly to both. The current CAO, Keith Comrie, was appointed by Mayor Tom Bradley and confirmed by the Council in 1979.

The Treasurer, appointed by the Mayor and confirmed by the Council, receives and is the custodian of most funds of the City and affiliated entities. The current Treasurer, J. Paul Brownridge, was appointed by Mayor Tom Bradley and confirmed by the Council in March 1991.

The City has 36 departments, bureaus, commissions and offices for which operating funds are annually budgeted by the Council. In addition, six departments (the Department of Water and Power, Harbor, Airports, and three pension systems), the Community Redevelopment Agency of the City of Los Angeles and the Housing Authority of the City of Los Angeles are under the control of Boards appointed by the Mayor and confirmed by the Council.

Public services that are provided by the City include police; fire and paramedics; residential refuse collection and disposal, wastewater collection and treatment, street maintenance, and other public works functions; enforcement of ordinances and statutes relating to building safety; public libraries; recreation and parks; community development, housing and aging services; and planning.

BUDGET AND REVENUES

Budgetary Process

The City's fiscal year extends from July 1 through June 30. Under the City Charter, the Mayor is required each year to submit to the Council a Proposed Budget by April 20. The Proposed Budget is based on the Mayor's budget priorities, the responses of the City Administrative Officer and City Departments to the Mayor's policy letter which is distributed early in the fiscal year, and estimates of receipts from the City's various revenue sources

The Mayor's Proposed Budget is reviewed by the Council's Budget and Finance Committee, which reports its recommendations to the full Council. The Council is required by law to adopt the Mayor's Proposed Budget, as modified by the Council, by June 1. The Mayor has five working days after adoption to approve or veto any items modified by the Council. The Council then has five working days to override by a two-thirds vote any items vetoed by the Mayor.

The final Adopted Budget is subject to revision to reflect any changes in revenue projections and to make necessary adjustments to appropriations.

Fiscal Year 1997-98 Budget

The 1997-98 budget incorporates projected growth (2% to 4%) in several important revenue categories, including sales tax, utility users tax, transient occupancy tax, vehicle license fees and property tax. A higher growth rate is projected for municipal court fines due to an anticipated $13 million in revenue expected as a result of additional officers added for parking enforcement and increased fines. Franchise income is also expected to increase ($10 million) as a result of an increase in the wastewater franchise fee from 2% to 5%. The documentary transfer tax is expected to grow by $7 million as a result of recent increases in the number of deeds recorded and the revenue per deed (an indication that real estate prices are rising). As compared to the prior fiscal year, it is anticipated that total General Fund revenues will experience modest growth (1.5% or $36 million).

The budget maintains level expenditures as compared to the prior fiscal year. The total budget being $4.1 billion in 1996-97 and $4.0 billion in 1997-98. The budget continues new programs to reduce operating expenditures, and promotes the continued restructuring of fleet operations and purchasing reform to generate savings from current expense levels. More than 470 positions are eliminated, offset by new positions for public safety and public services. Through the addition of 165 new police officers, civilianization of 218 positions, new technology and additional overtime funds, the 1997-98 budget adds the equivalent of 846 officers.

The 1997-98 Estimated Results

Revenues through April 1998 are exactly on target. Projected general receipts in the budget were $2.59 billion. The City currently estimates that actual General Fund receipts will come in at $2.6 billion. While there are revenue reductions in some categories (Street Deterioration Fee, Airport Reimbursements) these are offset by higher revenues in property tax, utility users tax, hotel tax and property transfer tax.

The 1997-98 Budget provided for a new Street Deterioration Fee. This new fee was intended to recover the long-term damages associated with cuts in public streets made by private and public utilities. The reduction in expected revenue is due to delays in implementing the new fee.

The Budget anticipated $26 million in reimbursements from the Department of Airports for services funded by the General Fund. Since budget adoption, federal audit findings have disallowed some prior-year reimbursements. These disallowed prior-year receipts will offset a portion of the transfer from the department this year. The City believes a $7.2 million reduction in reimbursements is most likely.

As part of continuing to control expenditures, the City has extended its hiring freeze through the end of the fiscal year. In addition, the Mayor and Council have implemented various expenditure reductions and revenue options as part of the mid-year budget review in order to maintain a balanced budget. These actions have been implemented as of February 1998.

1998-99 Proposed Budget

The total 1998-99 Proposed Budget is $4.07 billion representing a very modest increase of about 1% over the previous year's budget of $4.02 billion. The Proposed Budget maintains City staffing at about the same level as the previous year and incorporates an end to the citywide hiring freeze.

Some of the major initiatives in 1998-99 include the funding of a new firefighter recruit training program for 126 new recruits; funding of a new fire station to improve response time in the San Fernando Valley; funding for technology and equipment to improve library services while maintaining expanded hours; funding for newly created Department on Disability to upgrade City facilities for disabled access; commitment to reducing solid waste to landfills by 60% by the year 2000, and funding of technological enhancements in payroll, personnel, accounting and budgeting in order to improve overall efficiency.

The 1998-99 Proposed Budget reaffirms the City's commitment to maintain fiscal stability by increasing undesignated cash reserves to $44 million (an increase from $38.3 in the prior year) and decreasing the annual transfer to the Budget (designated cash) to $8 million, the lowest in the last ten years. The Proposed Budget reduces reliance on one-time revenues by 27% from the previous year and continues to reduce expenditures across expense accounts.

The City expects to adopt a formal debt policy that will become effective in 1998-99. The proposed policy would limit non-voter approved debt payments to 7.5% of General Fund revenues in any given year, and would limit voter-approved and non-voter approved debt payments to an overall cap of 15% of General Fund revenues in any given year adjusted for incremental taxes from voter-approved debt. The formulation and adoption of a formal debt policy will be a key element in the City's ongoing efforts to maintain low debt levels.

Budgeted revenues in 1998-99 represent a 4% increase over fiscal year 1997-98, reflecting continued economic growth. Business Tax is expected to grow by 4% ($11.5 million) due to increased collection efforts, a new home-based business tax and general economic improvement. Sales Tax and Vehicle License Fees are also expected to grow by 4% due to improvements in the local economy. Transient Occupancy Tax revenue is expected to increase by 10% as a result of strong growth in the City's hotel tax and increased tourism from new attractions such as the new Getty Center and California Science Center. Documentary Transfer Tax is expected to increase by 15% due to continued improvement in the real estate market. Other revenues are expected to remain fairly level or to show modest increases.

MAJOR GENERAL FUND REVENUE SOURCES

Following is a discussion of the City's principal General Fund revenue sources.

Property Taxes

Under Article XIII A of the State Constitution (enacted in 1978 through the passage of Proposition 13) and its implementing legislation, ad valorem taxes on real property (other than taxes relating to certain voter-approved indebtedness) are limited to one percent of the "full cash value". Full cash value is generally defined as the valuation of real property as shown on the 1975-76 tax bill, or thereafter, as the appraised value of property when purchased or newly constructed after the 1975 assessment period. Real property valuation may be increased to reflect inflation, not to exceed two percent a year. (See "LIMITATIONS ON TAXES AND APPROPRIATIONS" herein.)

The assessed valuation of property is established by the County Assessor, and reported at 100% of the full cash value as of January 1, except for public utility property, which is assessed by the State Board of Equalization. Beginning in 1983, State law provided for the establishment of a "supplemental roll"; real property is reassessed at market value on the date property changes ownership or upon completion of new construction (known as the "floating lien date"). A supplemental tax is collected for the remainder of the tax year.

The County collects the ad valorem taxes. Taxes arising from the one percent levy are apportioned among local taxing agencies on the basis of a formula established by State law in 1979. Under this formula, the City receives a base year allocation plus an allocation on the basis of growth in assessed value (consisting of new construction, change of ownership and inflation). Taxes relating to voter-approved indebtedness are allocated to the relevant taxing agency. Beginning in fiscal year 1990-91 (with the adoption of new State legislation), the County deducts the pro-rata cost of collecting property taxes from the City's allocation.

The State Constitution and statutes provide exemption from reassessment for certain changes of ownership, and from ad valorem property taxation for certain classes of property such as local governments, churches, colleges, non-profit hospitals, and charitable institutions. State law also allows exemptions from ad valorem property taxation at $7,000 of full value of owner occupied dwellings and 100 percent of business inventories. Revenue losses to the City from the homeowners exemption are replaced by the State.

The California Community Redevelopment Law authorizes redevelopment agencies to receive the allocation of tax revenues resulting from increases in assessed valuations of properties within designated project areas. In effect, the other local taxing authorities realize tax revenues from such properties only on the base year valuations which are frozen at the time a redevelopment project area is created. The tax revenues which result from increases in assessed valuations flow to the redevelopment areas. The City has created redevelopment project areas pursuant to California law. Generally, funds must be spent within the redevelopment areas in which the tax increment revenues were generated, and may only be spent on projects which qualify under California redevelopment law.

All taxable real and personal property is classified as either "secured" or "unsecured" and is listed accordingly on separate parts of the assessment roll. The "secured roll" contains real property (land and improvements), certain taxable personal property (such as business equipment on business-owned property), and possessory interests (a leasehold on otherwise exempt government property). The "unsecured roll" contains taxable property that is not secured by the underlying real property, the majority of which is business equipment on leased or rented premises, and other taxable personal property such as boats and aircraft, as well as delinquent possessory interests. The balance of personal property has been exempted by State law from property taxes. Approximately 94% of the City's assessed valuation represents property contained on the secured roll.

Property taxes on the secured roll are due in two installments: on November 1 and February 1 of the fiscal year. If unpaid, such taxes become delinquent after December 10 and April 10, respectively, and a 10% penalty is added to delinquent taxes. In addition, property on the secured roll on which taxes are delinquent has a delinquency certificate recorded after June 30 of the fiscal year. Such property may thereafter be redeemed by payment of the delinquent taxes and the delinquency penalty, plus a redemption penalty of 1½% per month to the time of redemption. If taxes are unpaid for a period of five years or more, the property is deeded to the State and is subject to sale by the County Tax Collector.

Property taxes on the unsecured roll are due as of March 1 and become delinquent on August 31. A 10% penalty attaches to delinquent taxes on property on the unsecured roll, and an additional penalty of 1½% per month begins to accrue on November 1. The taxing authority has four ways of collecting delinquent unsecured personal property taxes: (1) a civil action against the taxpayer; (2) filing a certificate in the Office of the County Clerk specifying certain facts in order to obtain a judgment lien on certain property of the taxpayer; (3) filing a certificate of delinquency for recordation in the County Recorder's Office, in order to obtain a lien on certain property of the taxpayer; and (4) seizure and sale of personal property, improvements or possessory interest belonging or assessed to the delinquent taxpayer.

(1) Represents secured and unsecured assessed valuations.

(2) Consists of gross assessed valuations, less deduction for homeowners exemptions and redevelopment project area incremental assessed valuations, the taxes on which are payable to the Community Redevelopment Agency of the City of Los Angeles.

(3) City's allocated share of one percent basic levy, which is a General Fund revenue; excludes City levy for debt service.

(4) Percent of total City tax levy that was uncollected or unremitted by the County as of June 30 for the given tax year.

(5) Includes collections received for delinquent prior year taxes and penalties and current year receipts from supplemental taxes levied due to reassessment upon change of ownership.

(6) State replacement payments for lost revenues due to homeowners exemption and for 1987-88 business inventory exemption.

(7) Excludes administrative charges deducted from the levy pursuant to State legislation enacted in 1990-91.

(8) Collections as of April 20, 1998.

Source: City Controller's Office.

In preparing its budget, the City forecasts property taxes based on each of the specific categories of receipts (secured and unsecured, current and delinquent receipts, and State replacement funds). Current receipts are based on the County Assessor's estimate of growth in assessed valuation, adjusted for estimates in growth for redevelopment project areas. The estimate of current secured levy receipts is discounted by eight percent for delinquencies; current unsecured levy receipts are discounted by one percent. Estimates of other property tax receipts are primarily based on historical collections.

A list of the ten largest taxpayers, based on secured assessed valuations, within the City for the 1997-98 fiscal year are listed in Table 15. The total secured assessed valuation of these taxpayers represents approximately 3.2% of the total City assessed valuation for fiscal year 1997-98.

Other Taxes

The revenue category of "Other Taxes" consists of receipts from: Utility Users Tax, Sales Tax, Business Tax, State Motor Vehicle License Fees, Transient Occupancy Tax, State Cigarette Tax, Real Property Transfer Tax, and other miscellaneous taxes. A discussion of the major revenue sources within this category follows.

Utility Users Tax

The Utility Users Tax is imposed on all users of natural gas, electricity and telephone services within the City's limits. The tax rate is established by the City Council. The tax is a percentage of utility charges based on the following rates: Residential – 10% of utility bill for users of electricity, gas, and telephone services and commercial – 10% of utility bill for users of gas and telephone services and 12½% of utility bill for users of electricity. These tax rates have been in effect since July 1983. Effective October 1, 1987, the telephone users tax was expanded to include interstate and international long distance calls. Prior to that date, the tax included local and intra state calls only. In connection with the 1993-94 Budget, the Council extended the telephone users tax to cellular phone usage.

An exemption from the Utility Users Tax is available to senior citizens over the age of 62 and to disabled individuals, provided that the combined adjusted gross income of all household members is below $15,300. As provided by the State Constitution, insurance companies are exempt from the tax. In addition, county, state, federal and foreign governments within the City are not subject to this tax as the City has no authority to impose a tax on these entities. Exemptions account for approximately 10% of the total tax base.

Utility taxes are forecast based on analysis of each of the three taxed commodities. Electricity tax revenues are derived from the Department of Water and Power's long-term power sales forecast, modified by an analysis of recent trends and a forecast of business activities. Natural gas sales are based on Southern California Gas Company historical trends, modified by approved and anticipated rate increases. Both electricity and natural gas sales are sensitive to weather (warm winters and cool summers reduce demand); forecasts are based on average weather. Telephone services forecasts are based on historical trends of major telephone companies, adjusted by growth in volume and major pending rate adjustments.

Utility companies, with the exception of the Department of Water and Power, collect and transmit the tax monthly to the City Clerk who deposits the revenue into the General Fund. Tax revenue collected by the Department of Water and Power is transferred directly to the General Fund on a monthly basis.

Table 16 shows the actual or budgeted receipts from the Utility Users Tax since fiscal year 1991-92:

Table 16
UTILITY USERS TAX RECEIPTS
CITY OF LOS ANGELES

Fiscal Year	Receipts
1991-92	$406,071,791
1992-93	415,069,047
1993-94	433,533,319
1994-95	426,479,057
1995-96	428,167,000
1996-97	466,206,000
1997-98 (Estimated)	478,122,000
1998-99 (Proposed Budget)	477,625,000

Sales Tax

A sales tax is imposed on retail sales or consumption of personal property. The tax rate is established by the State Legislature. Effective July 15, 1991, the statewide tax rate became 7.25 percent (up from 6 percent). An additional 1 percent is collected in Los Angeles County for transportation purposes. The State collects and administers the tax, and makes distributions on taxes collected within the City as follows:

State General Fund	5.50%
Public Safety Augmentation	.50%
County	.25%
City	1.00%
Metropolitan Transportation Authority	1.00%
Total	8.25%

The State's administrative costs of 0.82% are deducted before distribution to the City. Sales Tax revenue collected by the State is directly deposited monthly to the City's General Fund.

The City's budgeting forecast of Sales Tax receipts is based on State officials' estimates and the forecast of local economists. The City's budgeting forecast also includes a half-cent sales tax extension approved by the voters on the November 1993 ballot. This half-cent sales tax is deducted from the State's six percent and allocated to cities and counties to fund public safety.

Table 17 shows the actual or budgeted receipts from the Sales Tax since fiscal year 1991-92:

Table 17
SALES TAX RECEIPTS
CITY OF LOS ANGELES

Fiscal Year	Receipts
1991-92	$270,382,765
1992-93	267,238,080
1993-94	257,685,776
1994-95	268,870,794
1995-96	277,468,000
1996-97	283,604,000
1997-98 (Estimated)	297,250,000
1998-99 (Proposed Budget)	309,140,000

Business Tax

The Business Tax is imposed on persons engaged in a business in the City. The tax rate formula, which is established by the City Council, varies based upon the type of business. Most businesses are taxed on gross receipts at rates varying from $1.18 per $1,000 of gross receipts for wholesalers to $5.91 per $1,000 of gross receipts for selected businesses and occupations.

The City's budgeting forecast of Business Tax receipts is based on State officials' estimates and the forecast of local economists. The City's estimate is adjusted for anticipated rate adjustments and major refunds and temporary tax amnesties.

The California Supreme Court rendered a decision unfavorable to the City on July 29, 1991 in the *California Federal Savings and Loan Association v. City of Los Angeles,* a coordinated action involving more than 90 separate claims for refund of business taxes paid by financial corporations. This decision resulted in the need to refund approximately $225 million in past Business Taxes and an annual loss of approximately $22 million in Business Tax receipts beginning in Fiscal Year 1991-92. The City financed payment of the Business Tax refund through the issuance of $198.3 million Judgment Obligation Bonds, Series 1992-A on August 4, 1992 and $15.4 million Judgment Obligation Bonds, Series 1993-A on March 3, 1993.

The California Supreme Court has denied the City's petition for review in *General Motors v. City of Los Angeles*, an action filed in the Los Angeles Superior Court for the refund of business taxes. The California Court of Appeals, in a reversal of a Superior Court ruling, has ruled that the City's Business License Tax, under which an out-of-City manufacturer wholesaling in the City pays a wholesaling tax which an in-City manufacturer wholesaling in the City does not, is discriminatory against interstate and intercity commerce and unconstitutional. The City does not plan to appeal the California Supreme Court decision. In February 1996 the City Council eliminated the manufacturer's tax altogether so that only selling activities within the City are taxed, regardless of where the manufacturing occurred. Preliminary estimates of the reduction in City business tax revenues from the elimination of the manufacturer's tax total $10 million. The General Motors case was settled for $7,200,000. The potential liability in other related cases, including some that were recently settled, could be as much as $25,000,000.

Table 18 shows the actual or budgeted receipts from the Business Tax since fiscal year 1991-92:

Table 18
BUSINESS TAX RECEIPTS
CITY OF LOS ANGELES

Fiscal Year	Receipts
1991-92	$257,962,442
1992-93	273,305,113
1993-94	267,721,131
1994-95	268,474,803
1995-96	283,200,000
1996-97	283,384,000
1997-98 (Estimated)	287,400,000
1998-99 (Proposed Budget)	298,900,000

State Motor Vehicle License Fee

A license fee equivalent to two percent of the market value of motor vehicles is imposed annually by the State in lieu of local property taxes. The rate is established by the State Legislature. The State allocates proceeds to the Department of Motor Vehicles and the California Highway Patrol to cover operating expenses, and to the State General Fund for administrative expenses. The remaining revenues are apportioned equally between counties and cities on the basis of relative population within the State. While the City's population has been increasing over time, it has not increased at the same rate as other cities and counties. As a consequence, the City's percentage share of receipts has declined from 14.4% in 1991-92 to 13.7% in 1996-97. Revenues received are also affected by the stock of cars maintained and the number of new car sales. The actual receipts received from the State have continued to increase due to a concurrent increase in car stock during this period.

The fiscal year 1998-99 budget for these revenues is derived from a forecast of statewide license receipts, which are prorated according to the ratio of the City's population to the State's population. The statewide receipts forecast is based on historical data, State Officials' estimates and the forecast of local economists.

Table 19 shows the actual or budgeted receipts from State Motor Vehicle License Fees since fiscal year 1991-92:

Table 19
STATE MOTOR VEHICLE LICENSE FEE RECEIPTS
CITY OF LOS ANGELES

Fiscal Year	Receipts
1991-92	$121,279,721
1992-93	125,743,595
1993-94 (1)	139,922,330
1994-95	126,460,023
1995-96	134,035,000
1996-97	141,800,000
1997-98 (Estimated)	148,800,000
1998-99 (Proposed Budget)	153,201,000

(1) Includes a one-time transfer of $20 million from the State to offset property taxes taken by the State to balance its budget.

Licenses, Permits and Fees

Receipts received from Licenses, Permits and Fees are based primarily on charges imposed to meet regulatory measures by City departments. A significant portion is generated from fees in connection with construction-related activities. Consequently, economic conditions and interest rates for construction loans have a direct effect on this revenue source.

The fiscal year 1998-99 budgeted amount for these revenues is based on the UCLA Business Forecasting Project's forecast of building permits in California, historical averages adjusted for more recent trends in construction activity and known and anticipated changes in permit rates. Construction-related receipts are derived primarily from fees charged by the Department of Building and Safety. The fee is set according to a formula established by the City Council. Table 20 shows the actual or budgeted receipts from the Department of Building and Safety since fiscal year 1991-92:

Table 20
DEPARTMENT OF BUILDING AND SAFETY RECEIPTS
CITY OF LOS ANGELES

Fiscal Year	Receipts
1991-92	$45,694,714
1992-93	42,400,703
1993-94	41,019,805
1994-95	43,496,661
1995-96	39,525,000
1996-97 (1)	53,518,000
1997-98 (Estimated)	57,138,942
1998-99 (Proposed Budget)	60,100,187

(1) Significant increase from1995-96 receipts is due to building permit fee increase.

Examples of other major sources from which receipts are accounted for as Licenses, Permits and Fees are as follows: parking revenues; animal licenses; paramedic ambulance services; reimbursements from the Sewer Construction and Maintenance Fund for staff costs for maintenance and operation of wastewater facilities; and reimbursement from the Departments of Airports, Harbor and Water and Power for services provided by other departments (e.g. Information Technology Agency for computer-related activities, Department of General Services for building maintenance, and Department of Public Works for engineering and construction-related services).

Fines, Forfeits and Penalties

The significant source of these receipts is parking fines. The schedule of fines is established by the City Council. Other receipts include fees charged for laboratory work in connection with sobriety tests conducted by the Los Angeles Police Department, and fines paid for citations issued for violations of the Los Angeles Municipal Code (e.g. lease law violations).

Parking ticket revenue forecasts are based on the number of parking enforcement officers employed by the City's Department of Transportation, an estimate of average revenues per ticket based on historical trends, and an estimate of average worker productivity.

Table 21 shows the actual or budgeted receipts from parking fines since fiscal year 1991-92:

Table 21 RECEIPTS FROM PARKING FINES CITY OF LOS ANGELES	
Fiscal Year	Receipts
1991-92	$66,852,454
1992-93	60,555,475
1993-94	61,346,226
1994-95	62,037,642
1995-96	59,936,000
1996-97 [1]	77,661,000
1997-98 (Estimated)	84,000,000
1998-99 (Proposed Budget)	86,497,000

[1] Increase over 1995-96 receipts is due to additional officers added for enforcement in 1996-97.

Transfers to General Fund

The largest revenue source in this category is the annual transfer to the General Fund of approximately five percent of the total operating revenue of the Power Revenue Fund in the preceding fiscal year. The transfer is made pursuant to Charter Section 382 which provides that, with the consent of the Board of Water and Power Commissioners, the Council may direct by ordinance the transfer of surplus revenue to the General Fund. The transfer is restricted by the City Charter and the Department's revenue bond covenants which specify that a transfer may not be greater than the previous fiscal year's net income, nor may it result in a reduction of the surplus to less than 33 1/3% of the Department's total outstanding debt. Transfers are made periodically following Council's adoption of the ordinance. Budget estimates for the succeeding year are based on actual revenues for the first three quarters for the final quarter of the current fiscal year.

Table 22 shows the actual or budgeted transfers from the Power Revenue Fund since fiscal year 1991-92:

Table 22 TRANSFERS FROM POWER REVENUE FUND CITY OF LOS ANGELES	
Fiscal Year	Receipts
1991-92	$90,597,000
1992-93	74,160,000
1993-94	101,880,000
1994-95	131,648,000
1995-96	62,717,000
1996-97 [1]	97,343,000
1997-98 (Estimated)	85,000,000
1998-99 (Proposed Budget)	106,910,000

[1] Includes transfer from the sale of surplus oil ($4 million) and from the sale of other assets ($4.9 million). The normal transfer would have otherwise been $92 million.

Another transfer of funds to the General Fund is from the Harbor Department. Public Resources Code Section 6010 (enacted October 1992) permits the transfer of "discretionary reserves", as defined in the statute, from a port to the City of which it is part, to be spent for municipal purposes. To date, $69,315,000 has been transferred to the City. Litigation has arisen over the transfers from the Power Revenue Fund and from the Harbor Department. For more discussion, see "LITIGATION" herein.

Impact of Assembly Bill 62 on Revenues

At the present time it is uncertain as to whether the Valley Secession Bill ("AB62") will impact future revenues and expenses of the City. Should an area of the City be successful in a detachment proceeding, all revenues from existing taxes could be reduced as well as operations and expenses of the City's refuse collection and disposal system. It is possible that the residents of the San Fernando Valley may file a petition for detachment from the City. However, the timing, outcome and impact of such an effort cannot be determined at this time.

LIMITATIONS ON TAXES AND APPROPRIATIONS

Article XIII A of the California Constitution – Proposition 13

Article XIII A of the California Constitution limits the amount of ad valorem taxes on real property to one percent of "full cash value" as determined by the County Assessor. Article XIII A defines "full cash value" to mean the County assessor's valuation of real property as shown on the 1975-76 tax bill under full cash value, or thereafter, the appraised value of real property when purchased, newly constructed, or when a change in ownership has occurred after the 1975 assessment period. The full cash value may be adjusted annually to reflect inflation at a rate, as shown by the consumer price index, not to exceed two percent per year, or may be reduced. Article XIII A also permits the reduction of the "full cash value" base in the event of declining property values caused by damage, destruction or other factors. Article XIII A exempts from the one percent tax limitation any taxes to repay (a) indebtedness approved by the voters prior to July 1, 1978, or (b) any bonded indebtedness for the acquisition or improvement of real property approved on or after July 1, 1978 by two-thirds of the votes cast by the voters voting on the proposition.

On June 3, 1986 California voters approved Proposition 46, which added an additional exemption to the one percent tax limitation imposed by Article XIII A. Under this amendment to Article XIII A, local governments and school districts may increase the property tax rate above one percent for the period necessary to retire new general obligation bonds, if two-thirds of those voting in a local election approve the issuance of such bonds and the money raised through the sale of the bonds is used exclusively to acquire or improve real property.

On June 18, 1992, the United States Supreme Court upheld the constitutionality of certain challenged provisions of Article XIII A in connection with its review of the *Nordinger v. Hahn* case.

Article XIII B of the California Constitution – Gann Limit

On November 6, 1979, California voters approved Proposition 4, the so-called Gann Initiative, which added Article XIII B to the California Constitution. In June 1990, Article XIII B was amended by the voters through their approval of Proposition 111. Article XIII B of the California Constitution limits the annual appropriations of the State and any city, county, school district, authority or other political subdivision of the State to the level of appropriations for the prior fiscal year, as adjusted annually for changes in the cost of living, population and services rendered by the governmental entity. The "base year" for establishing such appropriation limit used to be the 1978-79 fiscal year, but is now the 1986-87 fiscal year as a result of Proposition 111. Increase in appropriations by a governmental entity are also permitted (i) if financial responsibility for providing services is transferred to the governmental entity, or (ii) for emergencies so long as the appropriations limits for three years following the emergency are reduced to prevent any aggregate increase above the Constitutional limit. Decreases are required where responsibility for providing services is transferred from the government entity.

Appropriations subject to Article XIII B include generally any authorization to expend during the fiscal year the "proceeds of taxes" levied by the State or other entity of local government, exclusive of certain State subventions, refunds of taxes, benefit payments from retirement, unemployment insurance and disability insurance funds.

"Proceeds of taxes" include, but are not limited to, all tax revenues and the proceeds to any entity of government from: (1) regulatory licenses, user charges, and user fees to the extent such proceeds exceed the cost of providing the service or regulation; (2) the investment of tax revenues; and (3) certain State subventions received by local governments. Article XIII B includes a requirement that if any entity's revenues in any year exceed the amounts permitted to be spent, the excess would have to be returned by revising tax rates or fee schedules over the subsequent two fiscal years.

Appropriations subject to limitation pursuant to Article XIII B do not include debt service on indebtedness existing or legally authorized as of January 1, 1979, on bonded indebtedness thereafter approved according to law by a vote of the electors of the issuing entity voting in an election for such purpose or appropriations required to comply with mandates of courts or the federal government.

As amended in June 1990, the appropriations limit for the City in each year is based on the limit for the prior year, adjusted annually for changes in the cost of living and changes in population, and adjusted, where applicable, for transfer of financial responsibility of providing services to or from another unit of government. The change in the cost of living is, at the City's option, either (1) the percentage change in California per capita personal income, or (2) the percentage change in the local assessment roll for the jurisdiction due to the addition of nonresidential new construction. The change in population is, at the City's option, either the percentage change in the City or County population.

Article XIII B permits any government entity to change the appropriations limit by vote of the electorate in conformity with statutory and Constitutional voting requirements, but any such voter-approved change can only be effective for a maximum of four years.

Table 23 is a comparison of the City's appropriations limit and appropriations subject to limitation for the past seven fiscal years and for fiscal year 1998-99.

Table 23
APPROPRIATIONS LIMITS AND APPROPRIATIONS SUBJECT TO LIMITATIONS
CITY OF LOS ANGELES

Fiscal Year	Appropriations Limit	Appropriations Subject to Limitations	Amount Appropriations are Under the Limit
1991-92	$2,144,379,936	$1,873,438,009	$270,941,927
1992-93	2,156,388,427	1,832,939,344	323,449,083
1993-94	2,199,978,184	1,817,229,950	382,748,234
1994-95	2,231,104,002	1,863,442,118	367,661,884
1995-96	2,341,766,758	1,806,731,403	535,035,355

Statutory Spending Limitations – Proposition 62

In November 1986, California voters approved a statutory initiative ("Proposition 62") that established certain voter requirements in order for local governments, such as cities, counties and districts to impose or raise taxes. Various provisions of Proposition 62 were declared unconstitutional at the appellate court level. In *Fielder v. City of Los Angeles,* the California Court of Appeal held in 1993 that charter cities, such as the City, have sovereign power over municipal affairs and that Proposition 62 does not necessarily restrict the power of a charter city to impose all taxes. On September 28, 1995, the California Supreme Court, in *Santa Clara County Local Transportation Authority v. Guardino*, upheld the constitutionality of the portion of Proposition 62 requiring a two-thirds vote in order for a local government or district to impose a special tax, and upheld by implication a parallel provision requiring a majority vote in order for a local government or district to impose a special tax, and upheld by implication a parallel provision requiring a majority vote in order for a local government or district to impose any general tax.

The Impact of the Right to Vote on Taxes Act – Proposition 218

On November 5, 1996, California voters approved an initiative known as the Right to Vote on Taxes Act ("Proposition 218") that adds Articles XIII C and XIII D to the California Constitution. Proposition 218 requires majority voter approval before the imposition, extension or increase of general taxes, and 2/3 voter approval before the imposition, extension or increase of special taxes by a local government, which is defined in Proposition 218 to include charter cities such as the City. Such voter approval requirements would apply to all general and special taxes that were newly-created or increased after January 1, 1995. Proposition 218 also extends the initiative power to reducing or repealing local taxes, assessments, and property related fees and charges, regardless of the date such taxes, assessments, fees and chargers were imposed. In addition, Proposition 218 limits the application of assessments, and fees and charges and requires them to be submitted to property owners for approval or rejection, after notice and public hearing.

Proposition 218 will restrict the City's ability to impose or increase certain taxes and assessments and land-based user fees and charges and would subject existing sources of City revenue to reduction or repeal.

Impact of Proposition 218 on Current Revenue

At the present time, the City is unable to predict whether or to what extent Proposition 218 may be held to be constitutional. If certain portions are substantially upheld, the City believes that Proposition 218 could result in the loss of approximately $31 million in General Fund revenue in the areas described below. Proposition 218 would not affect revenues from existing taxes at existing levels such as the Utility Users Tax, Documentary Transfer Tax, Parking User Tax, Sales Tax, Vehicle License Fees, Municipal Court Fines, Transient Occupancy Tax, and Licenses, Permits, Fees and Fines. The City's Sanitation Equipment Charge and fees may be subject to Proposition 218 if such change is deemed a property-related fee. Fees and charges of the Power System and the Power System Transfer are exempted from Proposition 218.

Business Tax Surcharge: Proposition 218 provides that any general tax imposed, extended, or increased, without voter approval, by any local government on or after January 1, 1995, shall continue to be imposed only if approved by a majority vote of the electorate by November 6, 1998. The City business tax surcharge was extended by ordinance in July 1995. This increase in the Business Tax of 3.7% was placed on the April 1997 ballot for a vote of the electorate. The measure failed to pass by a majority vote. As a result, the City will not collect an estimated $10 million from the Business Tax Surcharge in 1997-98. The City Attorney advises there is no impact to previously collected revenue during 1996-97.

Impact of Proposition 218 on Future Revenue

Proposition 218 will require a vote of the electorate to either increase an existing tax or levy any new tax. Assuming Proposition 218 withstands likely legal challenges, the impact on future revenues will depend on the willingness of the electorate to support new taxes and cannot be determined at this time.

A lawsuit has been filed against the City of Modesto, California claiming that the transfers from the sewer and water funds to the city's general fund are prohibited by Proposition 218. The Los Angeles City Attorney has stated that the basis for the water and sewer charges in the City of Modesto differs from the City's. The City of Los Angeles bases its water and sewer charges on usage for both commercial and residential customers. As such, they are not property related taxes or fees as defined in Proposition 218. Accordingly, an adverse decision on the Modesto case should not impact the transfer from the Department of Water and Power or the Franchise fee for the City's Wastewater System. The legality of the City's transfers from the Department of Water and Power franchise fee has not been challenged. However, the legality of the City's Wastewater System franchise fee has been challenged based on Proposition 218 (See "LITIGATION").

FINANCIAL OPERATIONS

Financial Statements

For the 1996-97 fiscal year, the City has issued its audited General Purpose Financial Statements prepared in accordance with generally accepted accounting principles (GAAP), which meet the Charter requirements for an annual audit.

Tables 24 and 25 summarize financial information contained in the City's General Purpose Financial Statements for the periods indicated. The tables include information solely on the General Fund of the City and the debt service funds which are funded from General Fund revenues.

Reserve Fund and Unappropriated Balance

The Reserve Fund was created by the City Charter and contains those actual General Fund cash receipts which are not otherwise appropriated to the City's Adopted Budget. The City expects that funds will be transferred from the Reserve Fund as part of the Adopted Budget or throughout the fiscal year for appropriation, or may be transferred as a loan to other funds to maintain those funds on a parity with their obligations. All unencumbered cash amounts in the General Fund revert to the Reserve Fund at the end of the fiscal year; some of those funds will be reappropriated at the beginning of the following fiscal year (primarily for General Fund capital projects). The Reserve Fund is reported as part of the General Fund in the City's General Purpose Financial Statements.

An analysis of the City's Reserve Fund as a percent of General Fund revenues is shown in Table 26.

Table 26
ANALYSIS OF RESERVE FUND BALANCES
CITY OF LOS ANGELES
(in millions)

	Available Reserve Fund Balance				
Fiscal Year as of June 30,	Designated[1]	Undesignated	Total	Budget Basis General Fund Revenues	Available Cash Balance as Percent of Revenues
1989-90	$90.7	$20.7	$111.4	$2,260.4	4.9%
1990-91	61.4	69.4	130.8	2,371.3	5.5
1991-92	33.9	6.0	39.8	2,420.2	1.6
1992-93	33.0	7.0	40.0	2,382.1	1.7
1993-94	16.1	64.4	80.5	2,355.5	3.4
1994-95	30.7	111.1	141.8	2,491.9	5.7
1995-96	71.1	11.1	82.2	2,462.5	3.3
1996-97	33.2	0[2]	33.2	2,542.3	1.3
1997-98 (Estimated)	21.9	38.3	60.2	2,604.9	2.3

(1) Consist primarily of year-end cash balance which is (a) reappropriated for prior year's unencumbered capital improvement appropriations or (b) transferred to the subsequent year's budget.

(2) Total reserve fund balance ($33.2 million designated and $0 undesignated) at year-end were lower than anticipated primarily due to decreased receipts in the Licenses, Permits Fees & Fines revenue category which were not recognized until late in the year, and interfund loans which will not be repaid until fiscal year 1997-98. In fiscal year 1997-98, the City has implemented closer oversight of these revenues and has taken corrective action earlier in the year to achieve a higher undesignated reserve balance than the budgeted $28.8 million.

Source: Office of the City Administrative Officer

As part of its budget process, the City targets a beginning year Reserve Fund cash balance. In addition to its Reserve Fund, the City annually allocates funds to the Unappropriated Balance to be available for appropriations later in the fiscal year to meet contingencies as they may arise. Any funds remaining at the end of the fiscal year revert to the Reserve Fund.

A summary of budgeted allocations to the Unappropriated Balance and Budgeted Reserves is listed in Tables 27 and 28.

Risk Retention Program

Because of its size and its financial capacity, the City has long followed the practice of directly assuming virtually all insurable risks without procuring commercial insurance policies. The extent and variety of City exposure is such that the cost of the premiums would outweigh the benefits of such coverage. The City administers, adjusts, settles, defends, and pays claims out of budgeted resources. Additionally, the City is self-insured for workers' compensation as permitted under State law. The City procures commercial insurance when required by bond or lease financing covenants and for other limited purposes.

California

The state profile is designed [illegible] with the county data for comparison purposes. Some of the statewide data, specifically Wage and Salary Employment (BLS series) [illegible] income, may not incorporate the latest revisions or be the latest available.

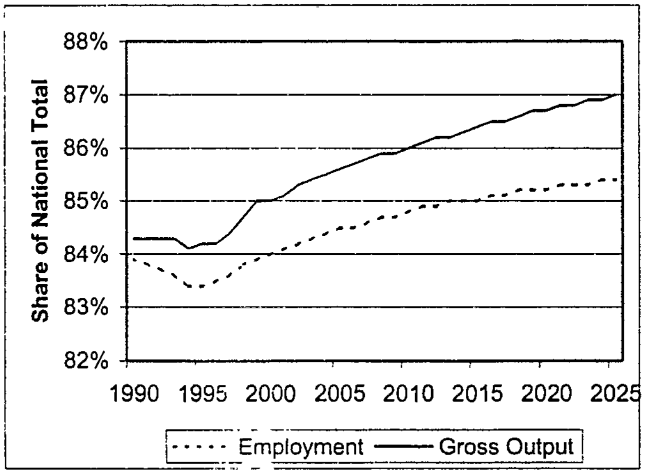
The Role of Metropolitan Areas in the National Economy

As the focal points of economic activity, metropolitan areas are vital to the nation's economic development. While states are defined by geographic and political boundaries, metro areas are shaped by economic activity, sometimes across state or national borders. The concentration of people and business in metro areas creates unique economic conditions that give rise to new industries, speed the diffusion of knowledge, spur technological innovation, and increase productivity. The economic dynamism and creativity found in metro areas enables American industries to thrive in global competition. Historically, most of the largest U.S. industries began in cities, where access to labor, capital, and customers fostered business development. Today, metro areas generate more than 80% of the nation's employment, income, and production of goods and services.

1 The Recent Performance of Metropolitan Area Economies

The contribution of metro areas to the national economy has increased over the last decade, a trend that is expected to continue over the next twenty-five years. Metro area employment increased from 92.1 million in 1990 to 110.8 million in 2000, growing at a 1.9% annual rate over the decade. In 2000, metro area employment posted a solid 2.6% gain. The share of employment in metro areas fell slightly in the first half of the 1990s before rebounding to a new high of 84.0% last year.

Figure 1 - The Contribution of Metro Areas to the National Economy Will Continue to Grow



Gross metropolitan product, the value of goods and services produced in metro areas, increased from $4.812 trillion in 1990 to $8.476 trillion in 2000, an average gain of 5.8%

annually. After adjusting for inflation, this represented an annual growth rate of 3.5%. The share of the nation's output produced in metro areas advanced from 84.3% at the beginning of the decade to 84.7% in 2000. DRI-WEFA projects that the contribution of metro areas to U.S. gross domestic product will increase steadily over the next 25 years, reaching 86.9% by 2025.

Metro area economies now compare even more favorably with international economies than they did a decade ago. The ranking of New York City's gross metro product among international economies rose from 21st in 1990 to 14th last year; its economy is now ranked ahead of Australia's. The economy of the Washington, D.C. metro area ranks 27th, up from 35th in 1990, and ahead of Austria and Hong Kong; the gross product of the Dallas metro area surpassed Denmark, Saudi Arabia, and Thailand on its rise from 47th to 35th. Denver's ranking increased from 77th to 60th, as it's GDP grew to exceed those of Malaysia and the Philippines.

Many other key indicators of the contribution of metro areas to the national economy have also increased steadily. Metro area employment in the financial services and transportation, communications, and utilities sectors, which are two of the nation's highest value-added industries, grew 1.3% and 2.0% annually, respectively, from 1990 to 2000. Metro area business services payrolls rose 6.8% annually. Following the national pattern, high-tech employment in metro areas declined from 1990 to 1993 in response to defense spending reductions. In the second half of the 1990s, high-tech employment surged 5.4% annually, lifting its ten-year growth rate to 2.6%. Metro area per capita income increased by 4.4% over the last decade, a gain of over $3,100. After accounting for inflation, this represented a real gain of 2.1% annually.

2 The Contribution of Metropolitan Areas to the National Economy

2.1 The Scope of Metro Area Economies

The size of metro area economies illustrates their importance to the nation. If they were counted as a single country, the gross product of the five largest U.S. metropolitan areas ($1.59 trillion) would rank fourth among the world's economies, trailing only the U.S. ($9.96 trillion), Japan ($4.6 trillion) and Germany ($1.87 trillion). The importance of metro area economies can also be illustrated by their size relative to the output of U.S. states. The gross product of the 10 largest U.S. metro areas exceeds the combined output of the 31 smallest states. Last year, the five largest metro areas produced more goods and services than California; $1.59 trillion compared with $1.3 trillion.

Within a particular state, a single metropolitan area often dominates the state's economy. For example, the Atlanta metro area provides 55% of Georgia's employment and 56% of gross state product. In Minnesota, the Minneapolis-St. Paul metro area produces 66% of the state's output and employs 65% of the work force. In highly urbanized states, almost all economic activity occurs in metro areas. In Pennsylvania, 97% of employment and 98% of output is generated within metro areas.

2.2 Employment and Output

As previously noted, most of the economic activity in the United States occurs within metro area cities and counties. A total of 110.8 million workers were employed in metro areas in 2000, or 84.0% of national employment. The total value of goods and services produced in metro areas last year was $8.476 trillion, 85% of U.S. gross domestic product. Metro areas, though geographically smaller, contribute much more to the national economy than non-metro areas. The metro area percentages of national employment and gross domestic product both exceed metro area shares of population and land area, highlighting the geographic concentration of economic activity within urban and suburban areas.

This geographic concentration of companies and people is one of the main reasons metro areas are able to make a disproportionately large contribution to the national economy. Close proximity between producers and consumers reduces the costs of business operations, allowing more goods and services to be produced per person and per acre of land.

Table 1 - Most Economic Activity Occurs in Metro Areas

Shares of U.S. Economy (2000)		Metro Areas	Rest of United States	United States
Size	Population (Millions)	226	55	281
	Percentage	80%	20%	
	Land Area (Square Miles, 000s)	719	2,873	3,592
	Percentage	20%	80%	
Jobs & Output	Employment (Millions)	111	21	131
	Percentage	84%	16%	
	Gross Domestic Product (Billions)	$8,476	$1,501	$9,977
	Percentage	85%	15%	
High Value Added Employment Sectors	Financial Services (Thousands)	6,882	720	7,602
	Percentage	91%	9%	
	Transportation & Utilities (Thousands)	6,096	928	7,024
	Percentage	87%	13%	

The clustering of two of the nation's highest value added sectors in urban locations also magnifies the metro area contribution to the national economy. In 2000, 91% of financial services employment and 87% of transportation, communications, and utilities sector employment was located within metropolitan areas. The financial services sector had the highest level of output per employee last year, $257,000. Financial services companies choose to locate in metro areas for proximity to major securities and commodity markets and access to highly skilled workers. Companies maximize the efficiency of their transportation and communications networks by locating hubs and distribution centers in metro areas, taking advantage of extensive road, rail, shipping, and communications infrastructure.

From 1990 to 2000, most of the economic gains made in the United States were generated within cities and counties in metro areas. Of the 22.2 million jobs created in the U.S. over that period, 18.7 million, or 84%, were created in metropolitan areas. The contribution of metro areas to gross domestic product, meanwhile, increased by nearly $3.7 trillion in the last decade, representing 86% of the national gain.

Table 2 - Most Economic Gains Were Made in Metro Areas

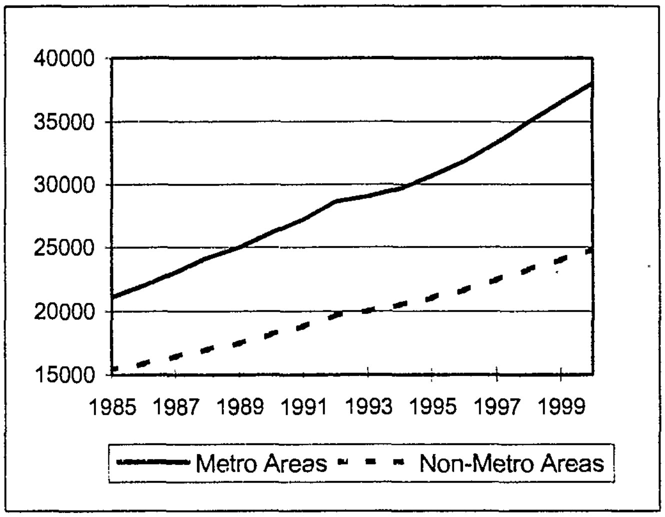
Additions to U.S. Economy (1990 to 2000)		Metro Areas	Rest of United States	United States
Size	Population (Millions)	28	5	33
	Percentage	84%	16%	
Jobs & Output	Employment (Millions)	18.7	3.5	22.2
	Percentage	84%	16%	
	Gross Domestic Product	$3,664	$606	$4,270
	Percentage	86%	14%	
High Value Added Employment Sectors	Financial Services (Thousands)	804	106	910
	Percentage	88%	12%	
	Transportation & Utilities (Thousands)	1,116	124	1,240
	Percentage	90%	10%	

2.3 Income Creation

Most of the nation's labor income is also generated by metro area economies. In 2000, metro area workers earned $4.22 trillion in wages and salaries, while non-metro area workers earned $554 billion. Metro area economies also create more income per person than non-metro areas. Last year, the average metro area worker collected $38,000 in wages and benefits, while the average non-metro area worker earned $24,800, a difference of $13,200 per worker. The gap between metro and non-metro area workers has grown consistently since 1985, when the difference between metro area and non-metro area earnings was only $4,600.

In most labor markets, earnings are directly related to labor productivity--workers that are more productive receive higher wages and benefits. Figure 2, therefore, provides an indirect measure of the higher labor productivity in cities and counties within metro areas. Metro area workers are able to produce more goods and services than non-metro area workers because of the clustering of specialized industries within urban areas, access to superior training and educational facilities, and a greater degree of knowledge-transfer and interaction between companies.

Figure 2 - Metro Area Workers Earn More Than Non-Metro Area Workers



2.4 Generating New Industries

With few exceptions[1], most major industries in the United States started in cities, including automobile manufacturing (Detroit), television broadcasting (New York), and personal computer manufacturing (San Jose). Metro areas provide new industries with crucial amenities--a diverse and ample supply of labor, financial and physical capital, access to national and international markets, a local base of technical knowledge--that are essential for their initial development and eventual success. As an industry matures, technological advances often allow companies within that industry to move to non-urban locations. As a consequence, newer, faster-growing industries tend to cluster within metro areas, while older, slower-growing industries are less tied to urban locations.

Table 3 shows that two of the fastest-growing segments of the U.S. economy, high-tech and business services, are almost entirely concentrated within metro areas. These two sectors of the economy contain some of the nation's newest and most innovative industries, including computer hardware, computer software, telecommunications equipment, optical instruments, Internet publishing, and management consulting. From

[1] The major exceptions are resource-extraction industries (e.g., forestry, coal mining, oil drilling) which are tied to the geographic location of a particular natural resource.

R0011021

1990 to 2000, employment in high-tech industries grew 2.6% per year, while employment in the business services sector increased by a remarkable 6.8% per year.

Table 3 - Most High-Tech and Business Services Employment is Located in Metro Areas

Shares of U.S. Employment (2000)		Metro Areas	Rest of United States	United States
High Growth Employment Sectors	High-Tech (Thousands)	7,345	524	7,869
	Percentage	93%	7%	
	Business Services (Thousands)	9,140	642	9,783
	Percentage	93%	7%	

Over the past ten years, the majority of these new jobs in the high-tech and business services segments have been created in metro areas. Metro area business services employment increased by close to 4.4 million from 1990 to 2000, compared with an increase of only 312,000 outside of metro areas. Over the same period, almost 1.66 million jobs were created by high-tech companies in metro areas, while only 52,500 jobs were added outside of metro areas.

In the future, metro areas will play a larger and larger role in the national economy. The movement of people from rural to urban areas will continue unabated, providing a steady stream of labor, knowledge, and capital to the businesses located there.

Table 4 - Gross Product of Metro Areas

R0011079

fourth largest economy in the world ($1.59 trillion), trailing only the U.S., Japan and Germany.

National

- The combined gross economic output of the top ten U.S. metro areas in 2000 was $2.43 trillion—an amount greater than the combined economic output of 31 states ($2.39 trillion).
- In 2000, U.S. metro areas contributed to the U.S. economy 84 percent of employment (111 million jobs); 85 percent of Gross Domestic Product ($8.476 trillion); and 88 percent of labor income ($4.22 trillion).
- Over the past decade, the majority of new jobs in the financial services and transportation and utilities sectors were created within cities: 88 percent, or 804,000 jobs in financial services, and 90 percent, or 1.116 million jobs in transportation and utilities.

The 1990s

- U.S. metro areas' contribution to Gross Domestic Product grew from 84.3 percent in 1990 to 84.7 percent in 2000 and is forecast to increase steadily over the next 25 years, reaching 86.9 percent in 2025.
- U.S. metro areas contributed an astounding 86 percent, or $3.66 trillion, of economic growth to the U.S. economy during the 1990s—an amount larger than the 2000 gross domestic product of Germany and the United Kingdom combined.
- Las Vegas (10.3%), Austin (9.8%), Boise (9.4%), Laredo (9.4%) and Phoenix (9.2%) had the fastest average annual growth rate for gross metropolitan product in the 1990s.

Mayors believe national and international economic policies must focus on the needs of the 319 economically potent metropolitan regions surveyed in the report. "We believe that the data we've seen sustain our call to the Congress and the Administration to support local and metropolitan economic growth by investing in transportation, distressed communities, and education and training," Morial said.

Nationwide Competitive Cities Tour

Mayor Morial also announced a nationwide "Competitive Cities Tour" to promote America's metro areas as competitive powerhouses in the national and international economic arenas.

The tour, scheduled to begin in September, will highlight the best practices and strategies employed by Mayors across the country to foster what Mayor Morial calls the *six keys to keeping cities competitive:*

- Safe streets and communities;
- A skilled workforce;
- The arts, as both a cultural/educational and economic force in communities;
- Strong infrastructure;
- Good, affordable housing; and
- Strong economies.

"America's cities are cultural destinations for people around the world," Morial said in his address. "Cities are economic powerhouses. You may not see it, but every day, in cities across the nation, Mayors are working to forge partnerships on the national and international economic stages. What does it mean when the City of Denver opens trade offices in London and China, or negotiates with airlines for international non-stop flights bringing tourism and business travel into the city? Or when the Mayor of Akron brokers an agreement which locates a German business in that city, bringing with it 70 new jobs and millions of dollars annually in economic output?

"It might mean, if you really think about it, that there are a number of Mayors in this country who are taking their rightful places as world economic leaders. Because of their economic clout, in the coming years you will see mayors leading trade delegations as much if not more so than governors. Institutions involved in promoting trade, such as the Commerce Department, will have to reinvent themselves to think metro economies, not states." Morial continued." If this nationwide tour of America's Competitive Cities accomplishes one goal, I hope that it's to secure our cities' rightful place in the dialogue on national and international economic issues and development."

Copies of the report, charts, graphs and accompanying data and information, as well as the full text of Mayor Morial's address, will be posted on the Conference's website, www.usmayors.org, as of 2:00pm EST on Tuesday, July 10.

CONTACT: Jubi Headley, (202) 861-6766 (office); (202) 744-9337 (mobile)

The U. S. Conference of Mayors is the official nonpartisan organization of cities with populations of 30,000 or more. There are about 1,200 such cities in the country today. Each city is represented in the Conference by its chief elected official, the Mayor.

PRESS RELEASES HOMEPAGE

R0011081

Storm Water 2000

Monitoring Efforts

1. History of storm water monitoring in Santa Monica Bay

Storm water monitoring in Santa Monica Bay began more than 30 years ago. Water quality data was collected in Ballona Creek as early as 1967 by the then Los Angeles County Flood Control District (now the County Dept. of Public Works). Water quality data collection continued, though intermittently, through the 70s and 80s. In addition to Ballona Creek, scattered data exist for Ashland Ave. drain, Pico-Kenter drain, Imperial Hwy. drain, Ave. I drain, Malibu Creek, Santa Monica Canyon, Topanga Canyon, Trancas Canyon, Solstice Canyon, Corral Canyon, Santa Ynex Canyon, Dume Creek, etc. as well as drains at several urban street intersections. However, data from these time and locations were all collected as a one-time event such as part of a special study. Usefulness of the data (for estimating loading, trend and impacts) is severely limited by their small size, the absence of continuous time series, and the lack of flow rate information.

2. Overview of existing storm water monitoring programs

Systematic and continuous monitoring of the urban runoff/storm water quality in Southern California was first started in the Santa Monica Bay watershed during the 1994-95 storm season, as required under the 1990 Municipal Storm Water NPDES permit. This is a result of a tiered approach designed for implementation of the 1990 municipal permit, which required municipalities located within the Bay watershed to implement a set of early actions, including the monitoring components. The SMBRP played a key role in facilitating the early implementation of the permit in the Bay watershed. In particular, by initiating a series of three technical studies[1] the SMBRP was instrumental in designing the first watershed-wide monitoring program implemented in Southern California. LAC-DPW, which as the Principal Permittee for the Los Angeles County Municipal Storm Water NPDES permit bears the primarily responsibility for conducting storm water monitoring in the County, adopted key recommendations of the SMBRP with regard to monitoring objectives, pollutants of concern, and land use models.

Monitoring objectives

- Mass loading estimate
- Land uses
- Critical Sources

[1] The three studies were: Assessment of Annual Pollutant Loadings to Santa Monica Bay from Storm Water Runoff, Review of Water and Wastewater Sampling Techniques with an Emphasis on Storm Water Monitoring Requirements, and Development of a Surface Drainage Water Quality Monitoring Program Plan.

- Receiving water impacts

The first two years of monitoring fell under the 1990 Permit and the main objective of the monitoring was to collect base-line mass loading information (watershed-wide and four key land uses) for the pollutants of concern. Since then the monitoring efforts in the region has been enhanced gradually both in geographical scale and in monitoring components. The current monitoring program, which is defined in the 1996 Municipal Permit collect monitoring data throughout the County and consists of four major elements: mass emission monitoring, land use runoff monitoring, critical industry monitoring, and Santa Monica Bay receiving water impacts study. Several peripheral and supportive studies were also conducted since 1996. Those consisted of a study of sampling in wide channels, a study of the feasibility of sampling storms down to 0.1" rainfall, an El Niño season supplemental study, and freshwater toxicity studies on the Los Angeles and San Gabriel Rivers. In 1999, the County also voluntarily funded half of a study of impacts on stormwater quality from aerial deposition.

Meanwhile, besides the County-wide monitoring program carried out by the LAC-DPW, storm water monitoring has also be conducted by California Department of Transportation (CalTrans) and industrial dischargers, under the State-wide CalTrans and industrial permits respectively. Up to now, monitoring of the bacterial indicators in the receiving water (surfzone near storm drain outlets) are conducted by the City of Los Angeles, Bureau of Sanitation, Los Angeles County Sanitation District, and the Los Angeles County Department of Health Services.

LAC-DPW Monitoring Program

In compliance with the 1996 municipal storm water permit, the LAC-DPW currently maintains 24 automated sampling stations within in the County. Among the 24 station, 10 were designated as mass emissions stations and the rest 14 were designated as land use specific stations. Nine of the 24 stations are located in the Santa Monica Bay watershed. Currently, there are two mass emission stations in the Bay watershed, one for Ballona Creek, and one for Malibu Creek.

The primary focus of the County's monitoring program is flow and concentration measurements of storm events during wet weather. Mass loading of each pollutant of concern was later calculated for from the flow and concentration measurements for the monitored areas, and estimated using a GIS model for the unmonitored areas. The GIS model was first introduced by the UCLA and employed by the SMBRP to produce the first estimated annual pollutant loadings to Santa Monica Bay in 1991. In essence, the model derives a loading estimate through three steps: 1) calculate runoff volume from observed rainfall volume and assigned runoff coefficient; 2) calculate land use-specific loading using observed and assigned event mean concentrations (EMC) and the modeled runoff volume for each land use; and 3) add up loading from each land use to derive total loading from the entire study area.

CalTrans' Monitoring program

Caltrans' storm water monitoring in the region began in 1997 as part of its statewide 3-Year Storm Water Monitoring and Research Plan. The Monitoring and Research Plan was developed to comply with a statewide NPDES storm water permit, the NPDES storm water permit for Caltrans' District 7 (Los Angeles) and for complying a 1996 court order under a litigation settlement with the Natural Resources Defense Council. The primary focus of Caltrans' monitoring is understandably transportation land use. Specifically, CalTrans' program has included monitoring and research in the areas of

- storm water characterization,
- pollutant source identification,
- management practice assessment,
- watershed planning
- Solids transport

Until now, most Caltrans' monitoring efforts have been described as elements of separate "studies" in its reports, indicating that the monitoring objectives, locations, frequencies, etc. may change in future years based on the knowledge and experiences gained from these studies. Table XX summarizes the studies that Caltrans has completed, continues to conduct, or plans to conduct statewide. Many of the studies are located in the Los Angeles region. Even for studies that are not taking place in this region, most of their results are considered applicable.

In Los Angeles region up to the end of 1999 wet season, Caltrans has collected water quality data from 130 locations (Figure XX). Among these locations, three are "permanent" storm water monitoring stations. One is located adjacent to I-405 North in the West LA area between Olympic and Santa Monica Blvd. and is designated to collect mass emission information. The other two (Interstate 210 mile post 40.8 and Interstate 91 mile post 8.92) were designated to collect information on the effectiveness of inlet cleaning as well as information on mass emission. The remaining locations were used in sampling events associated with studies in the region (Table XX).

Study Name	Number of Stations
District 7 Storm Water Monitoring	3
Roadside Erosion-Control Effectiveness	2
Drain Inlet Cleaning Effectiveness Study	8
District 7 BMP Evaluation Pilot Studies	21
Solids Transport and Deposition Study	72
Litter Management Pilot Studies	24

3. Brief Summary of Monitoring Results

The ultimate goal of storm water monitoring is to provide technical data and information to support implementation of an effective storm water quality management program. With that in mind, all monitoring efforts combined should achieve the following:

- Track status and trend in water quality (concentration) and pollutant loads (mass emission) from specific land uses and watershed areas.
- Identify pollutants of concern
- Identify sources of pollutants in stormwater runoff
- Assess the impacts of stormwater runoff on receiving waters (within the watershed and coastal waters)
- Evaluate the effectiveness of management programs, including pollutant reductions achieved by implementation of best management practices (BMPs)

This section briefly summarize the monitoring efforts and findings (if available) in each of the above five areas over the last six years. In general, there has been significant achievement, thanks for the resourcefulness of agencies involved and professionism and diligence of their employees. Unlike many other type of monitoring, people who conduct storm water monitoring must cope with unexpected seasonal events and hazardous situations. Uncommon climatological events, such as the El Niño in 1997-98 (twice the normal annual rainfall) and the La Niña 1998-99 (less than half the normal annual rainfall) certainly created new logistical and technical challenge. Since January 1995, 212 mass emission and 396 land use monitoring station events have been sampled by the LAC-DPW alone.

Achievements are evident in every one of the five areas of storm water monitoring. Yet, there is more progress in some areas than in others, reflecting partly whether the area of monitoring has been implemented for years or just started recently. It has been augured that many of the relatively new monitoring efforts could not be initiated sooner because there was no existing scientifically valid monitoring tool.

Track status and trend in water quality and pollutant loads

This area is the core of the storm water monitoring program in Los Angeles County. It is also the area where the longest time series and most amount of data have been collected up to date. Basically, a network of so-called mass emission stations has been established in the watershed since 1995. A subset of these stations are located near the ocean outlets of major river and storm drain channels while the rest are placed upstream, usually collecting runoff from an area dominated by a single land use. The purposes of this arrangement are to obtain direct measurements of the mass loading for all major watersheds in the region, and indirectly model and calculate mass loading from other watershed areas where directly monitoring were thought to be either too difficult or not cost-effective.

Data on pollutant mass loading from the two largest sub-watersheds in Santa Monica Bay, Ballona Creek and Malibu Creek have been collected since 1994-95. Since 1996-97 Total annual pollutant loading from the entire Santa Monica Bay watershed was estimated using model calibrated with land use monitoring data. The results of these loading measurements and estimates are summarized in Table 3.

Existing data summarized in Table 3 reveal no obvious upward or downward trends in pollutant loading from year to year except that loading in 1997-98 season is much higher than other years. 1997-98 happened to be the wettest among the four years based on precipitation records though the total runoff volume from the Santa Monica Bay watershed were not the highest over years. On the other hand, pollutant concentrations measured during 1997-98 were significantly higher than other years, which seems to be the key factor that results in the high mass loadings in that year. The loading estimates are generally lower comparing to the estimates made by the SMBRP in 1992, several degree of magnitude lower in some cases. These disparities most are due to the high concentration estimate used in the SMBRP study. Higher runoff volume estimate also contributed to the disparity.

Generally speaking, he mass emission element of the monitoring program has been successful in achieving its objective of tracking water quality status from year to year. Determine trends in pollutant loading may require at least several more years of data from this monitoring elements, given the expected high variations in annual runoff volumes. The strategy of combining direct measurements with land-use calibrated modeling is scientifically sound, cost-effective and seems to work well.

On the other hand, improvement may be needed in accuracy of sampling and lab analysis. For example, the non-detection of lead in 98-99 and 99-00 seasons and non-detection of zinc in 99-00 season, both in Malibu Creek, are hard to explain except for analytical errors.

Water quality status, pollutant trends and loads were successfully addressed by all of the major monitoring program elements: the Santa Monica Bay receiving waters impact study, the mass emission monitoring element, the land use monitoring element, and the critical source monitoring element. The total cost incurred by the monitoring program to date has been more than $4.8 million.

Identify Pollutants of Concern

The objectives of the storm water monitoring program with regard to pollutant identification are three-fold: they include (1). Determine if known pollutants are discharged above the levels of concern; (2). Determine which pollutants or forms of pollutants are of concern because of their impacts; and (3). Detect and identify unknown pollutants in storm water.

The core list of constituents monitored under the County Program covers most of the pollutants of concern identified in the Bay Restoration Plan. The list was developed initially by the LARWQCB and the LAC-DPW with input from the SMBRP as well as other stakeholers. In addition to those pollutants of concern already identified for Santa Monica Bay, the LAC-DPW was required to analyze additional constituents, especially

SVOCs and pesticides in light of evidence that certain pesticide (diazinon, etc.) found in runoff has contributed to toxicity.

Toxicity test of storm water runoff, which was first conducted by the SMBRP in 1994, has also become a routine part of the County's storm water monitoring program. (Test . done by other agencies?). Most significantly, between 1996 and 1998, the LAC-DPW funded a project to study the impacts of storm water runoff on Santa Monica Bay. The study collected water column and sediment quality data, data on bethos, as well as toxicity and TIE.

Up to date, he results of the monitoring activities aimed at pollutant identification are mixed. Several pollutants, including indicator bacteria, copper, lead, zinc (both total and dissolved), phenanthrene, and pyrene have been shown discharged at concentrations (undiluted) above existing water quality criteria (Ocean Plan, Basin Plan, AB 411, California Toxics Rule). However, because there has been no numerical effluent limits established for storm water runoff and no sediment quality criteria, it is still difficult to determine if current loading of these pollutants are above a level of concern. On the other hand, from TIE work done by the SMBRP and during the Santa Monica Bay Impacts study, Copper and Zinc have been identified as likely causes of toxicity.

Monitoring since 1994 (for some since 1996) have generally found low levels on non-detect of pesticides in storm water runoff. However, whether appropriate detection limits were applied in analysis of those pesticides is up to debate.

Trash is the only major pollutants of concern that has not been systematically monitored in the watershed. Studies have been carried out in targeted areas upstream, including monitoring of cleaned catch basin, CDS, and trash net, and the trash characterization study conducted by Caltrans. However, there is no reliable estimate on the annual trash load into the Bay and contributions of major land uses.

The monitoring program was successful at identifying toxic levels of zinc and copper from Ballona Creek discharge, toxicity in the Los Angeles and San Gabriel Rivers, and the extent and severity of bacterial indicators in both dry and wet weather.

Identify sources of pollutants in storm water runoff

Source identification has been primarily carried out through two-tiers of monitoring. Under the LAC-DPW monitoring program, the first-tier is composed of a number of land use stations aimed at assessing pollutant loads from specific land uses and watershed areas. The second-tier is done through the critical source monitoring project. This monitoring element is also supported by the County and city's efforts in identifying and eliminating illicit discharges, by Caltrans' monitoring of highway runoff (equivalent of land use monitoring), by special studies such as the City of LA's study on street washing, and by the SMBRP and other agency's effort to develop sanitary survey tools.

Samples have been collected between 1994 and 2000 from eight land use categories (commercial, vacant, high density single family residential, transportation, light industrial educational, multifamily residential, and mixed residential). Data from analysis of these samples seem to suggest wide dispersion of pollutants across different land uses with a few exceptions. The land use monitoring identified light industrial, transportation, and retail/commercial land uses as developing the highest median concentrations for total and dissolved zinc. Light industrial and transportation land uses displayed the highest median concentrations for total and dissolved copper, and light industrial produced the highest concentrations of suspended solids. Higher bacterial indicator counts were found in commercial and high-density residential land uses. Open space seems to generate higher amount of TSS but lower amount of heavy metals and bacteria.

As part of its Marina del Rey/Ballona Creek feasibility study, the Army Corps of Engineers in 1999 did a summary

Five commercial/industrial categories were currently included in the critical sources monitoring which was started in 1999. These six categories are auto dismantlers, automotive repair, fabricated metal products, motor freight companies, auto dealers. Available data from three of the.categories, auto dismantlers, auto repairs, and fabricated metal businesses, showed that these categories produce significantly higher concentration of many pollutants than the land use and watershed stations. The pollutants with high concentrations are primarily those associated with the operations of these businesses such as copper, lead, zinc, nickel, TSS, COD, oil and grease. Fabricated metal businesses produced the highest concentrations of zinc, copper and suspended solid; and auto repairs produced highest concentration of lead. Indicator bacterial counts were also extremely high at these sites(with auto dismantlers being the highest) though not as high as in some commercial and residential land uses.

Each Permittee has a program to identify and eliminate illicit connections to the storm drain system to the maximum extent practicable. The County has been successful in the inspection of open channels and underground storm drains to identify illicit connections. Most Permittees perform random area surveillance during dry and wet weather to inspect for potential illegal discharges. The Permittees also conduct educational site visits at businesses. During these visits, flyers with information on Best Management Practices (BMPs) applicable to that business are distributed. As of July of 1999, routine inspections hav resulted in the discovery of 1,992 undocumented connections. However, the type and amount of pollutant loading these connections would contribute had they been not removed are not clear.

In general, monitoring data collected by Caltrans over the last few years have revealed that transportation-related land use/activities could be a major source for several pollutants of concern especially copper, lead, nickel, zinc, and bacterial indicators. Analysis of samples from storm water runoff off freeways have shown not only the highest average concentration but also the highest maximum concentration for these contaminants. Also, there seems to be several hot spots in the County's freeway system, one being on Interstate 91 and one being on Interstate 60. However, since Caltrans monitoring reports reveal little detail on the characteristics of its monitoring locations, no analysis can be conducted to establish a cause-effect relationship.

Assess the impacts of storm water runoff on receiving waters (within the watershed and coastal waters)

Currently there is no routine monitoring specifically conducted to collect information on the impacts of storm water runoff on receiving waters. Most information to date come from the receiving water study, which was conducted between 1996 and 1998 storm seasons by the SCCWRP, the USC, and UCSB, and funded by the LAC-DPW. The study discerned the existence and extent of the storm water plume in Santa Monica Bay, identified two trace metals in Ballona Creek. Storm water discharge that are toxic to simple sea creatures, and concluded that sediments offshore of Ballona Creek generally had higher concentrations of urban contaminants. This study, one of the first in the nation to assess storm water impacts on the marine environment, was successful at assessing storm water impacts on Santa Monica Bay. The study's findings and techniques explored during the study set the stage for development and implementation of a long-term impact monitoring program.

A re-tooled shoreline bacteriology monitoring program has since the summer 1994 tracked the impacts of bacteria-contaminated runoff on Santa Monica Bay beaches. It is conducted collaboratively by the City of Los Angeles' Bureau of Sanitation, County Sanitation District of Los Angeles, and the Los Angeles County Department of Health Services. Information collected under this program has been used by Heal the Bay to publish weekly Beach Report Card. Recently, as part of the pathogen TMDL development, the LARWQCB initiated a study to model the dispersion/degradation patterns of indicator bacteria from storm water runoff in surfzone.

The Bight'98 survey of 99-00 collected a wide range of information from nearshore areas potentially impacted by storm water runoff. The dry and wet weather microbiological survey showed clearly high bacterial counts attributable to storm water runoff. Analysis of the survey data on sediment quality, water quality, benthic infauna, and fish population is in progress.

Much more need to be done to further assess the impacts of storm water runoff in ocean receiving waters. On the other hand, even more work is needed to assess the impacts of storm water runoff in freshwater bodies within the watershed. Systematic bio-monitoring and assessment virtually did not exist until recently when a watershed monitoring prgram was developed for the Malibu Watershed and Heal the Bay initiated bio-monitoring efforts in the watershed through its Stream Team project. The SMBRP recently initiated a sediment transport study in the Topanga Creek watershed.

Evaluate the Effectiveness of Management Programs, including Pollutant Reductions Achieved by Implementation of Best Management Practices (BMPs)

As part of the Critical Source element of the monitoring program, in 1999-2000 season LAC-DPW examined the potential effectiveness of several voluntary good housekeeping and preventive types of Best Management Practices at one critical source industry. There was no significant difference at other critical source industries at which BMPs were implemented. The inability to control the voluntary usage of good housekeeping BMPs at these critical industries may have compromised the study's effectiveness for those industries.

During the 1998-99 season, CalTrans also conducted several studies to evaluate the effectiveness of several BMPs including roadside erosion control, drain inlet cleaning, highway extended detention basin, sand filter, media filter, drain insert, and four litter management measures. Data are available from several of these studies and findings were mixed as shown by the following brief summary.

The drain inlet cleaning effectiveness study monitored the runoff quality from four cleaned and four uncleaned drain inlets. The monitoring data revealed no significant difference in runoff quality between cleaned and uncleaned sites.

Monitoring data characterizing ***the effectiveness of extended detention basin treatment of highway runoff*** were collected at four sites (two in this region and two in District 11). Comparison of influent and effluent from the detention basins at each site showed that the detention basin is effective in removal of total suspended solids but not in removal of hydrocarbons, metals, and nutrients.

Monitoring data characterizing ***the effectiveness of sand filters in the treatment of maintenance yard and park & ride runoff*** was collected at five sites. Comparison of influent and effluent from the two park and ride sites (in District 11) showed that sand filter is effective in removing TSS and some heavy metals (Pb and Zn), but not in removing hydrocarbons and nutrients. Results from the three maintenance yard sites (2 in LA region) are similar to the park and ride sites.

The four litter management measures evaluated in Caltrans studies include ***street sweeping, litter pickup, modified grate, and bicycle grate***. Statistical analysis of the data indicates that increasing the frequency of street sweeping from monthly to weekly does not reduce the count or weight of litter, but increasing the frequency of litter pickup from monthly to weekly does. Also, the standard Caltrans bicycle grate does not reduce litter but the modified inlet grate does. On the other hand, these litter control measures generally do not help to reduce the load of other contaminants such as TSS, hydrocarbons, heavy metals, nutrients and indicator bacteria.

4. Major achievements and deficiencies

Achievements

It is fair to say that the key achievement in this area is the establishment of a baseline program for loading of major pollutants of concern. Though many improvements are needed and we may need few more years of data for meaningful trend analysis, this baseline program nevertheless is the backbone of all storm water monitoring components. It will provide for the first time baseline storm water quality information, both temporary and spatial, that are critical for any subsequent monitoring efforts to be meaningful. It also laid the groundwork and set the standards for all other monitoring components such as those discussed in this report.

Other major achievements of the current monitoring efforts include the basic understanding of land use characteristics, preliminary understanding of the major sources of pollutants of concern, and preliminary understanding of the storm water impacts on nearshore environments. Although most of the knowledge we have in these areas is preliminary at the best, what we know now is a big leap forward compared to ten years ago. In ten years, we have moved from very little to wide recognition that storm water runoff is the major source of beach pollution, that land uses characteristics play an important role in pollutant loading and, that the pollution is attributable to a wide range of daily activities. There is no doubt that the results of many important monitoring and research projects, several are spearheaded by the SMBPR, are the catalytic to these changes.

Deficiencies

Collecting and conducting meaningful analysis of storm water monitoring data remain a daunting challenge for both storm water management agencies and academia. Two to three years might have been lost due the slow set up of the baseline monitoring program. This slow start-up could be blamed partly by the lack of political will, but also many technical difficulties one could expect in setting up a new system.

Even after a slow start, the current monitoring program is far from perfect. One of the major deficiencies of the current program is the lack of monitoring data for a couple of pollutants of concern. On the top of this list is trash. There is no systematic monitoring of trash in the watershed and therefore its loading is poorly characterized. It is encouraging that trash monitoring has become a priority because of the TMDL process. However, more efforts are needed to develop a standardized protocol for estimate trash loads.

Although except for trash most pollutants of concern identified by the Bay Restoration Plan are routinely monitored under the baseline program, there is an imbalance between monitoring taking place upstream and downstream. On one hand, in the case of bacterial monitoring, most storm drain outlets along Santa Monica Bay are monitored daily, there are only infrequent in channel bacterial monitoring at limited locations. In general, the effort devoted to source identification of bacterial contamination is deemed insufficient and there is a lack of coordination among the already limited efforts.

On the other hand, there seems to be an over-emphasis on monitoring of effluents for toxic chemicals in contrast to the receiving water. Little has been known about the fate and transport of toxic contaminants in the receiving water, thus up to date it is still difficult to link pollutant loading to potential impacts.

Many issues need to be addressed in order to improve the quality of the monitoring data and the reliability of loading estimates. Understandably loading estimates are much difficult to make and less reliable for storm water discharge primarily because of the high variability in rainfall and flow volume. However, the loading estimate can be improved based on knowledge of the characteristics of the storm water discharge. This knowledge can be obtained through studies of pollutagraph, power analysis of existing monitoring data, and development and application of new computer models.

An issue related to estimation of mass loading is the adequacy of detection limits used in currently monitoring program. The hit-or-miss nature of storm water monitoring plus a relative high detection limit often result in a large proportion of a data set rendered as non-detect, thus hindered the value of the monitoring efforts.

Perhaps the biggest challenge that the storm water monitoring program facing today is how to collect and use monitoring data to evaluate the effectiveness of BMPs. So far, the results from limited efforts in this area are mixed to say the best and sometime contradictory. A major research program is needed to study what tools, indicators, and methodology should be used, or be developed, for assessment of the BMP effectiveness.

Demonstrating the impacts of storm water runoff on receiving waters is probably equally challenging as BMP evaluation. The storm water impact study over the last three years is a good start. Yet the information is limited in time and scale and most evidence of impact the study provide are indirect in nature. There is a need to develop and implement a long-term program for monitoring the impacts of storm water runoff. As part of this process, major effort is needed to conduct baseline bioassessment develop biological indictors.

Finally, there is a growing need for development of a comprehensive watershed monitoring program that integrate various monitoring components and coordinate activities of different monitoring agencies in order to answer key, regional management questions. The need for such coordination and integration was not imperative when LAC-DPW was the agency who had taken on the responsibility of storm water agency for the region. However, other agencies/organizations have implemented new monitoring programs in recent years, including the programs/projects of Caltrans, local cities, Heal the Bay, and Santa Monica Bay Keeper. While some of the agency have coordinated with the LAC-DPW in developing their programs/projects, others have essentially no coordination at all. The lack of coordination is most obvious between LAC-DPW and Caltrans.

Ultimately, a comprehensive monitoring program similar to the one for Santa Monica Bay should be developed for the Bay watershed. Under this new comprehensive program, existing efforts and resources from all agencies organizations should be combined to collective monitoring data in a most meaningful and cost-effective manner. These agencies/organizations should collaborate in building consensus on monitoring objectives, coordinating monitoring location, time and frequency, standardizing protocol, methodology, detection limits, and data transfer format, developing an integrated data management system, and coordinating in data analysis and other research projects.

5. Recommendations

Recently, storm water management agencies in Southern California collaboratively established a Storm Water Monitoring research Cooperative Program. Its initial project is the development and prioritization of a research agenda with the assistance of water quality resources management/regulatory experts. The following is a list of the issues that the Program would like to see being addressed by future research/monitoring projects:

- Develop monitoring designs appropriate to assess storm water discharges, potential water quality impacts, and the effectiveness of storm water management programs.
- Develop standardized field and laboratory protocols.
- Develop (standardized, meaningful) tests to evaluate the toxicity of urban pollutants of concern.
- Evaluate the aquatic toxicity of heavy metals and their relationship to water quality thresholds
- Improve methodologies for identifying unknown toxicants.
- Develop biological indicators and biocriteria.
- Evaluate the impacts of physical characteristics (e.g. flow rate, volume, temperature, etc.) of urban storm water discharges.
- Improve understanding of fate, transport and plume dynamics of urban storm water discharges.
- Use advanced information technologies in monitoring, modeling and information exchange.
- Study the use of sensitivity analysis in evaluating the effectiveness of BMPs.
- Develop appropriate pathogen indicators.

Table 1. Summary of storm water monitoring in Los Angeles County (Santa Monica Bay) in FY 1999-00.

Monitoring Agency	Type of Station	# of Station (# in SM Bay)	Sampling Season	# of Sampling Events	Monitoring Constituents	Sampling Methods
LAC-DPW	Mass emission	10 (2)	Wet	12/station		Mostly automatic composite
	Land Use	14 (5)	Wet	77 total station events		Automatic composite
	Critical Source					
CalTrans	General, transportation landuse	1	Wet	1?		Automatic sampler

I. EXECUTIVE SUMMARY

INTRODUCTION

Urban storm water is considered as one of the largest sources of pollution to the coastal waters of the United States. Storm drains convey runoff from streets, urban centers, industrial sites, and open spaces into streams, creeks, rivers, beaches, and the ocean. Industrial operations represent one contributor to storm water pollution, but they are known to be a major source of heavy metals, oily waste, and other substances. Many industrial operations involve manufacturing, storage, and shipping activities which, when conducted outside and are exposed to storm water, can be sources of pollutants in storm water.

Federal regulations issued pursuant to the 1987 amendments to the Clean Water Act mandate the regulation of point source discharges of storm water from industry and from municipal separate storm sewer systems serving 100,000 or more people. California, one of 44 states with delegated authority from the United States Environmental Protection Agency (EPA), implements its own storm water program. The State Water Resources Control Board (State Board) and the nine Regional Water Quality Control Boards (RWQCBs) are the state agencies charged with the primary responsibility for overseeing the implementation of storm water regulations in California. In 1991, State Board issued the Industrial Activities Storm Water General Permit (General Permit No. CAS000001; hereafter, GISP), subsequently reissued in 1997, to control pollutants associated with storm water runoff from industrial sources (GISP 1997). As of August 2000, approximately 9,200 industrial facilities in California were covered under the GISP, with nearly one-third of the facilities located in the Los Angeles region.

The overall goal of this study was to assess the effectiveness of the GISP program for one industrial sector, as implemented in the Los Angeles region, in reducing water quality impacts due to storm water pollution. This executive summary is divided into five sections: introduction, background, methodology, key findings, and conclusions. The background provides a general description of the objectives of the study. The methodology summarizes the approaches used in the study to fulfill the objectives. The key findings present highlights on important results. And the conclusions provide synthesis and recommendations based on the key findings.

BACKGROUND

The Los Angeles Regional Water Quality Control Board (the Los Angeles RWQCB) initiated this compliance assessment project in 1998, recognizing the need to adequately characterize the effectiveness of its industrial storm water program, as implemented at the facility level. The specific objectives of this study were: 1) to evaluate the state of compliance of one industrial sector, the auto dismantling industry, with the GISP requirements and associated water quality implications; 2) to identify limitations of the GISP program in effectively controlling pollutants in storm water runoff; and 3) to provide specific recommendations and regulatory alternatives to help guide management actions to improve water quality. This study is one of the few *comprehensive* assessments investigating the state of compliance of a particular industrial sector with storm water regulatory requirements.

This study chose to focus on the auto dismantling industry because the typical operational and material handling practices conducted by the facilities of this industry represent a potential significant source of conventional and toxic pollutants, including heavy metals and certain hydrocarbons, in storm water. Also, the industry represents a significant portion (about 15 percent) of the facilities covered in the Los Angeles RWQCB's GISP program.

For the purpose of evaluating compliance, this study categorized the GISP requirements into the following three tiers:

Initiation (Tier 1)
Facilities subject to coverage under the GISP, based on their standard industrial classification (SIC) codes or other specific conditions stated in the GISP, must file a Notice of Intent (NOI) with the State Board. (The auto dismantling industry with SIC code of 5015 has been mandated for coverage);

Documentation/Reporting (Tier 2)
Facilities must report their self-monitoring activities and results by submitting an Annual Monitoring Report by July 1st of each year. In addition, facilities must prepare an appropriate storm water document, known as Storm Water Pollution Prevention Plan (SWPPP), along with a written monitoring program to help guide their efforts in implementing appropriate storm water control measures and monitoring the quality of storm water runoff from their facilities.

On-site Implementation (Tier 3)
Facilities must implement appropriate storm water control measures known as Best Management Practices (BMPs) described in their SWPPPs and perform the required monitoring activities.

METHODOLOGY

The methods used to conduct this assessment include database analysis, in-depth document review, and onsite case study investigations.

Non-filer Identification
Auto dismantling facilities in Los Angeles County that have failed to apply for coverage under the GISP program by filing a NOI, also known as "non-filer", were characterized using the following sources of information: 1) a list obtained from the California Department of Motor Vehicles, Occupational Licensing Division (DMV) of auto dismantling facilities in Los Angeles County that maintain a current dismantling license issued from the DMV, and 2) results from the door-to-door site visits conducted

by the City of Los Angeles inspectors from January 1999 to May 2000, specifically aimed at identifying non-filers in parts of Los Angeles city. Facility names and addresses were screened using the Los Angeles RWQCB's NOI database to verify their status of coverage under the GISP.

Document review
A detailed review of SWPPPs and written Monitoring Programs was completed for a study pool of 52 auto dismantling facilities. The purpose of the review was to assess the effectiveness of these storm water documents in guiding facility operators into compliance. The 52 facilities were selected randomly from the NOI database using a systematic, replicable process and are considered to be representative of the industry.

Case study investigations
Site inspections and storm water sampling were performed on the nine selected auto dismantling facilities located in San Gabriel River and Los Angeles River watersheds. The nine facilities were selected out of the study pool of 52 facilities, based on their proximity to the San Gabriel River watershed, the Los Angeles RWQCB's priority watershed for the 1999/00 fiscal year.

The purpose of these site-specific investigations was to take a hard look at the onsite component of compliance that may not be readily observable from document review alone. Storm water analytical data were used to evaluate the quality of storm water runoff generated, impact of the BMPs implemented on water quality, and a simple load calculation for the industry. The EPA Simple Method was used to estimate load.

KEY FINDINGS

The following highlights the important findings of this study:

Initiation (Tier 1)

<u>Non-filer Identification</u>
The problem of non-filers among auto dismantling facilities is significant. An assessment based on the DMV list revealed that one out of every five facilities with a valid DMV license was operating as a non-filer. The site visit results indicated a more serious degree of non-compliance for certain parts of Los Angeles city, with more than one-third (37%) of the auto dismantling establishments visited operating without a NOI.

A possible explanation for such a high ratio of non-filers observed from the site visit results- almost twice as that predicted by the DMV analysis- is that some areas of Los Angeles County, including the locations targeted by the City inspectors, potentially have a disproportionately high percentage of non-filers. Also, site visits can account for non-filers that may be operating without a valid dismantling license, thus not included in the DMV database. The actual number of non-filers in Los Angeles County could be somewhat or considerably higher than that predicted by the DMV/NOI analysis (perhaps somewhere between 19% and 37%), considering an unknown number of delinquent facilities operating with neither a dismantling license nor a NOI.

Documentation/Reporting (Tier 2)

Annual (Monitoring) Reports

Since the 1995/96 permit year, the proportion of the 52 selected facilities submitting Annual Reports has been steadily rising, with a peak submittal rate of 96% observed for the two most recent years considered by this study- 1997/98 and 1998/99. This is a significant increase in compliance, considering that less than half complied with the annual reporting requirement in some of the earlier years. Accelerated efforts expended by the Los Angeles RWQCB in outreach and enforcement activities, fueled by legislation such as Assembly Bill 2019 that mandates timely enforcement actions against violators of the GISP requirements, appear to have significantly contributed to an increased compliance.

SWPPPs/Written Monitoring Program

Initially when the Los Angeles RWQCB issued letters requesting for SWPPPs, nearly a quarter of the facility operators responded with phone calls, displaying little or no knowledge of the SWPPP requirement. Following the initial responses, most facilities (50 out of the 52 requested) did submit their SWPPPs and their written monitoring programs to the RWQCB (Formal enforcement actions were taken against the two delinquent facilities for their failure to submit the requested SWPPPs and past Annual Reports.)

This study found nearly all of the SWPPPs to be deficient in more than one area. The majority were boiler-plate documents prepared by consultants that lacked sufficient site-specific and/or procedural details crucial for proper implementation of BMPs. Many SWPPPs provided sets of "ideal" or "proposed" BMPs but were vague about specifying the measures that were chosen for implementation by the facility operator. BMPs considered universally applicable and important for pollution prevention, such as employee training, site inspection, and good housekeeping programs, were missing from a considerable number of the SWPPPs reviewed.

The majority of the written monitoring programs were prepared by consultants and contained many of the deficiencies found in the SWPPPs. Most documents failed to provide sufficient procedural details necessary to ensure proper quality assurance and quality control (QA/QC), especially regarding sample collection, storage, handling, and transport procedures.

On-site Implementation

BMPs

Staff inspections of the nine case study facilities revealed that the facilities were not fully implementing the BMPs outlined in their SWPPPs, especially measures that are more cost- and/or effort– intensive. Judging from the extent of spills and leaks observed on facility ground, it was evident that the existing BMPs, at the level implemented at most of the facilities, were not adequately controlling the pollutant sources present onsite. Some BMPs such as providing an overhead coverage for dismantling areas or storing motor parts in an enclosed area were limited in their effectiveness because dismantling and storing activities were commonly conducted outside of the designated areas due to inadequate workspace or other physical constraints. One facility eliminated the exposure of vehicle parts to storm water by storing them in large autobodies. An example of an innovative, cost-effective BMP that was implemented unsuccessfully at many of the selected facilities was using truckbeds to store vehicle parts. The facilities that used truckbeds for parts storage had failed to seal the cracks in the truckbeds to prevent potential leaks.

One factor that could potentially obscure a facility operator's assessment of compliance is the lack of a clear standard of compliance in the permit; GISP specifies neither a specific set of required BMPs nor a quantifiable performance or pollutant level to be achieved. (Many of the RWQCBs' staff members use and encourage the permittees to use a set of parameter benchmark values from the USEPA's "Final National Pollutant Discharge Elimination System Storm Water Multi-Sector General Permit for Industrial Activities" (most recently reissued in 2000) for the purpose of gauging potential harm or impact on water quality. However, these benchmarks are not specified in the GISP and are typically not used for gauging compliance or for enforcement purposes.)

Facility Self-monitoring

Review of the Annual Reports submitted by 50 of the 52 selected facilities indicated that the degree of compliance with the monitoring requirements did not match the success observed with submitting the monitoring reports. Based on our review of the 1997/98 Annual Reports, less than 20% of those required successfully completed the sampling & analysis requirement. Not all facilities that collected samples analyzed for the required toxic constituents (lead, zinc, and copper). Less than half conducted the monthly visual observation of storm water runoff. Despite the deficiencies in their monitoring activities, many facility operators still self-certified their Annual Reports for compliance.

Water Quality Impacts

Storm Water Sampling and Analysis

There was a wide range in the concentrations of pollutants in storm water samples obtained from the eight (out of the nine) case study facilities. The majority of the storm water analytical data exceeded the USEPA benchmark levels, in particular, for metals and oil & grease. The general trend identified in this study is that facilities that diligently implemented BMPs, especially good housekeeping practices, and had an overall neat and organized site appearance generally had lower pollutant concentrations in their storm water samples, as expected.

Load

A simple load calculation for 1998/99 suggested the following range for pollutant loads in storm water runoff from the auto dismantling industry in Los Angeles County: 30,570 lbs. of total suspended solids, 7,460 lbs. of oil & grease, 40 lbs. of copper, 30 lbs. of lead, and 130 lbs. of zinc.

CONCLUSIONS/RECOMMENDATIONS

- There is still a substantial number of auto dismantling facilities that need to be identified and permitted under the GISP program. A combined approach using currently available databases supplemented by site visits appears to be an effective method for capturing non-filers. The existing agreement between DMV and the State Board offers a good example of interagency cooperation that helps to elucidate the non-filer identification process-- a model that could be applied to other industrial sectors, including but not limited to the transportation and recycling industries. At this time, additional information is needed to evaluate if the quality of storm water from the non-filers is significantly different, on average, from the permitted facilities.

- In general, the level of understanding among the auto dismantling facility operators of the intent and the significance of the GISP program and its requirements appeared to be low when this study was conducted.

- Compliance among many auto dismantling facilities was achieved mostly on paper, primarily reflected in the quantity of the required documents or reports submitted to the agency and perhaps less in terms of the quality. Site inspections revealed that the degree of field compliance achieved through proper implementation of appropriate BMPs is low and trails behind paper compliance.

- In light of the fact that it is only the field implementation component that substantively contributes to pollution reduction and given the high levels of oil & grease and metals found in storm water runoff from auto dismantling facilities, it may be concluded that the GISP program, as currently implemented by many auto dismantling facilities, does not appear effective in controlling storm water pollution.

- Despite an increase in compliance with the annual reporting requirement, incomplete monitoring results, especially the analytical data, limit the usefulness of the Annual Reports in developing a comprehensive data inventory needed to: fully assess the quality of runoff from regulated facilities; measure progress in pollution prevention efforts over the years; assess water quality impacts from industrial storm water runoff based on load estimates; and develop water quality standards, including total daily maximum loads (TMDLs). To improve both the compliance with monitoring requirements and the quality of the Annual Reports being submitted, the RWQCB must step up its efforts to provide timely responses, for compliance assistance and enforcement purposes, when deficiencies are noted.

- Many of the storm water documents - SWPPPs and written monitoring programs- failed to serve as useful guides for facility operators in the selection and implementation of appropriate BMPs and in monitoring activities due to the absence of sufficient procedural and site-specific details. A time-efficient solution recommended by this study is to target those the consultants (who work closely with the industry as a group monitoring leader or prepare storm water documents on behalf of the facilities) for regular training, education, and certification to ensure that SWPPPs and written monitoring programs prepared by third parties are up to par with the GISP requirements.

- One factor that potentially obscures the efforts of facility operators and regulators in assessing compliance is the lack of explicit, quantifiable standards that facilities must attain in order to demonstrate compliance with the GSIP requirements and with applicable water quality standards. Determination of compliance should not be left up to the subjective interpretation of uninformed permittees or regulators. Thus, the GISP program needs a more clear-cut standard of compliance based on a combination of a minimum set of specific BMPs and/or numerical effluent limitations. The following tiered approach is recommended for the auto dismantling industry: 1) a mandatory set of specific, baseline structural (excluding treatment) and non-structural BMPs for facilities with annual vehicle throughput less than 500 (which includes mom-and-pop and medium-sized facilities); and 2) mandatory treatment of storm water for facilities with annual vehicle throughput greater than 500. (Note: The annual volume of vehicles processed at many of the mom-and-pop facilities, which make up over three-quarters of the industry in the Los Angeles Region, is less than 300 vehicles. The threshold of 500 vehicles was chosen to include typical mom-and-pop and medium-sized facilities in the Region). Also, in lieu of requiring treatment, numerical effluent limitations could be applied to the latter group as a standard of compliance. A compliance schedule could help phase facilities into compliance over a certain specified timeframe. Facilities with less than 500 annual vehicle throughput that persistently demonstrate problems with meeting a certain water quality standard, e.g. the USEPA benchmark levels, should also be considered for inclusion in the mandatory storm water treatment category.

- The lack of sufficient resources was identified as the primary reason for the limited compliance assurance and enforcement activities performed by the RWQCB in the past and when this study was being conducted. One way to reduce the workload associated with assessing compliance of industries subject to the GISP requirements is to employ a semi-privatized certification program, such as that implemented in the State of Wisconsin, that relies on licensed, private inspectors to oversee the compliance activities of a group of facilities that voluntarily choose to participate and help fund the program. The aim of such a program is to help reduce some of the workload of the regulators and to allow facilities that diligently work toward and maintain a specified level of compliance to be certified for compliance by professional inspectors. Such certification could (partially) exempt them from certain regulatory responsibilities, such as monitoring activities, and indirectly shield them from third-party lawsuits by reducing the degree of their environmental liability. (Essential to the implementation of this type of program is regular training and (re-)certification of inspectors by the regulating agency to ensure quality assurance and quality control).

II. BACKGROUND

Storm water pollution has received steadily increasing attention from regulating agencies as well as environmental groups in the past decades. In California, efforts to better control industrial storm water pollution have resulted in legislation specifically aimed to improve the efficacy of the GISP program. Examples include Assembly Bill 2019, which mandates aggressive, mandatory enforcement actions to increase compliance with the NOI and annual reporting requirements, and Assembly Bill 1186, designed to substantially increase the funding available for the GISP program (AB 2019; AB 1186). Third-party lawsuits triggered by non-profit environmental organizations have contributed to raising the public's awareness of storm water pollution and of the importance of pollution prevention (P2).

There exist several known evaluations or reports, which have assessed the effectiveness of industrial storm water program, on both the regional and national levels. The Water Environment Federation, under a cooperative agreement with the EPA in 1994, conducted a nationwide assessment of the federal industrial storm water program implemented by USEPA (WEF 1996). The study presented the permittees' perceptions of how effective they thought the individual components of the federal industrial storm water program were in controlling and reducing storm water pollution. Two of the key findings from the study were that 1) of those companies regulated by the storm water permit program, 12.5% appeared to be out of compliance with the requirement to develop and maintain a SWPPP onsite; and that 2) small businesses spend less money on compliance and are more likely to be out of compliance because they lack environmental staff and a clear understanding of the requirements.

On a regional level, a 1998 report by Heal the Bay, a non-profit environmental organization with a primary focus on the protection of Santa Monica Bay in Southern California, criticized the lack of accomplishments of the industrial storm water program implemented by the Los Angeles Regional Water Quality Control Board (Los Angeles RWQCB), in areas of compliance assurance and enforcement activities conducted since the adoption of the GISP in 1991 (HTB 1998). In 1998 a Los Angeles RWQCB staff generated and submitted a draft report to the State Board titled, "Analysis of the Sampling Results: 1996-1997 Annual Report for Storm Water Industrial Activities General Permit". The draft document showed that a substantial fraction of the storm water data submitted for the 1992/93 and 1996/97 years exceeded the USEPA benchmark levels (RWQCB 1998). In February 2000, the National Resources Defense Council, a non-profit organization of attorneys working for environmental causes, submitted a formal written petition to EPA asking it to correct deficiencies or to withdraw from the State of California the delegated authority to implement its own storm water program, *specifically in the Los Angeles Region*. The petition documented the failure of the Los Angeles RWQCB to fully implement its storm water programs and cited the lack of sufficient funding and resources as the primary reason for the noted deficiencies (NRDC 2000). USEPA also cited similar findings in several of its annual audit summaries of the Los Angeles RWQCB's storm water programs and strongly recommended a significant augmentation in the available funding to provide the resources needed to fully implement the program (USEPA 1998; USEPA 2000a).

USEPA recognized that the RWQCB staff had achieved significant accomplishments given severely constrained resources (USEPA 1998).

Whereas many of the cited studies and analyses primarily focused on the deficiencies in the overall programmatic implementation at the RWQCB level, this study shifts the focus of its evaluation to the facility level where pollution control occurs. And by assessing the permittees' performances and compliance with the GISP requirements, this study attempts to shed light on the drawbacks and the barriers associated with the GISP program that must be addressed in order to improve the program's efficacy in controlling industrial storm water pollution. In addition, this study takes a hard look at whether the GISP requirements and its terms of compliance have been defined in such a way as to ensure adequate protection of water quality and beneficial uses of receiving waterbodies. Lastly, this study provides specific recommendations to remedy the deficiencies noted in its evaluation. To fully characterize the state of compliance achieved by the target industry, this study employed a multi-tiered assessment approach looking at the full spectrum of requirements, from initiation of coverage to field implementation.

AUTO DISMANTLING INDUSTRY

Auto dismantling industry was targeted for compliance assessment for the following reasons:

- Auto dismantling facilities, also known as auto salvage yards or auto recycling facilities, represent a significant portion (about 15%) of facilities covered in the Los Angeles RWQCB's GISP program;

- Many of the typical operational and material handling practices conducted at auto dismantling facilities are performed outside and thus are exposed to storm water. Typical activities include dismantling vehicles and automotive parts; draining automotive fluids; storing auto parts, auto bodies and waste fluids, washing and rinsing of parts, and shipping and receiving activities;

- Spills and leaks of waste fluids and waste oil, which are common occurrences at auto dismantling facilities, contribute conventional and toxic pollutants, in particular, heavy metals and certain hydrocarbons, to storm water runoff (Swamikannu 1994); and

- The auto dismantling industry is difficult to regulate because the majority of businesses are small, mom-and pop facilities that tend to change ownership rather quickly, posing a special challenge in outreach and compliance assurance activities for the regulating agency (approximately 70% of all auto dismantling facilities in Los Angeles County covered under the GISP are 1 acre or smaller). Economic and personnel constraints impact the ability of smaller facilities to fully comply with the GISP requirements.

MULTI-TIERED ANALYSIS

Tier 1
File a Notice of Intent (NOI)

Tier 2
Prepare SWPPP and written Monitoring Program
Submit Annual Monitoring Report by July 1st

Tier 3
Implement Best Management Practices (BMPs)
Conduct required monitoring activities

For purposes of evaluation, compliance was divided into three tiers:

Tier 1 (Initiation)
Facilities classified under certain standard industrial classification (SIC) codes specified in the GISP for coverage (including the auto dismantling industry whose SIC code is 5015) must file a NOI to apply for permit coverage. Facilities that are required but fail to file a NOI are referred to as 'non-filers'.

Tier 2 (Reporting/Documentation)

After submitting a NOI, facilities must submit an Annual Monitoring Report by July 1st of each year that summarizes both the qualitative and quantitative results from their monitoring activities. In addition to the annual reporting requirement, facilities must prepare appropriate storm water documents known as a Storm Water Pollution Prevention Plan (SWPPP) and a written Monitoring Program (MP) necessary to guide them in their P2 efforts. The purpose of a SWPPP is to serve as a "blueprint" for achieving compliance by specifying specific BMPs and a schedule of BMP implementation. Written monitoring programs must contain adequate procedural details to ensure that proper monitoring of facility condition and its storm water is provided.

Tier 3 (Implementation):

Facilities must implement BMPs provided in their SWPPP and conduct monitoring activities required by the GISP. BMPs include both non-structural and structural controls that can reduce the level of pollutants in storm water. Monitoring requirements may be broadly grouped into visual observations, storm water sampling and analysis, site inspection, and SWPPP review and update. Storm water sampling and analysis, along with the other monitoring activities, help evaluate the quality of the storm water runoff generated from the facilities and gauge the effectiveness of the facility's efforts to control storm water pollution.

The state of compliance achieved by the permittees is a reflection of how diligently facilities have been implementing the GISP requirements. Knowledge of the current state of compliance achieved and an estimate of associated load can serve many useful purposes. For example, such an understanding could help gauge if an existing program, such as the GISP, has the potential to attain further pollutant load reduction if required, for example, as part of the implementation of a Total Maximum Daily Load (TMDL). TMDL is the "amount of a specific pollutant that a waterbody can receive and still maintain water quality standard" (TWA 2000). If the majority of dischargers permitted under a given regulatory program are shown to be at the high end of a compliance curve, this implies that the program has nearly reached its maximum attainable pollutant reduction. Under such a scenario, opportunities for significant additional reduction in load would be slim. Conversely, if most dischargers are found to be at the bottom of a compliance curve, then there may be opportunities for substantial pollution reduction to be achieved through increased compliance activities.

If the GISP requirements are implemented to their maximum at the facility level, and facilities are still unable to attain the assigned load, then perhaps the standard of compliance defined in the GISP or the existing approach used to implement the GISP program may need to be re-evaluated. California has yet to allocate load associated with industrial storm water pollution. Nevertheless, an understanding of the current state of compliance under the GISP program and getting a good sense of the magnitude of load generated by industrial sectors will no doubt be useful for making critical management decisions. Also, this type of assessment will help to identify priority or high-risk industrial sectors - e.g. those with low compliance and high load contribution - to direct limited resources to the most critical areas.

LACK OF NUMERICAL EFFLUENT LIMITATIONS IN GISP

Standards for compliance can be expressed in various ways. NPDES permits may contain both qualitative and quantitative effluent limitations with which permittees must comply. Numerical effluent limitations may consist of technology- and water quality-based limits. The GISP, which falls under the NPDES framework, does not contain numerical effluent limitations for the majority of dischargers permitted under the program (Facilities among the ten industrial categories listed in USEPA regulations (40 CFR Subchapter N) must comply with the technology-based limits established by USEPA for specific pollutants. These Subchapter N facilities represent only a small portion of the facilities under the RWQCB's GISP program.)

In the absence of numerical effluent limitations, BMPs form the pillar of the GISP program. This is consistent with the "Interim Permitting Approach for Water Quality-based Effluent Limitations in Storm Water Permits" (USEPA 1996). The interim permitting approach uses BMPs in first-round storm water permits, and expanded or better-tailored BMPs in subsequent permits, where necessary, to provide for the attainment of water quality standards. While it is recognized that numeric water quality-based effluent limitations could potentially provide a greater degree of confidence that a discharger will not cause or contribute to an exceedance of the water quality standards, the variable nature of storm water discharges and the lack of information on which to base numeric water quality-based effluent limitations are the main reasons that EPA developed the interim permitting approach.

There are several standards or conditions specified in the GISP that dischargers must attain including the Best Available Technology Economically Achievable (BAT) and Best Conventional Pollutant Control Technology (BCT) levels. In addition, one of the prohibitions in the GISP states that storm water discharge shall not cause or contribute to a violation of applicable water quality standards. Specifically, the achievement of BAT and BCT levels must be demonstrated by fulfilling the requirements of the GISP, which states "compliance with the terms and conditions of this General Permit constitutes compliance with BAT/BCT requirements and with requirements to achieve water quality standards." However, as discussed in the preceding section, determining compliance based on BMP implementation and performance is complicated by the absence of clear, uniform standards for measuring compliance, and because each assessment requires site-specific considerations. Prerequisites for successful attainment or measurement of progress toward desired goals are clear and adequate definitions of expectations or goals to be achieved. The lack of quantitative or numerical targets in the GISP inevitably generates questions and confusion as to whether a facility has indeed successfully achieved compliance. And herein lies one of the major handicaps of the GISP program.

A comparison of analytical monitoring data between facilities could shed light on the relative overall effectiveness of BMPs implemented at different sites. However, the bottom-line question is "how effective is effective?" Therefore, quantitative standards of some sort must be provided in order to determine the adequacy of storm water measures provided by facilities. One set of standards that has been used by RWQCBs in California and USEPA for its national storm water program is the USEPA benchmark values provided in the Final National Pollutant Discharge Elimination System Storm Water Multi-sector General Permit for Industrial Activities (hereafter USEPA Multi-sector Permit; USEPA 1995, USEPA 2000b). The benchmarks are indicators of potential impact of discharge but are not enforceable as numerical effluent criteria through the GISP program. These benchmark values are based on several sources of information, including fresh water criteria based on the effects on aquatic species, median concentrations from the National Urban Runoff Program, and minimum levels based on detection limit. However, for these numeric water quality standards to become enforceable through the NPDES framework, they must be translated into appropriate (numeric) *effluent limitations* that typically must be met "end-of-pipe". The Discussions section, under "Case study investigations: storm water analysis," explores the situation in greater depth and recommends some specific means to address this issue of whether compliance can be adequately defined to protect water quality in the absence of numeric effluent limitations.

III. METHODS

This study used database analysis, document review, and case study evaluations consisting of site inspections and storm water sampling and analysis to assess compliance of the selected auto dismantling facilities with the requirements of the GISP program. A mathematical equation, known as the EPA Simple Method, was used to quantify pollutant load in storm water runoff from the auto dismantling industry.

NON-FILER IDENTIFICATION (TIER 1 ANALYSIS)

To assess the non-filer situation, this study used two sources of data as presented in Table 1. First, to perform a county-wide evaluation, staff enlisted the cooperation of the California Department of Motor Vehicles, Occupational License Division (DMV) to obtain a list of auto dismantlers in Los Angeles County who had applied for and maintain a current dismantling license (DMV 1999). Each facility name and address on the DMV list was queried and checked using the RWQCB's NOI database to determine if the facility had filed a NOI. Facilities on the DMV list missing from the NOI database were contacted by phone to verify their operating status and the accuracy of the facility-specific information.

The second analysis focused on a four square-mile area within the County known to have high population of auto dismantling facilities. The data used in this study has been compiled by the City of Los Angeles inspectors who conducted door-to-door site visits between December 1998 and May 2000, specifically to identify non-filers in areas within the City of Los Angeles. The site visits were conducted as a Supplemental Environmental Project (SEP) that the City undertook, as part of its penalty under an Administrative Civil Liability issued by the RWQCB for City's past sewage spill incidents. A group of University of California at Los Angeles (UCLA) professor and students led the efforts to provide data QA/QC and data analysis.

TABLE 1. Data Source and Analytical Procedures for Non-filer Assessment

	Analysis I	Analysis II
Type	Auto Dismantling License Information	Door-to-door Site-visits
Source	California DMV Occupational License Division	RWQCB (City of Los Angeles' Supplemental Environmental Project)
Target area	Los Angeles County	City of Los Angeles (four square-mile area)
Analytical Procedures	1. Cross-check information on DMV list with NOI database 2. Perform over-the-phone verification of operating status and other information 3. Compile and analyze data	1. Query site visit results for auto dismantling facilities (conducted by UCLA) 2. Confirm NOI status (City of LA/ UCLA) 3. Analyze results by area (UCLA)

DETAILED STORM WATER DOCUMENT REVIEW (TIER 2 ANALYSIS)

The next level of evaluation focused on the facilities' compliance with the reporting and documentation requirement. To obtain a smaller pool of facilities for an in-depth review of storm water documents, this study selected 52 facilities from a total of 349 auto dismantling facilities from the NOI database. To ensure a representative pool, the facilities were chosen by first alphabetically sorting the 349 facilities by business name and choosing every sixth facility (A small number of the chosen facilities were located in Ventura County. These facilities were eliminated to limit the focus to Los Angeles County.)

To evaluate permittee compliance with the annual reporting requirement, this study chose to concentrate on trends observed in Annual Report submittal rates over times, based on the 52 selected auto dismantling facilities and on the quality of the Annual Reports submitted for the 1997/98 permit year. The proportion of facilities submitting the Annual Reports, among the 52 selected facilities, was determined by electronically querying the Annual Report databases maintained at the RWQCB. Similarly, the 1997/98 Annual Report database was queried for summaries of monitoring activities conducted by facilities. In addition, Annual Reports were reviewed for more detailed information not electronically available.

SWPPPs and written Monitoring Programs were requested from the selected 52 facilities through a formal letter issued by the RWQCB to each facility operator. An in-depth review of the SWPPPs and the written Monitoring Programs was provided using a checklist (see Appendix A) outlining the requirements specified in Sections A and B of the GISP.

CASE STUDY INVESTIGATIONS (TIER 3 ANALYSIS)

To investigate the onsite component of compliance, this study selected nine out of the 52 facilities for site-specific evaluation. These nine facilities were clustered in the San Gabriel River and Los Angeles River watersheds. Staff inspected all nine sites and collected storm water samples from the eight sites that produced sufficient volume of runoff to enable sample collection. Storm water samples were collected from primary discharge locations that conveyed runoff from the areas where principal industrial activities were conducted. The purpose was to assess the extent to which facilities implemented the BMPs indicated in their SWPPPs and to study the overall effect of the BMPs implemented based on the storm water analytical data. Storm water sampling activity and analysis were carried out under conditions consistent with the requirements in the GISP. Only fully-trained staff and interns participated in the storm water sample collection, handling, storage, and transport activities to ensure adequate QA/QC. Chain of custody forms were completed for all samples. Samples were analyzed by the California Department of Health Services laboratory.

WATER QUALITY IMPACT ASSESSMENT

EPA Simple Method

To provide a perspective on the potential water quality impact(s) associated with storm water runoff generated from the auto dismantling industry, pollutant load was estimated using storm water analytical data from the case study investigations. This study used the EPA Simple Method equation for load assessment:

$$L = 0.227*P*Pj*A*C(0.05 + 0.009*I)$$

where

L = pollutant load (pounds/ per year);
C = average flow-weighted concentration of the pollutant in runoff (mg/L or ppm);

P_j = fraction of rainfall events that produce runoff;
P = annual precipitation in inches per year (inches per year);
A = area of the site (acres);
I = the percent of the site's imperviousness; and,
0.227 = conversion factor (inches/foot)* (acre-feet-ppm/pounds).

IV. DISCUSSION OF RESULTS

This chapter presents key findings on the degree of compliance achieved by auto dismantling facilities; evaluates the quality of storm water runoff generated from selected facilities; estimates the load contributed by the industry in the form of storm water pollution; and discusses water quality implications associated with the key findings of this study.

NON-FILERS

Applying for coverage under the GISP does not guarantee that a facility will actually achieve pollution abatement, but it is an important first step. Also, from the perspective of "leveling the playing field," it is necessary for regulators to characterize the extent of non-compliance with the NOI requirement and take aggressive, timely actions once non-filers are identified to bring them into compliance. Auto dismantling facilities, due to the nature of the industrial activities conducted onsite, are subject to the GISP requirements. Facilities of this industry are informed about the GISP requirements through two main channels. First, auto dismantling facilities are notified about the NOI requirement by the California DMV when they apply for a dismantling license from the DMV's Occupational License Division. The DMV auto dismantling license application includes a questionnaire about whether the facility operator has filed a NOI with the State Board. (The DMV forwards a copy of the completed application to the State Board per pre-established interagency agreement/cooperation between the two state agencies.) The second channel of information regarding the industry's duty to comply is the mass-mailing that the State Board periodically conducts as part of its effort to reach potential non-filers.

Table 2 describes the results of non-filer identification using the DMV dismantling license list. Of the 463 facilities on the list that were checked against the RWQCB's NOI database, 147 were identified as potential non-filers. Phone verification identified 77 of the 147 facilities to be actually operating without a NOI. In other words, approximately one-fifth of the facilities on the DMV list comprised of non-filers. The rest of the 147 facilities had either terminated operation or could not be reached after multiple phone attempts.

Essential to obtaining an accurate estimate of non-filers is an understanding of the total universe of facilities regulated. In screening the DMV list against the NOI database for non-filers, this study assumed that the DMV list represented a relatively thorough estimate of the total universe of auto dismantlers in Los Angeles County. To test this assumption, staff screened to see whether the auto dismantlers in the NOI database appeared on the DMV list. This screening effort yielded 72 facilities that could potentially be operating without a dismantling license. Phone verifications confirmed 35 of these to be in operation. This effort yielded a conservative estimate of 404 for the total universe of auto dismantling facilities operating in Los Angeles County, as of August 1999, when this analysis was conducted. This estimate includes facilities operating with either or both a NOI or a dismantling license. The number of facilities operating with neither a NOI nor a dismantling license is unknown and is needed to

TABLE 2. Non-filers Among Auto Dismantling Facilities, Los Angeles County: DMV Licenses vs. NOIs Filed[1]

DMV COVERAGE[3]	NOI STATUS[2]					
	Active NOI[4]	Suspended NOI	Terminated NOI	No NOI[5] (Potential Non-filers = 147) Verified **Non-filers**	Out of Operation	Unverifiable
DMV Licensed	292	1	23	**77**	25	45 (21)[6]
No DMV License (72)						
Verified Non-licensed[5]	**35**	-[7]	-	Unknown	-	-
Out of Operation	34	-	-	-	-	-
Unverifiable	3	-	-	-	-	-

The proportion of non-filers among auto dismantling facilities operating in Los Angeles County is estimated at 19% (77 out of 404). The total universe of auto dismantlers in Los Angeles County exceeds 400, based on the number of active NOIs and verified non-filers. For a more accurate characterization, those operating with neither a NOI nor a DMV license need to be accounted for in the total universe of facilities.

---

[1] Table 2 originally appeared in a doctoral dissertation (*Chang 2001*).
[2] A RWQCB's NOI database contains information on facilities with NOIs.
[3] In California, auto dismantlers are required to obtain a dismantling license from the Department of Motor Vehicles (DMV), Occupational Licensing Department prior to operation. The list of facilities in Los Angeles County with auto dismantling license was obtained from the California DMV in August 1999.
[4] Note that the total number of auto dismantlers in the NOI database with active status is 364, slightly higher than the total number (349) that was used to select the study pool of 52 facilities. The pool of facilities with active NOIs changes over time as facilities begin and terminate coverage.
[5] Facilities that did not appear on both the DMV list and the NOI database were contacted by phone to confirm their operating status. The facilities were categorized as: "verified" non-licensed (DMV); non-filers; out of operation; and unverifiable if they could not be reached by phone after numerous attempts.
[6] Of the 45 facilities in the unverifiable category, 21 did not have phone numbers listed on the DMV list nor with directory assistance. Therefore, the operating status of these facilities could not be verified. The rest did have phone numbers listed but could not be reached.
[7] Dashes mean not applicable.

---

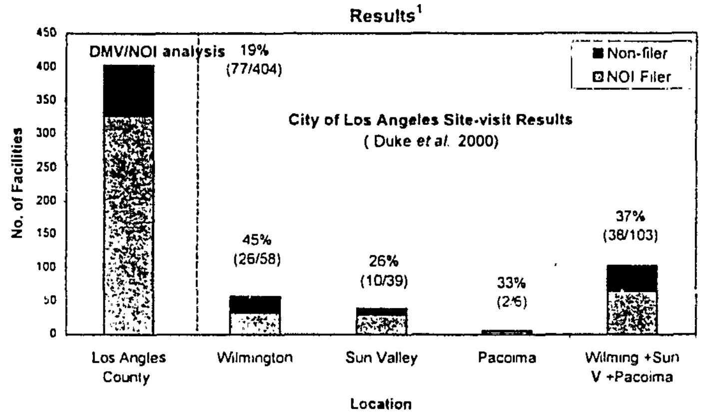
accurately characterize the total universe of facilities, is not known at this time. This estimate lies outside the realm of the objectives and methodology of this study. However, considering the potential severe consequences of violations under both regulatory requirements, the actual number of facilities in this category is probably a small percentage of the total number of auto dismantling facilities in operation.

This study further investigated the 10% (35 of the 364) of auto dismantling facilities with an active NOI that were verified to be operating without a dismantling license. The purpose was to shed some light on reasons that some facilities have apparently chosen to comply with one type of regulatory requirement over another. Each of these facilities were contacted by phone for explanations as to why the facility appeared to be in violation with a regulatory requirement so essential to its operational activities (a valid dismantling license is required for transactions at used auto auctions). It turned out that a small fraction of these facilities (less than 10% of those contacted) actually had a dismantling license, either under a slightly different address or business name, or under the name of the facility's headquarters. Facilities that knew they were in compliance cooperatively shared their dismantling license information with the

RWQCB staff The remaining facilities, however, refrained from revealing their dismantling license number or from discussing possible reasons why the facility is not represented in the DMV dismantling license database, even after repeated assurances from staff that the information was for research purposes only and not for enforcement activities. It is highly likely that these facilities were operating without a valid dismantling license.

Figure 1 illustrates the outcome of the two non-filer analyses, showing the percentages of non-filers for the overall County and at the sub-city level. Presented to the left of the dotted line is DMV/NOI analysis, and to the right are the site visit results. The site visits performed by the City inspectors targeted three areas within the City of Los Angeles boundary-- Wilmington, Sun Valley, and Pacoima-- with the first two areas accounting for over 40% of all auto dismantlers in Los Angeles County with an active NOI. A total of six auto dismantling facilities were identified and visited in Pacoima. Overall, non-filers accounted for 37% of the auto dismantling facilities identified in the three areas. The area with the highest ratio of non-filers was Wilmington (45%), followed by Pacoima (33%) and Sun Valley (26%). Only six auto dismantling facilities were identified in Pacoima.

Figure 1. Non-filers Among Auto Dismantling Facilities in Los Angeles County, CA.: Identified from Database Analysis and Site-visit Results[1]



[1] Figure 1 originally appeared in Chang 2001.

Because the site visits did not cover all of Los Angeles County, the results obtained from the site visits cannot be directly compared with the findings from the DMV license analysis. The site visit results, though, indicate that the proportion of non-filers among auto dismantling facilities in some areas of Los Angeles County could be twice as high as the average estimated by the DMV/NOI analysis for the entire County. Three reasons potentially account for the substantial difference between the ratio of non-filers estimated for the County and at the sub-County levels. First, Wilmington and Pacoima may have disproportionately high percentages of non-filers compared to the rest of Los Angeles County (Sun Valley had a similar percentage of non-filers as estimated by the DMV/NOI analysis). Second, the number of facilities delinquent with both the NOI and the dismantling license requirements could be significant. These facilities may be reflected in the site visit results but not in the DMV database. Another possible explanation is that the areas visited by the inspectors had both disproportionately high percentages of non-filers and non-DMV-licensed facilities. (Note: The RWQCB has started to follow up with facilities, across all industries, which were identified as potential non-filers by the City inspectors. Out of about 430 facilities fully inspected, approximately 200 facilities were identified as potential non-filers and are subject to follow-up activities, including a letter notifying their potential to file a NOI and an inspection, if necessary.)

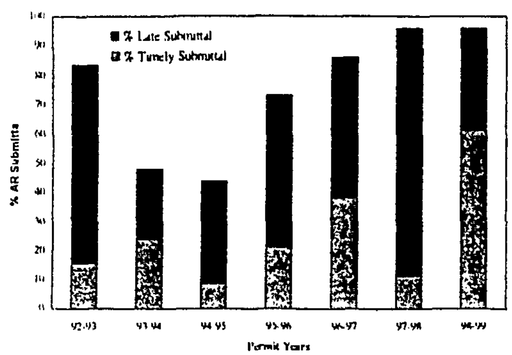
As demonstrated by the statistics, the non-filer problem is significant for the auto dismantling industry. However, to place the non-filer situation in the context of other industries, this study also looked at the City's site visit results for two other major industries mandated for coverage under the GISP- recycling and transportation sectors. Of the three sectors, the auto dismantling industry had the highest compliance rate with the NOI requirement of 63%, followed by transportation with 38%, and recycling with 13% (Duke et al 2000). The higher compliance by the auto dismantling industry could be attributed to the successful interagency coordination between the State Board and the DMV. As a way to effectively identify and reach out to potential non-filers, this study recommends that the State Board actively solicit the cooperation of other state/local agencies to enhance information sharing and to incorporate the NOI requirement by reference into other regulatory requirements, similar to the DMV dismantling application procedures. Auto dismantling licenses and construction grading permits (under the Municipal storm water requirements) are two examples where filing a storm water NOI has become a pre-requisite for license/permit issuance.

In conclusion, full compliance with the NOI requirement has not been attained by the auto dismantling industry. The DMV dismantling license analysis, which probably underestimates the number of non-filers for reasons explained revealed that, at minimum, one out of every five auto dismantling facilities in Los Angeles County is a non-filer. In some areas of Los Angeles County, such as Wilmington, the non-filer problem appears exacerbated, with approximately one out of every two facilities operating without a NOI. The recommended approach for identifying non-filers is to utilize interagency coordination and employ available databases, such as the DMV dismantling license and NOI information supplemented by site visits. Agency-generated data probably offers a higher degree of accuracy than commercially available databases. At this time, it is difficult to draw any quantifiable conclusions about the water quality implications associated with "non-filer" sites, including whether the quality of runoff from non-filers, on average, is expected to differ significantly from runoff from permitted facilities. because there are no known studies or data that specifically target the quality of storm water runoff from non-filer sites.

ANNUAL REPORTS

This sub-section describes the trend in compliance achieved by the 52 selected auto dismantling facilities with the requirement to submit Annual Reports by July 1st of each year. Also characterized are the facilities' performances in implementing the required monitoring activities for the 97-98 permit year. Both qualitative and quantitative monitoring data serve as an indicator of each facility's overall performance with BMP implementation, help build a comprehensive inventory of essential water quality data, assist in developing water quality standards, and more. For instance, analytical monitoring data provided in the Annual Reports present a potential source of information necessary to support the quantification of loads associated with storm water runoff from industrial sources, a step necessary to develop TMDLs. The types of monitoring summaries contained in the Annual Reports, if completed properly by facility operators, could reveal important facility-specific and compliance-related information such as how diligently a facility implemented the required monitoring activities, the quality of the storm water runoff generated from the facility, and whether the facility operator has reviewed and updated the facility's SWPPP, and reassessed the adequacy of existing BMPs in controlling storm water pollution.

Figure 2. Compliance with Annual Reporting Requirement among Selected Auto Dismantlers in Los Angeles County



[1] Figure 2 originally appeared in Chang 2001.

Figure 2 illustrates the trend in facilities' submittal of Annual Reports from 1992 to 1999. The overall height of a bar indicates the total percentage of Annual Reports submitted for a given permit year. The lower, lighter portion of bar indicates the proportion of facilities that submitted Annual Reports on or before July 1st. The upper, darker portion represents late submittals. Compliance is represented in percentages rather than actual number of reports submitted because the number of facilities *required* to submit Annual Reports varied over time because the facilities' coverage under the GISP program was initiated at different times (by 1996, all of the 52 selected facilities had filed a NOI).

As illustrated in Figure 2, compliance was low in the early years, with the majority of the facilities failing to submit the required Annual Reports for the 1993/94 and 1994/95 permit years, and with the majority of the reports arriving late. The lack of sound monitoring data, as a result of deficient reporting, would leave both the regulators and the dischargers in the dark about critical questions such as how successful an individual or a group of facilities' efforts have been in controlling storm water pollution at their site and their progress over the years. In addition, not having adequate analytical data substantially limits regulatory efforts to characterize the quantity of load associated with the storm water runoff from regulated communities. Without the data necessary to self-diagnose their facility's performance and a chance to address the deficiencies in a timely manner, facility operators are really placing themselves in jeopardy of increasing their environmental liability and the chances of regulatory enforcement actions and third-party lawsuits. Therefore, both the dischargers and the regulators are negatively impacted when facilities fail to monitor and report their monitoring results to the appropriate regulating agency.

Observations based on the 52 selected auto dismantling facilities revealed that starting in 1995/96, two-thirds or more of the required facilities submitted their Annual Reports. The highest Annual Report submittal rate (96%) achieved in 1997/98 and 1998/99 is an outcome of increased enforcement activities launched by the RWQCB in recent years and demonstrate the importance of and the need for aggressive, timely regulatory follow-up activities.

Several hundred enforcement letters were issued in 1997/98 to facilities across all industrial sectors that failed to submit Annual Reports on time. As apparent from Figure 2, the majority of the 1997/98 Annual Reports were received late, with most of them probably in response to the enforcement letters. The subsequent permit year had even greater success. While maintaining the Annual Report submittal rate at 96%, there was a substantial increase in the number of reports being submitted on time.

R0011129

Evidently, the large-scale enforcement activities, including the issuance of formal violation letters and mandatory penalties for recalcitrant violators, have resulted in tangible results and have demonstrated to be an effective tool for communicating to the regulated community the potential severe consequences of violating storm water regulations.

The usefulness of the Annual Reports to regulators and dischargers alike depends on the accuracy and the completeness of the reports being submitted. In the Los Angeles Region, much of the agency's limited resources have been dedicated in the past to identifying and following up with facilities that have failed to submit Annual Reports. Constrained by resources, limited regulatory attention was focused on the quality of the Annual Reports received or the monitoring results reported in the Annual Reports. This study conducted detailed reviews of the 1997/98 Annual Reports submitted by 50 of the 52 selected facilities to contribute to an increased understanding of the quality of Annual Reports and the monitoring data submitted by auto dismantling facilities.

Figure 3. Storm Water Monitoring Activities Conducted by 52 Selected Auto Dismantling Facilities (1997/98 Annual Reports)

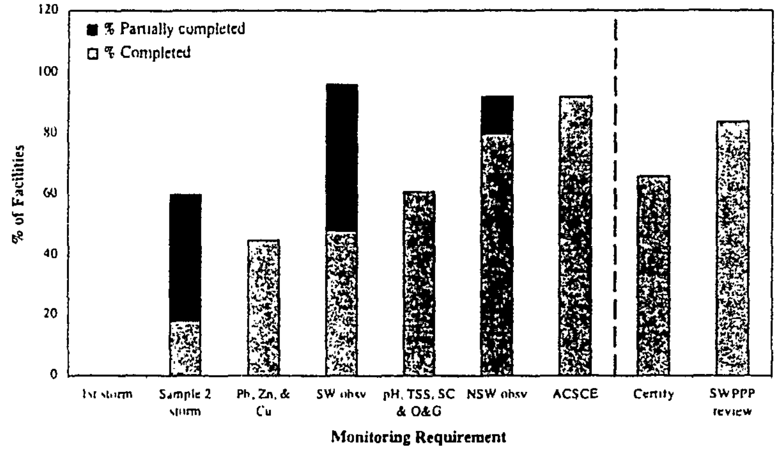


Figure 3 illustrates how successfully the 50 facilities that had submitted the Annual Reports fulfilled their required monitoring activities (two of the 52 facilities did not submit their Annual Reports). Results are presented in the order of low to high compliance, in terms of facilities that fully satisfied a monitoring requirement, as indicated by the bottom, lighter portion of a bar. The upper, darker portion represents facilities that partially completed a required monitoring activity. Bars to the left of the dashed line indicate monitoring activities and to the right are administrative requirements associated with the monitoring program. Monitoring requirements include: visual observations of storm water and non-storm water runoff, storm water sampling and analysis, and an annual comprehensive site evaluation that includes a full-scale site inspection and a SWPPP review and update. Table 3 augments the findings on the monitoring activities with detailed narrative description.

None of the individual categories of monitoring activities were completed by all 50 selected facilities. Overall, facilities were less likely to perform monitoring activities that are more cost- and effort-intensive, such as storm water sampling and analysis, than activities that are simple to perform and involve little or no cost, such as visual observations. This trend was observed even among activities such as visual observations that require minimal resources to perform. Approximately 80% of the facilities fully complied with the quarterly observation of non-storm water (a total of four observations required to be conducted under *dry* weather conditions). A

Table 3. Summary of Monitoring Activities Reported by for 50 Selected Auto Dismantling Facilities (1997/98 Annual Reports)

MONITORING REQUIREMENT	FACILITY COMPLIANCE						COMMENTS
	Completed		Partially Completed		Did Not Attempt		
1. Submit Annual Report by July 1st deadline	31	62%	19	38%	N/A	N/A	• "Completed" means facility submitted the Annual Report before or on 7/1/98. • "Partially Completed" means facility submitted Annual Report after 7/1/98. • "Did Not Attempt" means facility did not submit Annual Report.
2. Sample from two storm events	7	18%	16	42%	15	40%	• "Completed" means facility collected and analyzed sample(s) from two qualifying storm events. • "Partially Completed" means facility collected and analyzed sample(s) from one storm events. • "Did Not Attempt" means facility did not collect or analyze any sample. • Twelve out of the 50 facilities belonged to a Group Monitoring Program and were exempt from sampling during the 97-98 year. Therefore, statistics for Requirements #2-#4 reflect results for 38 facilities. • Most facilities that failed to collect samples from two storm events did not have adequate explanations. The 97-98 wet year is marked by unusually plentiful rainfall due to the El Niño phenomena.
3. Sample from the first storm	0	0%	N/A	N/A	38	100%	• The first flush occurred on a weekend. GISP does not mandate facility operators to collect storm water samples outside of their typical operating hours or under hazardous conditions. • 19 out of the 38 facilities provided inadequate reasons for not sampling from first storm; four out of the 38 facilities that failed to sample from first storm did not provide any explanation.
4. Analyze samples for pH, TSS, SC, and O&G	23	61%	0	0%	15	39%	• About 39% of the facilities failed to collect any samples • All 23 who sampled from at least one storm tested for these basic constituents.
5. Analyze samples for Cu, Pb, and Zn	17	45%	N/A	N/A	21	55%	• Seventeen facilities tested at least one set of samples for Pb, Cu, and Zn. • About 55% of the facilities either failed to sample at all or sampled from at least one storm but failed to analyze for metal.

R0011131

Table 3. Summary of Monitoring Activities Reported by for 50 Selected Auto Dismantling Facilities in 1997/98 Annual Reports

(Continued)

MONITORING REQUIREMENT	FACILITY COMPLIANCE						COMMENTS
	Completed		Partially Completed		Did Not Attempt		
6. Conduct quarterly non-storm water visual observations	40	80%	6	12%	4	8%	• "Completed" means facility conducted four quarterly observations. • "Partially Completed" means facility conducted at least one but less than four quarterly observations. • Two facilities attached a narrative description of the type of authorized non-storm water discharges observed from their site. However, when asked in the Annual Report whether the facility ever had authorized non-storm water discharges, both facility operators answered negative.
7. Conduct monthly storm water visual observations during the wet season (Oct. 1st - May 30th)	24	48%	24	48%	2	4%	• "Completed" means facility conducted eight monthly observations during the wet season (October to May). • "Partially Completed" means facility conducted at least one but less than eight monthly observations during the wet season. • If a month had no storm, the facility operator must report so.
8. Conduct annual site evaluation	46	92%	N/A	N/A	4	8%	• Four facilities that failed to conduct Annual Comprehensive Site Compliance Evaluation (ACSCE) provided no explanation.
9. Review SWPPP for BMPs and compliance	42	84%	N/A	N/A	8	16%	• Eight facilities that failed to review SWPPP provided no explanation.
10. Certify for compliance	33	66%	N/A	N/A	17	34%	• Of the 17 facilities that did not certify for compliance, 16 facilities cited their failure to meet one or more of the monitoring requirements as the reason for not certifying. • One facility did not provide any explanation for not certifying for compliance.

substantially smaller proportion of facilities (less than half) completed the storm water runoff observations (a total of eight monthly observations activities during *rain* event).

None of the facilities were able to collect samples from the first storm event because the first storm event of the 1997/98 wet season occurred on a Sunday for most of the Los Angeles region (Facilities are not required to sample outside of their normal business hours or under dangerous conditions). Some facilities did not provide a valid explanation for their failure to sample from the first storm event. Less than 20% of those *required* actually sampled from two storms events, as required by the GISP (note: Some facilities that belong to a group monitoring program are subject to less frequent sampling. This study appropriately accounted for those facilities in its analysis). The 1997/98 wet season was impacted by El Niño and had unusually frequent and intense storm events, therefore ruling out the lack of sufficient rain as one of the valid excuses for not sampling. Less than half of those required actually analyzed for copper, lead, and zinc. And among the facilities that sampled from at least one storm, about a quarter did not analyze for the required metals. Failure of facilities to analyze for the designated constituents --i.e. specific pollutants determined by regulators to be of concern for a particular industry -- really hinders efforts to quantitatively evaluate a facility's performance and to gauge potential water quality impact.

Inherent to self-reported information without QA/QC procedures is the uncertainty in the accuracy of the data provided. Annual Reports are subject to similar deficiencies. Each Annual Report must contain a self-certification of compliance signed by the facility operator or equivalent. Whether self-certifications are a reliable gauge for measuring facility compliance depends on several factors including a facility operators' level of understanding and informed interpretation of the GISP requirements and their ability to appropriately assess and accurately report the facility's compliance status. To evaluate how accurately the Annual Reports reflect facility compliance, this study compared the number of Annual Reports self-certified for compliance against the number of facilities reported to have successfully complied with a particular category of monitoring requirement. We considered a monitoring activity that is required of *all* facilities- monthly visual observation of storm water discharges. According to Table 4, less than half, 48%, completed all eight monthly visual observations of storm water, which implies that an equal or smaller number should have certified for compliance, considering the fact that a facility must also satisfy all the other GISP requirements before certifying for compliance. About two-thirds of the Annual Reports were self-certified, pointing to a discrepancy of at least about 20% between those certifying for compliance and those actually complying. It should be noted that only one monitoring activity was considered here. In reality, the actual gap between the number that self-certified and the number that fully completed all required monitoring activities or all GISP requirements is expected to be considerably larger.

Whether this discrepancy is due to a flawed interpretation of compliance criteria, mere carelessness on the part of the facility operator, or unwillingness to openly expose or admit one's deficiency for fear of potential enforcement, one conclusion that can be drawn is that self-certification is not a perfect indicator of facility compliance and should be used with caution when used to estimate permittee compliance.

STORM WATER POLLUTION PREVENTION PLAN

A hallmark of the P2 approach, which drives the GISP program, is the reliance on the facility operators to identify potential pollutant sources and appropriate site-specific BMPs to achieve P2 at their facility. The underlying assumption is that facility operators are the ones most familiar with the facility operations and other site-specific conditions. Therefore, facility operators are considered the ideal candidates for identifying site-specific solutions for their facility.

The GISP requires each facility operator to develop a SWPPP, which is a site-specific document that lays out exactly how a facility will control storm water pollution associated with its industrial activities. Compliance with the SWPPP requirement has not been well characterized because, unlike Annual Reports, SWPPPs are not required to be submitted to the RWQCB. An in-depth review of SWPPPs that considers the site-specific nature of each facility requires a substantial amount of time. This study is one of the first attempts in California and perhaps in the nation to characterize, on a large scale, the quality of the SWPPPs prepared by and for a specific industrial sector. A detailed review was provided for the 50 SWPPPs received based on specific SWPPP-related requirements outlined in Section A of the GISP. A summary of the deficiencies found in the SWPPPs are described in Table 4.

One major deficiency noted in many of the SWPPPs was that they were boiler-plate documents that lacked specific details on the actual BMPs chosen for implementation by the facility operator. Also missing were procedural details about how the BMPs would be implemented. About 90% of the SWPPPs reviewed were prepared by one of four consulting companies. Many of the SWPPPs were written in a vague manner that made it difficult to determine exactly which measure, among a set of "ideal" or "proposed" BMPs described in the document, was chosen for implementation by the facility operator.

As indicated in italics in Table 4, these SWPPPs provided no or limited information on: 1) the name(s) of individual(s) responsible for the implementation of various monitoring activities; 2) a detailed, comprehensive site map that describes the locations of pollutant sources and where industrial activities are conducted; and 3) BMPs that are fundamental to the P2 efforts, such as employee training, site inspection, and good housekeeping programs. In essence, a SWPPP is a "blue-print" that describes specific measures and a schedule of implementation a facility will employ to achieve P2 and regulatory compliance. The SWPPP should be a "living" document that is regularly updated and reflects the actual site conditions. Given their generally poor quality, the majority of the SWPPPs reviewed fail to effectively guide facility operators in the field implementation phase. From verbal communication with facility operators, it appeared that many SWPPPs were being developed by a third party with little involvement or input from the facility operators or key personnel. About a quarter of the 52 facility operators who had called after receiving the RWQCB's formal request for SWPPPs demonstrated little or no knowledge of the SWPPP requirement, indicating

Table 4. Review of SWPPPs and Written Monitoring Programs Submitted by about[1] 50 Selected Auto Dismantling Facility Operators (Los Angeles County, 1999)

Element Specified in General Permit	Missing	Inadequate Description

Submission of Annual Report by July 1st of each year	5	0
C. Standard Provisions		
Certification and signature of facility operator	3	0

[1] SWPPPs and written monitoring programs were received from 50 and 47 of the 52 selected facilities, respectively.
[2] GISP encourages facility operators to consider structural BMPs *if* the non-structural BMPs chosen are considered insufficient to adequately address the pollutants present. Therefore, the review of structural BMPs was limited to evaluating whether the facility had considered any of the five categories of structural BMPs described in the GISP. For example, it was considered adequate for the purpose of this study if a SWPPP cited that structural BMPs were reviewed and considered but not chosen for implementation because the non-structural BMPs were considered sufficient.

how closely they were involved with preparing their facility's SWPPP. Also, discussions with facility operators during the case study investigations indicated that the facility operators were either unfamiliar or unsure about many BMPs described in their SWPPP. Some facility operators admitted to not fully understanding all aspects of the SWPPP, including the BMPs described, and expressed reservations about their ability to implement certain structural BMPs described in the SWPPP, when it was explained to them what those measures were and the potential consequences for failing to fully implement the SWPPP which they had certified to implement. The lack of or limited facility operator involvement in preparing the facility's SWPPP and in selecting the appropriate BMPs for the facility appears to be one of the main reasons for the disconnect observed between the descriptions provided in a facility's SWPPP and what is actually being implemented in the field.

WRITTEN MONITORING PROGRAMS

How does a facility measure its performance or progress in P2 efforts or gauge the effectiveness of the BMPs implemented? By monitoring. As a requirement of the GISP, facilities must prepare a written monitoring program. The purpose of a written monitoring program is to ensure that proper methods are provided so that facility operators may employ these methods consistently in monitoring their site conditions and the storm water runoff generated from their site. In turn, this would generate monitoring results - both qualitative and quantitative - that are representative of the facility's site conditions and which could provide useful information on a facility's progress over the years.

Out of the 52 requested, 47 auto dismantling facilities submitted their written monitoring programs. The majority of the monitoring programs were prepared by consultants, and had characteristically similar problems as the SWPPPs. Table 4 summarizes some of the deficiencies found in the written monitoring programs per requirements outlined in Section B of the GISP. The documents generally lacked in procedural details explaining how each monitoring activity would be performed. For example, sections on sampling and analysis requirements did not describe the type of sampling equipment to be used, QA/QC procedures, or special precautions needed to provide a well-controlled environment for collecting, storing, and transporting the samples to certified laboratories for analysis. The lack of sufficient procedural details in the written monitoring programs raises questions about the QA/QC procedures used by facilities for their monitoring activities, especially during sample collection, storage, and transport. And this deficiency limits the reliability and the credibility of the storm water analytical data reported in the Annual Reports. Thus, regulators should use the monitoring results provided in the Annual Reports with caution, keeping in mind some of the limitations discussed above. Another flaw observed in a significant number of the monitoring programs is outdated information that fails to reflect the changes included in the 1997 reissued permit. For example, the minimum period required for retaining records increased from 3 years to 5 years in the 1997 permit. However, many monitoring programs still specified 3 years for the minimum required record retention period. Also, many still used the old definition of a wet season (September to April) instead of October through May, as defined in the 1997 permit. Failure to update the SWPPP per new permit conditions affects a facility's ability to comply with the regulatory requirements.

Many of the nine case study facilities that hired consultants to prepare their storm water documents also depended entirely on them to conduct many, if not all, of their monitoring activities. It appears, from discussions with facility operators, that some consultants perform the required monitoring activities alone, unaccompanied by any facility personnel, and provide a written report, summarizing qualitative and/or quantitative monitoring results, to the facility operator at a later time. Although this type of monitoring may technically meet certain regulatory requirement(s), it tends to remove from the facility operator or other key facility personnel the opportunity to fully assess and understand the site conditions first-hand and to seek out the additional steps that may be necessary to make further progress.

Increased compliance assurance activities by regulators, including random audits and formal request of SWPPPs and monitoring programs for review, as well as timely follow-up responses, are some ways to enhance the quality of these storm water documents. In addition, since some of the major problems, including the lack of site-specificity of the documents, are due to the consultants working on these documents, a time-efficient and effective approach would be for the regulating agency to target those few consultants who prepare the documents for the majority in the industry for regular education and training them so that the SWPPPs and the monitoring programs they prepare are up to speed with the GISP requirements. Another recommendation is for the regulating agency to consider the option of requiring all SWPPPs prepared by a third party to be certified to ensure that the details of the monitoring programs selected for implementation have been fully discussed, understood, and agreed upon by facility operators, and that a key facility personnel will conduct or personally accompany the consultant(s) on all of the monitoring activities.

CASE STUDY INVESTIGATIONS: SITE INSPECTIONS

The first and second tiers of compliance establish the foundation for achieving pollution reduction and/or prevention. However, it is only the compliance with the third tier requirements, the onsite implementation, that results in actual pollution abatement and directly impacts water quality. Staff conducted field investigations of nine selected auto dismantling facilities to study their onsite performance.

The field compliance component of the industrial storm water program has generally not been well characterized for the Los Angeles region due to lack of resources available for the GISP program in the past and other competing priorities. However, the general perception is that field compliance is low especially among small facilities. Substantial staff time is required to complete a comprehensive site inspection, which includes pre-inspection preparation, the actual inspection, and post-inspection follow-up activities including completing an inspection report.

Table 5 summarizes some characteristics of the nine case study facilities, including their property size, percent of imperviousness, and the estimated annual vehicle throughput or the number of vehicles processed yearly. Percent imperviousness refers to the portion of a facility property that is paved, roofed (including buildings), or covered. As shown in Table 5, the case study facilities span a wide spectrum in terms of their annual vehicle throughput, property size, and percent imperviousness. One facility

Facility	Property Size (Acres)	Percent Imperviousness (% Paved, Roofed or Inside Building)	Annual Vehicle Throughput
A	2	60	175 - 250
B	0.7	100	80 - 120
C	2	100	180
D	1	100	50
E	1.5	100	75 - 200 (trucks)
F	0.7	100	120
G	1.5	100	150 (trucks)
H	13	100	16,800
I	0.6	32	110

Table 5. Characterization of Nine Case Study Auto Dismantling Facilities

(Facility H) offered "self-service"- i.e. it allows customers to dismantle desired parts directly from the vehicles. The rest of the Facilities, A through G and I, offered retail, "over-the-counter" service and sold already dismantled parts to customers.

Table 6 summarizes some key findings on facility BMP implementation based on staff site inspections. A more complete assessment is presented in Table 7, which provides numerical ratings (from 0 to 3) on how well individual case study facilities implemented the BMPs described in the facility's SWPPPs and other BMPs considered either universally applicable or especially effective for the auto dismantling industry. A facility's overall BMP implementation score -- the sum of individual BMP ratings -- was used to evaluate a possible correlation between a facility's performance and water quality impacts, which is presented in a subsequent section (Appendix B augments Table 7 with the information on the kinds of pollutant sources or activities conducted at each facility and the BMPs that were cited in the facility's SWPPP). The SWPPPs prepared for the nine case study facilities included very similar, overlapping BMPs, primarily consisting of non-structural measures. In general, the findings of this study concur with the trend analyzed in a previous study on the transportation industry by Duke and Chung (1996) that concluded that storm water control measures described similarly in SWPPPs at a number of case study facilities were not uniformly implemented and unequally effective at managing storm water pollutants. As shown in Table 6, some BMPs were more frequently implemented than others.

Table 6. Evaluation of BMPs Implemented at the Nine Case Study Auto Dismantling Facilities

BMP Types	Fully	Partially
Overhead cover for dismantling area	0	3
Cover parts	1	7
2° Containment for fluid-storing container	3	2
Overhead cover for fluid storage	4	3
Pave entire site	7	1
Conduct dismantling on impervious area	8	0

This study also found that BMPs that are more resource-intensive or pose physical constraints on daily operational activities are less likely to be implemented. The structural BMPs cited in the case study facilities' SWPPPs were often missing or if provided at all, were not fully implemented. The first four BMPs that appear in Table 6 (overhead coverage for dismantling and fluid storage areas, coverage for stored part, and secondary containment for fluid storage area) are examples of measures specifically designed to help eliminate or reduce the exposure of pollutant sources to storm water, but yield little apparent tangible benefits for daily operational activities. Only a few facilities successfully implemented these BMPs. More often than not, dismantling activities were conducted outside in an open space, even when a designated roofed area (with three-sided walls) was provided. Staff noticed that one deterrent was the

Table 7. BMP Performance Observed at the Nine Case Study Auto Dismantling Facilities

Activity/ Pollutant Source	Applicable BMPs	BMP Rating[a]								
		A	B	C	D	E	F	G	H	I
Dismantling (includes fluid draining)	Conduct Activity on Impervious area	3	3	3	3	3	3	3	3	0
	Provide overhead cover	1	0	2	0	0	2	0	0	0

General	Recordkeeping (copy of GISP, SWPPP, MP, Annual Reports, monitoring records)	1	1	2	1	3	3	1	3	1
General	Storm water treatment	0	0	0	0	2	0	0	2	0
Overall BMP Score		31	27	39	35	38	48	26	34	46

[a] For BMP implementation rating, 0=Not implemented; 1= Poorly implemented; 2= Somewhat poorly implemented; 3= adequately implemented, N/A= not applicable, N/O= Not observed during site inspection.
[b] An overall BMP score is the sum of individual BMP ratings. Two BMPs that were excluded when calculating an overall BMP rating scores. The two BMPs are related to auto compaction activities and recordkeeping activities. Auto compaction-related BMP was left out because eight out of the nine case study facilities did not perform auto compaction and to consider this BMP would necessarily bias the results against the eight facilities. Recordkeeping has a definite indirect contribution toward the successful implementation of a facility's storm water program, but was not included because it is an administrative procedure and in itself does not result in pollution prevention.

insufficient overhead and work space that restricted the movement or the maneuvering of employees during dismantling activities or imposed limitations in forklift-aided transfer of vehicles to and from the designated area. These limitations could have been avoided with a more careful strategic planning of the BMP, that considers adequate work space.

Some BMPs were not implemented by many facilities because of the effort involved in consistently implementing the BMP and other factors. These BMPs include covering parts during storm events and the use of absorbents to control spills. For example, most facilities cited in their SWPPPs that plastic sheets, tarpaulins, or other types of temporary covers would be used to shield vehicle parts from rain. The use of plastic sheets or tarpaulins involves minimal cost for material acquisition but is beset by the following difficulties: (1) unless secured appropriately, tarps or plastic sheets tend to be blown away by wind and provide minimal protection from rain, if any; (2) providing temporary covers depends entirely on the effort of facility employees and are less likely to be implemented consistently and completely, especially under severe storm conditions or if a storm event starts before or after normal business hours; and (3) some facility operators cited other factors, such as tarps placed over the parts storage areas disappearing over night, most likely claimed by itinerant individuals or children in the neighborhood. Given these limitations associated with using temporary covers, facility operators should be strongly encouraged to install permanent roofs or an overhead coverage to effectively reduce exposure of stored parts to precipitation. Another BMP shown to be inconsistently implemented is the use of absorbents to control spills and leaks. Supply maintenance and timely responses are especially crucial for spill-related BMPs. Many case study facilities were deficient in implementing their spill control measures, judging by the degree of spills, leaks, and stains from past spills present on the facility ground. Failure to maintain an adequate supply of spill absorbents on site, the diligent effort required to address small frequent spills, and the lack of urgency that small spills pose compared to large-scale spills are some reasons cited by facility employees for their failure to provide spill control and response measures mentioned in the facility's SWPPPs. Instead of providing immediate attention, many facility employees delayed spill clean-up activities until the end of the business day.

Several major sources contributing oil and grease in storm water runoff were visually identified during the site inspections. Qualitatively judging from the rainbow-colored sheen floating on top of the storm water runoff, failing secondary containment, such as leaky truckbeds used to store incompletely drained parts, fluid-storage areas missing adequate secondary containment or overhead covers, unprotected dismantling areas, and auto compaction location appeared to be the principal sources introducing high levels of oil and grease into storm water from the case study facilities. All of these sources represent areas associated with principal industrial activities.

A recommendation based on these site inspection observations is to provide both an overhead coverage and an adequate (secondary) containment for areas associated with principal industrial activities. Conducting all activities inside a building or roofed, bermed (or curbed) areas would really help minimize or eliminate the introduction of pollutants into storm water runoff. To maximize the usefulness of these structural BMPs, adequate working space and overhead room are two critical factors that need to be considered in the planning stage of these BMPs. There are BMPs such as storing well-drained parts in large autobodies (as observed at Facility I) that allows facility operators to use materials readily available onsite and does not necessitate building a structure. However, this type of BMP, to be effectively implemented, requires extra effort and vigilance on the part of the facility staff (and are thus less likely to be implemented successfully) since parts must be thoroughly drained prior to being placed inside the autobodies, as opposed to parts stored in bermed areas which prevent runoff of residual fluids. Some specific measures to protect the fluid storage areas that have been shown to be effective in the field include a combination of providing an overhead roof or a clean solid board (placed on top of fluid-storing drums) along with the use of sealed, flat-bottom truckbeds, berms, or a secondary drum large enough to fit another drum inside. Secondary drums should preferably be filled with sand or other spill absorbent material, and sufficiently large and low enough so that the inner fluid-containing drum could easily be transported in and out using a forklift.

The primary cause of significant spills observed during auto compaction is incomplete draining of fluids from parts that remain on the vehicles. Facility H, the only case study facility that conducted auto compaction activities, removed most cores (unwanted parts) prior to vehicle compaction after customers had a chance to claim the desired parts. Based on the substantial spills observed during its auto compaction process, the facility apparently had neglected to completely drain residual fluids from the parts remaining on the vehicles, causing fluids to jet out well beyond the surrounding berm during the compaction process. Complete fluid draining upon vehicle arrival is crucial to preventing spills generated during vehicle staging or compaction process.

Many BMPs must be implemented in combination with other BMPs to be effective. A set of BMPs that appears to be especially effective when implemented together is secondary containment and overhead coverage as mentioned above. Overhead coverage helps to eliminate the exposure of pollutants to storm water runoff but not for spills traveling away from, for example, a roofed fluid-storage area. Similarly, severe storms could flood uncovered, bermed areas and introduce pollutants to storm water runoff. When combined, these BMPs could effectively reduce pollutant contact with storm water. Few facilities provided both of these BMPs for the same source area.

Other BMPs implemented by the case study facilities (storing parts off-ground or removing greasy parts from vehicles) by themselves offer minimal or limited pollution control. For example, mounting partially-drained parts or fluid-storing drums on wooden pallets could appear to reduce contact with storm water runoff; however, spills and leaks generated during parts or fluid transfer typically flow over the pallets and contaminate the site ground and make contact with storm water. Mounting fluid-storing drums on top of pallets does not help contain spills and leaks and is not a secondary containment measure, contrary to the claims of some facility operators. Even when parts are fully drained before being placed on pallets, they must be provided with adequate cover to minimize exposure to storm water. Site pavement, which is considered as a stand-alone solution to controlling sediment in storm water, could only offer some degree of control of solids in storm water when facilities have poor housekeeping practices. Facility B had the entire site paved, but the level of total suspended solids (TSS) in its storm water samples substantially exceeded the USEPA benchmark for this constituent. In fact, the facility's TSS level was comparable to other case study facilities with partial or almost no site pavement. A potential source of sediment in storm water generated from completely paved sites is soil from vehicle tires or customers' shoes.

Several factors were considered in identifying potential reasons for the varying degree of BMP implementation observed at the nine case study facilities. The number of employees, facility size, and annual vehicle throughput did not appear to correlate well with a facility's ability to effectively implement BMPs for facilities with five or less personnel, of two acres or less, or with yearly vehicle throughput of less than 300. The eight facilities that fell within this category demonstrated significant differences in their BMP implementation efforts. Facility H, with 16,800 annual vehicle throughput and a 13-acre site, provided several environmentally-trained personnel onsite, maintained efficient recordkeeping, offered regular training for all its employees, and provided storm water treatment, including an oil and water separator for a portion of the site's storm water runoff and an adequate supply of excelsior in the primary discharge location. However, because of the small study pool, with only one facility of this caliber, it is difficult to arrive at a conclusion as to whether facilities with greater resources are more likely to fully implement their BMPs and other storm water program requirements. The performance of this facility could very well have been compelled by an aggressive third-party lawsuit launched by a local non-profit environmental organization against the facility in the recent past.

Cultural or language barriers and the lack of public outreach were identified as two potential reasons for the deficient BMP implementation. The different ethnic backgrounds represented among auto dismantlers in Los Angeles County include Armenian, Mexican, Korean, Persian, and Caucasian, with the first two groups representing the dominant ethnic groups in some areas. From phone conversations and discussions from the site inspections, it became apparent that many of the ethnic minorities did not fully understand the GISP instructions and some had trouble following the verbal instructions of staff. This may partially explain the apparent disconnect between the consultant-prepared SWPPPs and the actual implementation of BMPs onsite. Many of the case study facility operators displayed complete ignorance and a sense of apathy about the significance of storm water pollution, and complained about having to pay for the discharge of naturally-occurring storm water, clearly missing the key point that it is the *pollution* in the storm water runoff that they are responsible for.

One of the key findings of this present study based on the staff's site-inspection experiences is that determining onsite compliance can be rather challenging and not very straightforward for both dischargers and regulators. This is especially true for facilities that are not grossly deficient or sloppy in their housekeeping or operational practices. More accurately, if compliance is to be defined to ensure protection of waterbodies and to prohibit contributing to possible excursion of all applicable water quality standards, as is stated in the GISP, the task of accurately assessing compliance becomes even more daunting because of the following three reasons.

First, the GISP does not specify a mandatory, minimum set of BMPs that must be implemented by all permittees or by each industry. The GISP basically states that facility operators should *consider* the different categories of BMPs outlined in the permit and then select and implement appropriate BMPs to attain the Best Available

Technology (BAT) level. However, the permit does not define what the BAT level is or how to demonstrate that the BAT level has been ascertained. Therefore, facility operators belonging to the same industry may choose from a range of different BMPs - either a single, highly effective BMP, such as treatment, or a combination of multiple BMPs whose cumulative impact may be equally effective. The P2 approach with its primary reliance on facility operators to identify and implement site-specific solutions offers flexibility and room for economic considerations. However, it also presents difficulties for those charged with the responsibility of assessing whether the BMPs provided and as implemented are sufficiently adequate to ensure that the facility's storm water discharges are not contributing to or causing exceedances of water quality standards. There is still limited information on the effectiveness of specific BMPs or the cumulative effects of combined BMPs. And to leave this task of compliance determination up to the individual operator's judgement seems to be questionable regulatory policy.

Secondly, there are no numerical effluent limitations in the GISP, with the exception of a small group of facilities specified under USEPA regulations (40 CFR Subchapter N), that could provide a clear, objective standard for compliance for all regulated facilities across industries. In the absence of a quantifiable measure of compliance, site inspections can, at most, point out whether certain BMPs in a facility's SWPPP are being implemented and identify evidence of pollution, including spills and leaks, that could visually indicate a facility's overall BMP effectiveness. However, to be able to link (visual) compliance with water quality impacts, one must come up with a quantifiable or numeric compliance standard based on water quality criteria.

Thirdly, not all BMPs are readily observable, in particular the non-structural ones when the activities targeted are not being performed. Thus, the implementation status of certain BMPs can be difficult to determine for individuals not part of the facility since site inspections provide only a snapshot in time of the facility's performance. Examples of such BMPs include preventative maintenance of equipment (unless records are maintained on file) or if special caution is employed for certain operating procedures.

Clearly, the overall success of a facility's BMP implementation efforts could qualitatively be judged based on the evidence of pollution, such as spills and stains. However, such qualitative assessment necessarily introduces the subjectivity of the observer and is prone to different interpretations about how well the facilities may be complying with the intent and the requirements of the GISP. As the saying goes, "how clean is clean?" Should facilities feel "safe" as long as they provide reasonably adequate housekeeping (but according to whose standard?) and maintain an overall neat appearance, or do they need to make sure their site is meticulous? Are facilities considered to be in compliance as long as the BMPs provided in the SWPPP are being implemented, or would they be penalized for choosing BMPs inadequate for their activities? Of course, the use of a "common sense" approach and close interaction with the regulating agency could help facilities to move forward. However, for all these efforts of the regulators and permittees to pay off or result in substantially improved water quality, there must be some type of clear quantifiable standards of compliance that could be enforced.

two facilities which appeared more organized and had signs of good housekeeping practices.

Storm water analytical monitoring data demonstrated a substantial degree of variability between facilities, storm events, and sampling events. For the eight case study facilities, pollutant concentrations or measurements varied by more than a factor of seven for TSS, ten for specific conductance (SC), six for oil & grease (O&G), four for copper (Cu), ten for iron (Fe), eight for lead (Pb), and two for zinc (Zn). The lows and highs in the pollutant concentration range were: 6.8 and 9.0 for pH, 38 and 292 (mg/L) for TSS, 39 and 395 (μmho/com) for specific conductance, 11 and 73 (mg/L) for oil & grease, 812 and 3090 (μg/L) for aluminum, 67 and 259 (μg/L) for copper, 320 and 1170 (μg/L) for iron, 35 and 284 (μg/L) for lead, and 330 and 766 (μg/L) for zinc (some results for aluminum reported as < 1000 μg/L could be less than 812.).

Some interesting trends were observed in the self-monitored storm water analytical data (reported by the case study facilities) for samples collected over multiple years, for a given wet season, and on the same day. Figures 4 through 10, which evaluated the data reported by Facility H for the period between 1993 to 1999, clearly demonstrate the stochastic nature of storm water runoff. No clear increasing or decreasing trend in pollutant concentrations over time is recognized.

An analysis involving five sets of data generated by Facility H for the 1998/99 wet season demonstrated that the highs and the lows in pollutant concentrations of storm water from one facility could vary substantially for a given wet season: by more than a factor of seven for TSS, two for specific conductance, five for oil & grease, three for lead, twelve for aluminum, four for iron, and two for chemical oxygen demand (Facility H had submitted five sets of data for the wet year 1998/99). Again, no consistent trend of increase or decrease was observed in the data set spanning one wet season.

Table 9. Comparison of Pollutant Concentrations in Storm Water Samples Collected on Same Day by Different Individuals for Two Case Study Auto Dismantling Facilities.

Constituents	Facility B (sampled on 2/9/99)		Facility H (sampled on 3/25/99)	
	Facility	Staff	Facility	Staff
pH	9	9	7.42	8
TSS (mg/L)	100	210	183	202
SC (μmho/cm)	160	334	487	395
O&G (mg/L)	9	22	17	65
Pb (mg/L)	0.085	0.284	0.1	0.069
Cu (mg/L)	0.44	0.134	0.21	0.238
Zn (mg/L)	0.3	0.754	0.28	0.33
Al (mg/L)	N/A	N/A	0.21	3.09
Fe (mg/L)	N/A	N/A	4.8	2.8

We evaluated two sites (Facilities B and H) where the facility operator and our staff collected the storm water samples on the same day to determine the extent of variation in pollutant concentrations for samples collected on the same day. Table 9 compares the analytical data reported by the facility versus agency staff. Analytical results on Facilities B and H demonstrated that storm water samples taken on the same day by different individuals, in this case by RWQCB staff and by facility personnel, can display quite different results. Facility H's data (where staff collected samples immediately after a facility employees completed his sampling for the facility) indicated that the reported concentration for the following five constituents (TSS, specific conductance, oil & grease, lead,

copper, and zinc) differed by at least 20% and up to 1400% between the two sets of data, with the most significant differences observed for oil & grease (280%), and for aluminum (1400%). An interesting trend observed with Facility B's data was that for five out of the six constituents (TSS, specific conductance, oil & grease, lead, and zinc) agency-generated data were higher than the facility's self-reported data by at least 100% and up to 230%. This suggests that perhaps different sampling strategies -- agency staff attempted to capture storm water runoff with a visible oily sheen -- could produce substantially different results, even for a same-day sampling.

One of the goals of storm water sampling at the case study facilities was to provide a well-controlled sampling environment with an adequate QA/QC necessary to generate reliable data that could be used to relate meaningfully the effects of BMPs on water quality. Two methods were used to relate BMP implementation to pollutant concentrations in storm water runoff. The first method attempted to evaluate the overall BMP implementation scores of each facility, derived based on a systematic rating system, in the context of storm water concentrations. The second method used the overall site appearance or impression as a qualitative indicator of the relative concentration of pollutants in storm water runoff.

With the first method, we tested for both linearity (r) and causality (r^2) between BMP implementation and storm water concentration by plotting for each constituent the pollutant concentration against the overall BMP score of each facility (The overall BMP scores are presented in Table 7.) The r and r^2 values were all less than 0.5 and 0.25, respectively. This implies that a mathematical relationship of the type employed in this study may not be a suitable method for relating the effects of BMPs with the runoff quality, based on the results of our case study. Possible reasons that a clear relationship between overall BMP score and the pollutant concentrations were not observed include:

- the chosen method does not take into account the degree of effectiveness of individual BMPs (this study rated the BMPs only on how completely or satisfactorily each BMP was implemented at the facilities, and summed the ratings to obtain an overall BMP score. This is essentially equivalent to assuming that all BMPs are equally effective and assigining them equal weights);

- site-specific factors, such as annual vehicle throughput; when the last batch of vehicles arrived and were dismantled; how many storm events preceded the sampling activity; and the time lapsed between the start of a rain and a sampling event, and rainfall intensity, are not considered by the above method.

It should be noted that due to the short duration of storm events and the lack of staff to cover all eight case study facilities at the same time, sampling was collected over three separate events between February and April of 1999. The inspections were performed between November of 1998 and April of 1999.

The overall site appearance or evidence of diligent implementation of good housekeeping practices seems to be a useful indicator of the relative pollutant levels between sites with similar facility size, annual throughput, and operational activities. Generally, case study facilities that were organized and clean showed relatively lower pollutant concentration levels, with the exception of one site (Facility G). Storm water samples from Facilities A and B, on average, showed much higher pollutant concentrations than those from Facilities E and F. Facilities A and B were prime examples of sites with negligent housekeeping activities, prevalent spills on the ground, and little or no coverage provided for greasy parts. Facilities E and F had a relatively organized site, had minimal spills on the ground, and appeared to segregate parts (greasy parts stored indoors or protected from rain).

Facility G was conspicuously one of the dirtier facilities with prevalent spills and greasy parts covering the facility ground. Surprisingly, the facility had relatively low pollutant concentrations in its storm water samples. The facility had the following physical characteristics that could have contributed to masking or obscuring the effects of pollution present onsite. The facility ground had many depressions, which reduced the amount of runoff and created pools of standing water. The surface grade of this facility was not uniform, resulting not in sheet flow traveling in one direction but runoff meandering and exiting the site in multiple directions. Indeed, there was some runoff from the facility, but the hydraulic gradient of the facility was such that there was no single primary discharge point. The challenge was in determining whether the samples being collected were representative of runoff from areas of principal industrial activities. The uncharacteristically low pollutant concentrations imply that the samples were probably not representative of general site conditions. To rely only on one set of perhaps not-so-representative analytical results to judge the adequacy of one's BMP performance would be a major oversight in this case because the results do not accurately reflect the site conditions.

The above example points to some of the difficulties in collecting representative samples and the importance of not only obtaining indicative samples but also being able to properly interpret analytical results in the context of conditions under which sampling was conducted. One solution is to obtain grab samples from every discharge location to obtain representative samples. Although the GISP requires facilities to obtain samples representative of the site conditions (multiple sets if necessary), self-reported data submitted as part of the Annual Reports indicate that nearly all facilities that perform any sampling at all only obtain one set of samples for each storm event (For some facilities with only one primary discharge location, one set of grab samples may suffice.)

In conclusion, there is a substantial degree of variation in the pollutant levels in storm water samples from facilities conducting similar industrial activities. The observed trend between BMP implementation and storm water quality is that a more diligent implementation of (a greater number of) BMPs is likely to result in a lower pollutant concentration. The storm water programs, as implemented by the eight case study facilities, failed to attain the USEPA benchmark levels for most constituents. It is unclear whether the benchmark levels could have been met had the facilities diligently implemented *all* the BMPs described in their SWPPPs, or if additional BMPs would have been required. A more clear standard of compliance is needed in the GISP. The GISP should either specify a measurable endpoint -- either by establishing a minimum set of baseline BMPs to be implemented or by providing numerical effluent limitations- that could be used to demonstrate whether a facility has attained the desired BAT level and has indeed achieved compliance.

Now, how does all this relate to water quality impacts on receiving waterbodies? Here we turn our attention to pollutant loads.

POLLUTANT LOADS

Load estimates are necessary to accurately assess the potential impact of various sources of pollution on receiving waterbodies. In this section we evaluated the storm water-related load contributed by auto dismantling facilities in Los Angeles County. The following mathematical equation known as the EPA Simple Method was used to estimate the range of loads generated from the auto dismantling industry in the form of storm water pollution (Chandler 1994):

$$L = 0.227*P*Pj*A*C(0.05 + 0.009*I)$$

Parameters considered in load estimates include pollutant concentrations, rainfall intensity, and other site- and or industry-specific physical parameters. Loads were estimated for individual watersheds in Los Angeles County.

For the purpose of this study, rather than calculating the load for each individual site and then adding the loads to obtain an estimate for an entire watershed, we used a simpler approach by using average values for pollutant concentration, site percent imperviousness, and facility size based on self-reported information available in the RWQCB's NOI database or in the facility's SWPPP. For area, A, area occupied per watershed by auto dismantling establishments was estimated by multiplying the following three factors: a) the total number of auto dismantlers in Los Angeles County (404) estimated earlier in this study; b) the proportion of auto dismantling facilities located in each watershed area, determined based on zip codes of all dismantlers with an active NOI; and c) the average size of auto dismantling facilities located in each watershed. Precipitation information was obtained from Los Angeles County Department of Public Works, Hydrology Division. Precipitation of 0.1 inch was considered as the threshold or the minimum rainfall needed to generate runoff. One or two reference monitoring sites were chosen per watershed to determine the annual precipitation and runoff volume specific to each watershed. Appendix E provides more details on how each parameter was derived.

Although the EPA Simple Method specifies that flow-weighted concentrations should be used, this study used the storm water analytical data for the grab samples collected by RWQCB staff from the eight case study facilities for two primary reasons. First, there are no known flow-weighted (pollutant) composite data of storm water runoff from auto dismantling sites that reflect the climatic and precipitation patterns of Southern California. Second, the agency data was generated using reliable and replicable QA/QC procedures, which makes it more useful than self-reported data submitted by facilities with unknown QA/QC.

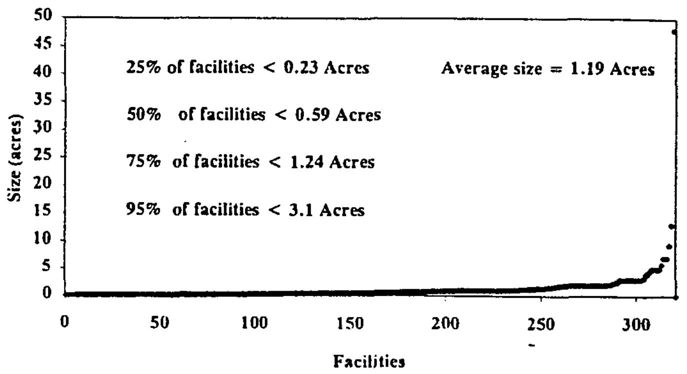
Table 10 summarizes the geographical distribution and the average size of auto dismantling facilities in Los Angeles County per watershed. As of August 1999, approximately 58% of the auto dismantlers in Los Angeles County were located in the Los Angeles River watershed; 25% in the Dominguez Channel watershed; 16% in the

Table 10. Geographical Distribution and Average Size of Auto Dismantling Facilities in Individual Watersheds in Los Angeles County.

Watershed	Estimated number of auto dismantling facilities	Average facility size (acres)	Estimated total source area (acres)
Los Angeles River	234 (57.8%)	1.215	284 (63%)
Dominguez Channel	103 (25.4%)	0937	96 (21%)
San Gabriel River	63 (15.6%)	1.06	67 (15%)
Santa Clara River	2 (0.6%)	1.31	3.2 (0.7%)
Santa Monica Bay	2 (0.6%)	0.2	0.4 (0.08%)
Total Source Area	404	1.12*	450

*county average

Figure 11. Size Distribution of Auto Dismantler Facilities in Los Angeles County



San Gabriel watershed; and 0.6% each in the Santa Clara River watershed and the Santa Monica Bay watershed. Figure 11 shows the size distribution of auto dismantling facilities in Los Angeles County. The County average is 1.2 acres, with 90% of the facilities under 3 acres.

Pollutant loads from the auto dismantling industry were estimated for the 1998 - 1999 storm year for the three watersheds with the highest number of auto dismantling facilities - Los Angeles River, San Gabriel River, and Dominguez Channel. Loads were calculated for TSS, oil & grease, copper, lead, and zinc. Table 11 presents the load estimates and information on parameters used to arrive at the estimates, such as average pollutant concentration, annual precipitation and runoff, and area within each watershed occupied by auto dismantling facilities. The total approximate loads for all of Los Angeles County contributed by the auto dismantling industry are: 22,400 lbs. of TSS, 4,650 lbs. of oil & grease, 35 lbs. of copper, 22 lbs. of lead, and 130 lbs. of zinc. These estimates may be slightly lower than for a typical wet season because the 1998/99 wet season was impacted by the La Niña phenomenon and had less-than-average

Table 11. Pollutant Load per Watershed Contributed by Auto Dismantling Industry in Los Angeles County based on the 1998/99 Wet Year (pounds/acre/year)[1]

Watershed	P[2] (in)	Pj[3]	TSS 116.3 mg/L[4]	O&G 28.4 mg/L	Cu 142 ug/L	Pb 103 ug/L	Zn 508 ug/L
Los Angeles River (284 Acres)	9.72[5]	0.72	22,950	5,600	30	20	100
Dominguez Channel (96 Acres)	4.71[6]	0.67	3,480	850	4	3	15
San Gabriel River (67 Acres)	7.48[7]	0.72	4,140	1,010	5	4	18
Total			30,570	7,460	40	30	130

[1] Based on average site imperviousness value of 43%. Rainfall data for the [illegible] wet year (Oct. - Oct.) was obtained for specific reference sites within each watershed from the Los Angeles County, Department of Public Works, Hydrology Division.
[2] P is annual precipitation in inches per year.
[3] Pj is fraction of rainfall events that produce pollutants in runoff. Pj was calculated using an assumption that the threshold rainfall greater than 0.1 inches is needed to produce runoff
[4] Average pollutant concentrations were estimated based on the storm water analytical data on the grab samples collected by RWQCB staff from the eight case study auto dismantling facilities.
[5] Rainfall data from the monitoring stations near Downtown Los Angeles and Sun Valley.
[6] Rainfall data from the monitoring station near Wilmington.
[7] Rainfall data from the monitoring station near Duarte.

precipitation On a watershed level, the Los Angeles River was the single most impacted waterbody, receiving the majority of the load. The San Gabriel River watershed, which has a smaller total "source" area than Dominguez Channel watershed, was characterized with a higher load due to the greater total precipitation and runoff experienced in the San Gabriel watershed area. Although not presented in Table 10, the loads from the auto dismantling facilities in the Santa Monica Bay watershed and the Santa Clara River watersheds are negligible given the fact that each watershed only had two known auto dismantling businesses within its respective area.

The load introduced by the auto dismantling industry to surface waters is significant. On a weight basis, the pollutant associated with the highest load by weight is TSS, followed by oil & grease, zinc, lead and copper. The estimates presented in this study may be improved by using flow-weighted composite data for pollutant concentration, accounting for the variability in the rainfall patterns within specific watersheds, and by using a more accurate estimate of the total universe of facilities that accounts for facilities that both the RWQCB and DMV failed to capture. For a more meaningful load analysis, the estimates should be evaluated in the context of loads generated from other major industrial sources, a task that lies outside the scope of this study.

Consideration of Other Approaches To Storm Water Pollution Control

The question of how compliance should be defined to protect water quality and beneficial uses of the receiving waterbody is an important one. The pollution prevention approach, as currently designed, lacks a clear, uniform standard for measuring compliance, and may require more resources than traditional (individual) NPDES to adequately monitor for compliance. An objective quantitative or measurable standard of compliance is also necessary for equitable and consistent enforcement. Two alternatives other than the current P2 approach are considered in this section. One alternative is to define compliance in terms of numerical effluent limitations. This approach is consistent with the traditional or individual NPDES permitting approach. Establishing numerical effluent limitations would help facility operators to determine whether the facility is indeed achieving the limits, and if not, how much the facility needs to ratchet down its pollutant levels to return to compliance. This simplifies compliance assessment for both regulators and the regulated community and provides a clear basis for enforcement actions. If feasible, numerical effluent limitations should be developed based on water quality criteria that are protective of beneficial uses. This would ensure that facilities, by meeting the established limitations, are not contributing to or causing exceedances of applicable water quality standards.

Another alternative is to prescribe a set of minimum, mandatory baseline BMPs for each industry. Compliance would be determined primarily by the effective and diligent implementation of these selected BMPs. To facilitate the compliance determination process, a minimum set of BMPs should consist of measures that are readily observable. This option limits the flexibility offered by the P2 approach that allows facility operators the freedom to choose from a wide range of BMPs and to tailor the BMPs to the facility's site and economic conditions. In addition to Appendix C and the sources cited for Appendix C, the list of BMPs compiled for the cooperative compliance program of Wisconsin is another comprehensive source of information on BMPs for the auto dismantling industry (KES 1999; CCP/DNR 1999)

This study recommends the following tiered approach for the auto dismantling industry that combines the core of the two alternatives outlined above: 1) a mandatory set of specific, baseline structural and non-structural BMPs for facilities with annual vehicle throughput of less than 500 (which represent "mom-and-pop" facilities); and 2) mandatory treatment of storm water for facilities with annual vehicle throughput greater than 500. Also, in lieu of requiring treatment, numerical effluent limitations could be applied to the latter group as a standard of compliance. A compliance schedule could help phase facilities into compliance over a certain specified time frame. Facilities with less than 500 annual vehicle throughput that persistently demonstrate problems in meeting certain water quality standards, for example the USEPA benchmark levels, should also be considered for mandatory storm water treatment.

Lack of sufficient resources has been identified as the primary reason for the limited compliance assurance and enforcement activities by the RWQCB. One way to help effectively implement the above recommended strategy and at the same time, reduce the workload associated with compliance assessment and assurance activities is to employ a semi-privatized certification program, such as that implemented in the State of Wisconsin, which relies on licensed, private inspectors to oversee the compliance activities of a group of facilities that voluntarily choose to participate and help fund the program. The aim of such a program is to help reduce some of the workload of the regulators and to allow facilities that diligently work toward and maintain a specified level of compliance to be certified for compliance by professional inspectors. Such certification could potentially shield them from certain regulatory responsibilities, such as monitoring activities, and indirectly from third-party lawsuits by reducing the degree of their environmental liability. (Essential to the implementation of this type of program is regular training and (re-)certification of inspectors by the regulating agency to maintain high QA/QC for the inspection procedures.)

V. CONCLUSIONS/RECOMMENDATIONS

Several conclusions can be drawn from the findings of this study. Compliance, in general, appears to be limited or low among the auto dismantling facilities in Los Angeles County, for all three tiers of the GISP requirements. Analyses based on site visits results and DMV dismantling license information showed that about one out of every five auto dismantling facilities operating in Los Angeles County are non-filers. Compliance with the annual reporting and SWPPP and written monitoring program requirements is also limited. Review of the 1997/98 Annual Reports revealed that many of the required facilities failed to conduct the key monitoring activities, such as storm water sampling and analysis, limiting the usefulness of the Annual Reports as a tool to gauge overall permittee performance. SWPPPs and written monitoring programs, due to their generally poor quality, fail to effectively guide facility operators in their P2 efforts and in proper monitoring procedures. Accelerated enforcement activities have proven to be effective for increasing the Annual Report submittal rate. Outreach to consultants is strongly recommended to upgrade or improve the quality of SWPPPs and written monitoring programs being prepared by third parties.

The GISP program has not effectively penetrated the auto dismantling industry in terms of compelling the kinds of behavioral changes needed to effectively control storm water pollution and to improve water quality. Case study investigations indicated that the selected facilities failed to select and implement appropriate BMPs to attain the USEPA benchmark levels. Pollutant load estimates based on this industry show that the magnitude of the load could be substantial. These findings imply that the current approach based on P2 and the primary reliance on facility operators to identify and implement appropriate BMPs, without establishing enforceable numerical effluent limitations, has not been shown to be effective, at least at the level currently implemented, in controlling storm water runoff from the auto dismantling industry. Past studies on other industries, including the metal plating and transportation sectors, support some of the findings and conclusions of this study (Duke and. Shaver 1999; Duke et al 1999a; Duke et al 1999b; Duke et al 1998; Duke and Bauersachs 1998; Duke et al 1998; Duke and Beswick 1997; and Duke and Chung 1996).

The lack of a clear, objective standard for compliance could pose a special challenge to dischargers when trying to determine if the existing BMPs are sufficient or need to be upgraded or supplemented with additional BMPs. The majority of the storm water analytical data from the eight case study facilities and the self-reported data provided by auto dismantling facilities in the past substantially exceeded the USEPA benchmark values. The GISP program, as currently implemented and enforced, appears to be not attaining the potential pollution reduction achievable as envisioned. For this reason, this study considered different regulatory alternatives to control industrial storm water pollution. This study recommends a tiered approach that offers different combinations of options -- including implementation of a set of minimum required BMPs, mandatory storm water treatment, or applying numerical effluent limitations -- based on each facility's annual vehicle throughput quantity.

Until now, the GISP program at the Los Angeles RWQCB has exhausted most of its resources for determining and enforcing against violators of the first and second tier compliance. In reality, it is the onsite implementation that actually achieves pollution prevention or reduction. Therefore, more resources should be allocated to assess and verify field compliance. Increase in compliance assurance activities and timely comprehensive enforcement activities would improve overall compliance. This study suggests a possible solution -- a semi-privatized compliance certification program -- that could substantially reduce regulators' workload and allow them to focus on high-risk sectors or facilities to more effectively regulate and control storm water pollution associated with industrial activities.

[1] Y= yes, N= no; N/A= not applicable.

[2] For BMP implementation rating, 0=Not implemented; 1= Poorly implemented; 2= Somewhat poorly implemented; 3= adequately implemented, N/A= not applicable, N/O= Not observed during site inspection.

Appendix C. Best Management Practices for Auto Dismantling Industry

ACTIVITY	PURPOSE	BEST MANAGEMENT PRACTICES (BMPs)
Vehicle Dismantling Dismantling Activities	Eliminate exposure	• Roof or cover to eliminate rain-in. Berm area to eliminate storm water run-on. Conduct dismantling work in this designated area. • Place a mat, plastic, or tarpaulin on the ground prior to placing parts on the ground. (Also, if no roof or cover provided over dismantling area, conduct dismantling activities on top of plastic or tarpaulin, which can be readily cleaned or replaced, and removed during storm events). • Drain all fluids (antifreeze/coolant, brake fluid, gasoline/diesel, motor oil, transmission oil) from vehicle prior to dismantling and parts removal. • Use drip pans to drain fluids. Do not overfill . • Drain oil filters before disposal/recycling. • Remove refrigerant prior to dismantling and parts removal. • Deploy airbags per guidelines or remove intact airbags for reuse and store under cover. • Dispose of greasy rags, air filters, spent coolant, and degreasers. • Remove batteries promptly after vehicle arrival. • Remove oil-bearing components prior to storage.
Fluid draining	Eliminate exposure	• Roof or cover to eliminate rain-in. Berm area to eliminate storm water run-on. Remove fluids in this designated area. • Use drip pans for draining vehicular fluid. • Use funnels, and stoppers for the containers. • Avoid discharge of vehicular fluid (as in drips or leaks) on the ground.
Parts Repair/ Wash	Eliminate exposure	• Designate contained areas for repairs and washing (curb, berm or dike area, if necessary. If not feasible, use oleophilic (oil- absorbing) boom bags to prevent washwater from running to the street / curb or other areas of facility.) • Wash parts in a wash- tray provided with secondary containment. • If area not otherwise contained, divert runoff from repair and wash areas with hydrophobic boom bags. • Transfer spent solvent or washwater into designated drums. • Recycle and reuse or release washwaters to sanitary sewer. • Use minimum amounts of solvents or detergents for parts cleaning. • Use water-based cleaning solvents and biodegradable (non-phosphate) detergents. • Wipe and sweep area regularly after activity. Dispose of greasy rags, air filters, spent coolant, and degreasers in appropriate containers.
Storage Vehicles	Eliminate exposure	• Keep vehicle engines covered with hoods or with plastic sheets secured in place. • Store vehicles on an impervious (e.g. concrete) surface (if possible). • Use drip pans under stored vehicles. • Minimize inventory during wet season. • Reduce holding time for scrap disposal.

Appendix C. Best Management Practices for Auto Dismantling Industry (Cont'd)

ACTIVITY	PURPOSE	BEST MANAGEMENT PRACTICES (BMPs)
Separated components	Eliminate exposure	• Confine to designated area. • Store indoors or under temporary or permanent cover (that sufficiently shields rainfall). • Curb, berm, or dike the area. (If not feasible, then: 1) store parts off-ground, for example on storage racks, with drip pans underneath to collect residual fluids; or 2) store parts in leak-free truck beds or plastic containers; or 3) place parts in auto bodies (intact), especially large-sized vans, which also provide an excellent storage places for parts; 4) divert runoff from scrap storage area with hydrophobic (water resistant) boom bags) • Place tires in semi-trailers, indoors, or covered area. Sell or recycle. • Store scrap parts/metals under cover and dispose of to scrap collector promptly • Divert runoff from scrap storage area with hydrophobic (water resistant) boom bags.
Batteries	Eliminate exposure	• Store batteries in covered storage area, on a paved surface that is bermed, or in plastic containers with lids.
Fluid	Eliminate exposure Improve materials management	• Store fluid containers (e.g. drums) on an impervious surface and under a roofed shed. • Provide secondary containment for the fluid-containing drums. • Keep separate (solvents, oils and fuel) and label accordingly.
Others Recycling	Waste minimization	• Recycle (or resell if possible) anti-freeze, fuel, waste oil, windshield washer and solvents. • Recycle usable recyclable parts. • Recycle tires and core/ scrap metals.
Spill Prevention & Clean-up	Minimize exposure Waste Minimization Contain/ cleanup pollutants	• Employee training (prepare for and clean up spills.) • Prepare a spill clean-up kit (absorbent sand, rags, adsorbent snakes, broom, etc.) and place in convenient readily accessible location. • Drain vehicular fluids at designated removal area. • Use the provided spill- kit to contain leaks or spills immediately. Dispose of properly. (Use oleophilic sands to absorb/contain small leaks, and boom bags for large spills.)
Employee Training	Waste minimization	• Train employees regularly in proper and environmentally safe practices.
Customer Education	Waste minimization	• Inform and require customers who remove parts to do so properly and appropriately dispose of waste (for example, posting signs that require the use of drip pans for parts removal and prohibit waste-generating activities in parking lot can be helpful).
Site Inspection	Good maintenance	• Inspect site regularly to ensure all appropriate BMPs are being implemented.
Preventative maintenance	Prevent pollution/ accidents	• Inspect to ensure integrity of tanks, containers, pipings and valves. Install safeguards against accidental release.

Appendix C. Best Management Practices for Auto Dismantling Industry (Cont'd)

ACTIVITY	PURPOSE	BEST MANAGEMENT PRACTICES (BMPs)
Site Maintenance	Minimize exposure	• Keep site clear of trash and debris. • Regularly remove and sweep sand (used to contain spills), trash or dirt from site. • Collect corrosion/ metal particles with magnet (survey the site with a forklift or small vehicle with magnet attached behind.)
Materials Inventory	Good management	• Maintain proper inventories of vehicles processed, materials stored, and wastes recycled or disposed of.
Site grading	Minimize exposure	• Repave area to direct flows to a low point (away from storage and waste areas) where leaking fluids can be collected.
Recordskeeping	Good management	• Maintain records of inspections, monitoring (including storm water sampling), Annual Reports, and training.
Storm Water Treatment Flow dissipation	Remove Pollutants	• Direct flow discharge over coarse gravel or cobblestones to facilitate settling out of particulates and sediment.
Vegetative belts	Remove Pollutants	• Direct flow discharge over vegetative belts or biofilters to enhance pollutant removal.
Sand/ gravel filters	Remove Pollutants	• Allow storm water from open parts storage areas to pass through sand-gravel filter with drain holes. Sand layer must be periodically replaced.
Detention ponds	Remove Pollutants	• Capture storm water runoff from high activity areas. Skim off surface oil and remove bottom sediment. Reuse or evaporate runoff water.
Oil-grit/ oil-water separator	Remove Pollutants	• Direct flows from high activity areas through OW separators. Off-line separators to bypass large storms are preferable. Maintain regularly.
Flotation/ coagulation	Remove Pollutants	• Store runoff flows, equalize, and provide flotation/ coagulation. High operation and maintenance costs. Inappropriate if used only intermittently.
Industrial sewer piping	Remove Pollutants offsite	• Pretreat as required and pipe to sanitary sewer if allowed (permit likely required).
Oil/grease - absorbents	Remove Pollutants	• Provide oleophilic booms or excelsior near runoff exit. Replace as needed. Dispose of properly.

COMPARISON OF BEST MANAGEMENT PRACTICES

BEST MANAGEMENT PRACTICES	Multi-Sector Permit Requires Consideration of These BMPs	Ability to Control: Sediment	Vehicle and Equipment Fluids	Metals	Solvents and Cleaners	Initial Cost	Operation and Maintenance Costs	Practicality
GOOD HOUSEKEEPING								
General Practices								
Develop a storm water management policy statement for your employees. Management can provide direction and support for pollution prevention by reviewing this policy with employees and keeping it posted.		■	■	■	■	★	★	★
An in-coming vehicle inspection inventory program should include a check for fluid leaks and for unwanted material that could have been placed in the vehicles.		■	●	■	■	★	★	★
Clean up debris and trash on a regular basis.		●	■	■	■	★	●	★
Construct fences or other physical barriers to act as visual and noise barriers, help to control dust, help prevent theft, and control the direction of runoff.		■	■	■	■	■	●	●
Maintain an organized inventory of materials used at the facility.	✔	■	■	■	■	●	●	★
Consider indoor storage of vehicles, parts, and equipment, and the use of berms and/or dikes to control storm water runoff.[1]	✔	●	★	★	●	■	●	■
Vehicle Dismantling Fluid Management								
Remove fluids from vehicles brought into the facility for processing or dismantling.	✔	■	★	■	■	■	■	★
Keep used oil separate from part cleaning solvents, antifreeze, and fuel. Engine oil, transmission fluid, brake fluid, and power steering fluid can be combined and stored together.		■	●	■	●	●	★	★
Label storage containers of all fluids and waste materials.	✔	■	■	■	■	★	★	★
Drain all parts of fluids prior to disposal.	✔	■	★	■	■	●	●	★
Confine the storage of vehicles, parts, and equipment to designated areas.	✔	■	■	■	■	●	●	●

COMMENTS

1 May interfere with operation and access. Indoor storage of vehicles is not appropriate or practical for an automotive recycling facility.

KEY TO THE TABLE

	■	●	★
Ability to Control Pollution	no significant removal	slight (<25%) removal	moderate to high (25%) removal
Initial Cost	>$5,000	$1,000 - $5,000	<$1,000
Operation and Maintenance Cost	>$1,000 / year	$500 - $1,000 / year	<$500 / year
Practicality	usually not practical	sometimes practical	practical for most facilities

COMPARISON OF BEST MANAGEMENT PRACTICES

BEST MANAGEMENT PRACTICES	Multi-Sector Permit Requires Consideration of These BMPs	Ability to Control: Sediment	Vehicle and Equipment Fluids	Metals	Solvents and Cleaners	Initial Cost	Operation and Maintenance Costs	Practicality
Use canvas or sheets of plastic to temporarily cover storage areas.[2]	✔	●	●	■	■	●	●	●
Transmission and engine cores may be stored in plastic storage boxes with leak proof tops; lugger boxes having solid bottoms and covered by a permanent roof, lugger boxes without a solid bottom stored under a permanent roof on a concrete pad with curbing; or an enclosed trailer with a steel floor to contain fluid runoff and a drain in the floor to properly remove waste fluids.		■	★	■	■	■	●	●
Engine oil should be drained and stored in labeled, doubled-walled, above ground tanks. Used oil can either be recycled for on-site use in a waste oil heater, or sent off-site for re-refining or fuel blending.		■	★	■	■	●	●	★
Antifreeze should be reclaimed and reused or properly disposed of.[3]		■	★	■	■	●	●	★
Drain window washer fluid for reuse.		■	★	■	■	★	★	★
Remove batteries as soon as possible after vehicle enters the yard. Store good batteries inside for resale. Store dead batteries inside on pallets (if your floor is gravel or dirt, put a layer of absorbent material below the pallet) or in storage containers, or store dead batteries outside in a leak proof, covered container.		■	●	●	■	●	●	★
Parts Cleaning								
Perform all parts cleaning operations indoors or cover and berm outside cleaning areas.[4]	✔	■	●	●	★	●	●	★
Clean parts by using minimal amounts of solvents or detergents.		■	●	●	★	●	●	●
Recycle and reuse cleaning fluids where practical.		■	■	■	●	★	★	●
Spent cleaning solutions should be removed by a waste hauler or recycler.		■	■	■	■	★	★	★
Use phosphate-free biodegradable detergents. Consider using detergent-based or water-based cleaning systems in place of organic solvent degreasers.		■	■	■	★	●	●	●
Vehicle Crushing Activities								
Consider providing a containment system—such as a concrete pad with berms—for vehicle crushers. Fluids and storm water runoff from such bermed areas could be discharged into a sump, oil/water separator, sanitary sewer, or other appropriate drainage system that prevents storm water contamination.		■	★	●	■	■	■	●

COMMENTS

2 May interfere with operation and access.
3 May need to check with the state to see if additional requirements are required.
4 May not be feasible or practical for all facilities.

COMPARISON OF BEST MANAGEMENT PRACTICES

BEST MANAGEMENT PRACTICES	Multi-Sector Permit Requires Consideration of These BMPs	Ability to Control: Sediment	Ability to Control: Vehicle and Equipment Fluids	Ability to Control: Metals	Ability to Control: Solvents and Cleaners	Initial Cost	Operation and Maintenance Costs	Practicality
If a gravel/geotextile fabric foundation is provided under a crusher, install a fluid collection system to capture fluids that are released during the crushing operation.		■	★	●	■	■	■	●
Capture crusher fluids to prevent spillage. Collect this mixture of fluids in a spill-proof covered container, test the fluid, and dispose of it properly. It should not be allowed to drain onto the ground. Keep the drain within the crusher clear so that the fluids do not collect and overflow from the crusher onto the ground.		■	★	●	■	●	●	●
PREVENTIVE MAINTENANCE								
Develop a preventive maintenance program that involves timely inspections and/or maintenance of the crusher and facility equipment and vehicles. The program may include: • Service checklists and maintenance logs for each piece of equipment; • Employee education and instruction material; and • Review of manufacturer-recommended parts replacement and maintenance activities and frequencies.		■	●	■	■	★	●	★
Keep the crusher and other equipment clean by frequently wiping off accumulated oil and grease that may be exposed to storm water (except where needed for proper operation of the equipment) or that may hide equipment trouble spots.		■	●	■	■	★	★	★
Conduct scheduled maintenance of facility equipment and vehicles in a covered or bermed area, where practicable.		■	●	■	■	●	●	●
Schedule periodic inspections of equipment for leaks, spills and malfunctioning, worn, or corroded parts. Regularly inspect tanks, valves, hoses, and containers. Look for signs of wear or weakness.		■	●	■	■	■	●	★
On secondary containment structures, regularly inspect the valve, seals around the outlet pipe, the outlet pipe itself, and the dike for cracks, damage, or leaks.		■	■	■	■	★	★	★
When secondary containment reservoirs require pumping or release, a sample of collected water should be visually inspected or tested for pollutants. If pollutant levels are significant or there is contamination, pump the accumulated water into barrels or into a tanker truck and haul to a wastewater treatment facility.		■	■	■	■	★	●	★
Repair or replace parts before they wear out.		■	●	■	■	★	●	★
Repair malfunctioning equipment that is responsible for any leak or spill as soon as possible.		■	★	■	■	★	●	★

COMPARISON OF BEST MANAGEMENT PRACTICES

BEST MANAGEMENT PRACTICES	Multi-Sector Permit Requires Consideration of These BMPs	Ability to Control: Sediment	Vehicle and Equipment Fluids	Metals	Solvents and Cleaners	Initial Cost	Operation and Maintenance Costs	Practicality
Secure and lock above ground tank storage areas. Tanks, pumps, fittings, pipes, and containers should be inspected routinely for integrity and leaks.		■	■	■	■	★	★	★
Perform maintenance activities indoors.[5]	✔	■	●	■	■	■	●	●
Valves on secondary containment structures should be kept in the "off" position at all time, except when collected water is being removed.		■	■	■	■	★	★	★
SPILL PREVENTION AND RESPONSE								
Make available MSDS sheets and other safety materials that identify types of fluids that have the potential to spill, indicate whether these fluids are hazardous or toxic, list appropriate safety equipment to be worn, and specify correct materials and procedures to use to clean up the spill.		■	●	■	●	●	★	★
Provide spill clean-up equipment at locations where spills are most likely to occur.		■	●	■	●	●	★	★
Identify clean-up procedures, including the use of dry absorbent materials or other clean-up methods to collect, dispose of, or re-cycle spilled or leaked fluids. Maintain an adequate supply of dry absorbent material on-site. Properly dispose of used absorbent materials.		■	●	■	●	●	★	★
Contain oil or other fluids spilled during parts removal.	✔	■	●	■	■	★	★	★
Never pour liquids or dry materials down a storm drain.		■	★	■	★	★	★	★
Place drip pans, plastic sheets, or canvas tarps beneath vehicles, parts, and equipment during maintenance and dismantling activities. If any parts are removed, they should be placed in a drip pan. Drip pans should not be left unattended.	✔	■	★	■	●	★	★	★
When refueling vehicles and equipment, park as close to the pump as possible. Keep fuel nozzle upright when not in use, and replace nozzle securely in the pump.		■	●	■	■	★	★	★
Pave refueling areas to prevent contamination of the soil if a spill occurs.		■	●	■	■	■	★	●
Equip fuel pumps and tanks with overflow prevention and automatic shut-off devices.		■	★	■	■	●	★	★
Control any spills that may occur around fueling areas.		■	★	■	■	★	★	★

COMMENTS

5 May not be appropriate for certain scheduled maintenance procedures.

COMPARISON OF BEST MANAGEMENT PRACTICES

BEST MANAGEMENT PRACTICES	Multi-Sector Permit Requires Consideration of These BMPs	Ability to Control: Sediment	Ability to Control: Vehicle and Equipment Fluids	Ability to Control: Metals	Ability to Control: Solvents and Cleaners	Initial Cost	Operation and Maintenance Costs	Practicality
Containers and tanks should be stored on a concrete or impermeable surface, and if feasible, under cover. All containers should be labeled according to content and hazard characteristics. Keep drums containing chemicals away from sumps and drains.[6]		■	★	■	●	■	★	●
Observed spills and leaks should be captured and cleaned up using dry absorbents, drip pans, towels, mops, pads, and booms.	✔	■	★	■	★	★	●	★
Maintain good integrity of all storage containers.		■	★	■	★	★	★	★
Install safeguards (such as diking or berming) against accidental releases at dismantling and storage areas.[7]	✔	■	★	■	■	■	■	★
EROSION AND SEDIMENT CONTROL								
Implement appropriate vegetative, structural, or stabilization measures to limit soil erosion.		★	■	■	■	●	●	●
Regularly sweep and clean paved surfaces to reduce sediment build-up. Sediment should be swept up and placed into a covered, watertight dumpster for proper disposal.[8]		★	■	■	■	●	■	★
Install filtering or diversion practices, such as filter fabric fences, sediment filter booms, earthen or gravel berms, curbing, or equivalent measures.[9]		★	■	■	■	■	●	●
Install sediment traps, vegetative buffer strips, silt fencing, or equivalent measures to remove sediment prior to discharge through an inlet or catch basin.[10]		★	■	■	■	■	●	●
Do not use vehicle fluids, oils, or fuels for dust control or weed control.		■	●	■	■	★	★	★
Establish and maintain a vegetative cover in areas not used for vehicle salvage activities.		★	■	■	■	★	★	★
RUNOFF MANAGEMENT								
Use vegetated swales and buffer strips, catch basin filters, and/or other similar measures to facilitate settling or filtering of pollutants in runoff.[10]		★	●	●	●	■	●	●

COMMENTS

6 Secondary storage inside a building is only recommended when there is a potential for a spilled liquid to flow outside and reach a waterway.

7 This may not be feasible or practical for some facilities.

8 May be labor intensive for some facilities.

9 Filtering measures may not be practical for facilities with unpaved surfaces with large sediment loadings. Filters would become clogged, possibly causing flooding. May be damaged by heavy equipment.

10 May not be practical in many industrial facilities that are storm sewered. May be damaged by heavy equipment.

COMPARISON OF BEST MANAGEMENT PRACTICES

BEST MANAGEMENT PRACTICES	Multi-Sector Permit Requires Consideration of These BMPs	Ability to Control: Sediment	Vehicle and Equipment Fluids	Metals	Solvents and Cleaners	Initial Cost	Operation and Maintenance Costs	Practicality
Construct grassed swales, berms, and diversions to direct water flow to a central point for better control and management.		★	●	●	●	■	■	●
Properly maintain grassed swales by keeping swales free of debris and litter, maintaining vegetation, and periodically removing accumulated sediment. Do not place material or waste in swales or in the runoff paths.		★	●	●	●	★	●	●
Divert runoff away from material storage areas through such practices as dikes, berms, containment trenches, culverts, elevated concrete pads, and/or surface grading.[11]		★	●	●	●	■	■	●
Consider installing a detention pond Monitor accumulation of sediments in the bottom of detention ponds. Remove accumulated metals and other materials from the bottom of detention ponds as needed.[12]		★	●	★	●	■	■	■
Considering installing oil-water separators to reduce the levels of petroleum-based oils in storm water runoff. Test and clean out sediments and oily deposits that have accumulated in the oil-water separator. Sediments should be tested for metals and other pollutants which may be expected to be present.		●	●	●	■	■	■	●
NON-STORM WATER DISCHARGES								
Disconnect or seal off all existing floor drains and sinks that are connected to the storm drainage system.		■	■	■	■	★	★	★
Wash vehicles and equipment in a contained area.		●	●	■	■	●	●	●
Do not steam clean parts outside without proper wastewater containment.		●	●	■	■	●	●	●
Do not discharge steam cleaned wastewater to a septic tank system because the oils may not be treated or removed in the system.		●	●	■	■	★	●	●
Do not pour liquid waste or parts wash water down storm drain inlets.		■	●	■	●	★	★	★
Do not hose down the shop floor if water would be conveyed to a storm drain.	✔	■	■	■	■	★	★	★

COMMENTS

11 Practices can be readily damaged by heavy equipment. Not practical in many paved facilities.

12 This BMP is not required by the U.S. EPA Multi-Sector Permit. The use of detention ponds and dikes may eliminate the need for a storm water permit if all storm water from the facility is detained and no water is discharged from the facility

Variety of BMPs at a sample automotive recycling facility. These BMPs are suggestions only. Select practices that are appropriate for your facility.

[1] Data represent grab samples of storm water from auto dismantling facilities collected by facility operators as part of the annual monitoring and reporting requirement or by the Regional Board staff as part of this study.
[2] The benchmark values are from the 1995 USEPA Multi-sector Permit (USPEA 1995).
[3] Represent samples collected by staff from the eight case study facilities.
[4] Represent samples collected by facility operators.
[5] Represent samples collected by group monitoring participants.

Appendix E. Description of Load Estimate Parameters

Each of the parameters in the EPA Simple Method equation were estimated as described below:

Average pollutant concentration, C: Ideally, Flow-weighted composites should be used to estimate load. Given the lack of flow-weighted composite storm water data on the auto dismantling industry reflective of the climatic and precipitation patterns of Southern California, grab sample data generated by staff sampling at the eight case study facilities were used. At this time, the approximate margin of error or uncertainty from using grab sample data instead of flow-weighted composite data is not known.

The total site area, A: For area, A, area occupied per watershed by auto dismantling establishments were estimated by multiplying the following three factors: a) the total number of auto dismantlers in Los Angeles County (404) estimated earlier in this study; b) the proportion of auto dismantling facilities located in each watershed area, determined based on zipcodes of all dismantlers with an active NOI; and c) the average size of auto dismantling facilities located in each watershed. It was assumed that, on average, non-filers are similar to NOI filers in size and in spatial distribution.

Annual rainfall depth, P: Rainfall records for certain parts of Los Angeles County were available from the Los Angeles County Department of Public Works, Hydrology Division (the County). This study chose reference monitoring sites chosen for each watershed with a significant number of auto dismantler establishments. Rainfall pattern could vary substantially even within a watershed. Therefore, it is important to use rainfall data as specific or closest to the source area as possible. The annual rainfall depth was calculated by adding daily rainfall (in inches) reported from October 1998 to September 1999.

Fraction of rainfall events that produce a runoff, Pj: This study used 0.1 inches as the threshold volume required to generate runoff. Pj was calculated by dividing the sum of the adjusted individual rainfall volume (i.e. minus the first 0.1 inches) for the 1998/99 wet season by the annual total rainfall volume. If Pj is known for a given geographical area for a certain wet season or for an extended period (for example 100 years), one could reasonably estimate the total annual runoff (by multiplying $P*P_j$) without the individual rain records as long as the annual total precipitation is known. Since the daily rainfall data were available from the County, we calculated the product P*Pj by simply adding the individual rainfall depth after subtracting 0.1 inch from each rainfall datum.

Site Imperviousness, I: The GISP defines percent imperviousness as the portion of a facility property that is paved, roofed (including buildings), or covered. A single value for imperviousness was derived by normalizing based on area, i.e. by dividing the sum of impervious areas calculated for each facility by the sum of facility size. An average site imperviousness of 43% was estimated for the auto dismantling facilities in Los Angeles County using the self-reported information in the NOI database (This value is significantly less than the 76% imperviousness estimated for light industrial land use in the Los Angeles County's Annual Monitoring Report submitted as a requirement under the municipal storm water program.) A source of uncertainty in this estimate is that facility operators could have misinterpreted the term "imperviousness."

Terry Roberts, *Manager, State Clearinghouse*

January 2001 Edition

INTRODUCTION

This is a citizen's guide to land use planning as it is practiced in California. Its purpose is to explain, in general terms, how local communities regulate land use and to define some commonly used planning terms. The booklet covers the following topics:

- State Law and Local Planning
- The General Plan
- Zoning
- Subdivisions
- Other Ordinances and Regulations
- Annexation and Incorporation
- The California Environmental Quality Act
- A Glossary of Planning Terms
- Bibliography

Cities and counties "plan" in order to identify important community issues (such as new growth, housing needs, and environmental protection), project future demand for services (such as sewer, water, roads, etc.), anticipate potential problems (such as overloaded sewer facilities or crowded roads), and establish goals and policies for directing and managing growth. Local governments use a variety of tools in the planning process including the general plan, specific plans, zoning, and the subdivision ordinance.

The examples discussed here represent common procedures or methods, but are by no means the only way of doing things. State law establishes a framework for local planning procedures, but cities and counties adopt their own unique responses to the issues they face. The reader is encouraged to consult the bibliography for more information on planning in general and to contact your local planning department for information on planning in your community.

STATE LAW AND LOCAL PLANNING

State law is the foundation for local planning in California. The California Government Code (Sections 65000 et seq.) contains many of the laws pertaining to the regulation of land uses by local governments including: the general plan requirement, specific plans, subdivisions, and zoning.

However, the State is seldom involved in local land use and development decisions; these have been delegated to the city councils and boards of supervisors of the individual cities and counties. Local decisionmakers adopt their own sets of land use policies and regulations based upon the state laws.

Plan and Ordinances

There are currently 533 incorporated cities and counties in California. State law requires that each of these jurisdictions adopt "a comprehensive, long-term general plan for [its] physical development." This general plan is the official city or county policy regarding the location of housing, business, industry, roads, parks, and other land uses, protection of the public from noise and other environmental hazards, and conservation of natural resources. The legislative body of each city (the city council) and each county (the board of supervisors) adopts zoning, subdivision and other ordinances to regulate land uses and to carry out the policies of its general plan.

There is no requirement that adjoining cities or cities and counties have identical, or even similar, plans and ordinances. Cities and counties are distinct and independent political units. Each city, through its council and each county, through its supervisors, adopts its own general plan and development regulations. In turn, each of these governments is responsible for the planning decisions made within its jurisdiction.

Hearing Bodies

In most communities, the city council or board of supervisors has appointed one or more hearing bodies to assist them with planning matters. The titles and responsibilities of these groups vary from place-to-place, so check with your local planning department regarding regulations in your area. Here are some of the more common types of hearing bodies and their usual responsibilities:

- **The Planning Commission:** considers general plan and specific plan amendments, zone changes, and major subdivisions.
- **The Zoning Adjustment Board:** considers conditional use permits, variances, and other minor permits.
- **Architectural Review or Design Review Board:** reviews projects to ensure that they meet community aesthetic standards.

In some cities and counties, these bodies simply advise the legislative body on the proposals that come before them, leaving actual approval to the council or board of supervisors. More commonly, these bodies have the power to approve proposals, subject to appeal to the council or board of supervisors. These hearing bodies, however, do not have final say on matters of policy such as zone changes and general or specific plan amendments.

Hearings

State law requires that local governments hold public hearings prior to most planning actions. At the hearing, the council, board, or advisory commission will explain the proposal, consider it in light of local regulations and environmental effects, and listen to testimony from interested parties. The council, board, or commission will vote on the proposal at the conclusion of the hearing.

Depending upon each jurisdiction's local ordinance, public hearings are not always required for minor land subdivisions, architectural or design review or ordinance interpretations. The method of advertising hearings may vary. At a minimum, counties and cities must publish notice of general plan adoption and amendment in the newspaper. Notice of a proposed general plan amendment affecting allowable land uses, zone change, conditional use permit, variance, and subdivision tract is published in the newpaper and mailed to nearby property owners.

THE GENERAL PLAN

The Blueprint

The local general plan can be described as the city's or county's "blueprint" for future development. It represents the community's view of its future; a constitution made up of the goals and policies upon which the city council, board of supervisors, and planning commission will base their land use decisions. To illustrate its importance, all subdivisions, public works projects, and zoning decisions (except in charter cities other than Los Angeles) must be consistent with the general plan. If inconsistent, they must not be approved.

Long-range Emphasis

The general plan is not the same as zoning. Although both designate how land may be developed, they do so in different ways. The general plan and its diagrams have a long-term outlook, identifying the types of development that will be allowed, the spatial relationships among land uses, and the general pattern of future development. Zoning regulates present development through specific standards such as lot size, building setback, and a list of allowable uses. In counties and general law cities, the land uses shown on the general plan diagrams will usually be reflected in the local zoning maps as well. Development must not only meet the specific requirements of the zoning ordinance, but also the broader policies set forth in the local general plan.

Contents

State law requires that each city and each county adopt a general plan containing the following seven components or "elements": land use, circulation, housing, conservation, open-space, noise, and safety (Government Code Sections 65300 et seq.). At the same time, each jurisdiction is free to adopt a wide variety of additional elements covering subjects of particular interest to that jurisdiction such as recreation, urban design, or public facilities.

Most general plans consist of: (1) a written text discussing the community's goals, objectives, policies, and programs for the distribution of land use; and, (2) one or more diagrams or maps illustrating the general location of existing and future land uses. Figure 1 is an example of a general plan diagram.

Each local government chooses its own general plan format. The plan may be relatively short or long, one volume or ten volumes, depending upon local needs. Some communities, such as the City of San Jose, have combined the required elements into one document and most communities have adopted plans which consolidate the elements to some extent.

State law requires that local governments make copies of their plans available to the public for reference. Copies can be sold to the public for the cost of reproduction.

Planning Issues

Although state law establishes a set of basic issues for consideration in local general plans, each city and county determines the relative importance of each issue to local planning and decides how they are to be addressed in the general plan. As a result, no two cities or counties have plans which are exactly alike in form or content. Here is a summary of the basic issues, by element:

- The **land use element** designates the general location and intensity of housing, business, industry, open space, education, public buildings and grounds, waste disposal facilities, and other land uses.

- The **circulation element** identifies the general location and extent of existing and proposed major roads, transportation routes, terminals, and public utilities and facilities. It must be correlated with the land use element.

- The **housing element** is a comprehensive assessment of current and projected housing needs for all economic segments of the community. It sets forth local housing policies and programs to implement those policies.

- The **conservation element** addresses the conservation, development, and use of natural resources including water, forests, soils, rivers, and mineral deposits.

- The **open-space element** details plans and measures for preserving open-space for natural resources, the managed production of resources, outdoor recreation, public health and safety, and the identification of agricultural land.

- The **noise element** identifies and appraises noise problems within the community and forms the basis for distributing new noise-sensitive land uses.

- The **safety element** establishes policies and programs to protect the community from risks associated with seismic, geologic, flood, and wildfire hazards.

Approving the Plan

The process of adopting or amending a general plan requires public participation. Cities and counties must hold public hearings for such proposals. Advance notice of the place and time of the hearing must be published in the newspaper or posted in the vicinity of the site proposed for change. Prior to approval, hearings will be held by the advisory body such as the planning commission. The general plan must be adopted by resolution by the legislative body of each city or county.

Community and Specific Plans

"Community plans" and "specific plans" are often used by cities and counties to plan the future of a particular area at a finer level of detail than that provided by the general plan. A community plan is a portion of the local general plan focusing on the issues pertinent to a particular area or community within the city or county. It supplements the policies of the general plan.

Specific plans describe allowable land uses, identify open space, and detail the availability of facilities and financing for a portion of the community. Specific plans must be consistent with the local general plan. A specific plan implements but is not technically a part of the general plan. In some jurisdictions, specific plans take the place of zoning. Zoning, subdivision, and public works decisions must be consistent with any applicable specific plan.

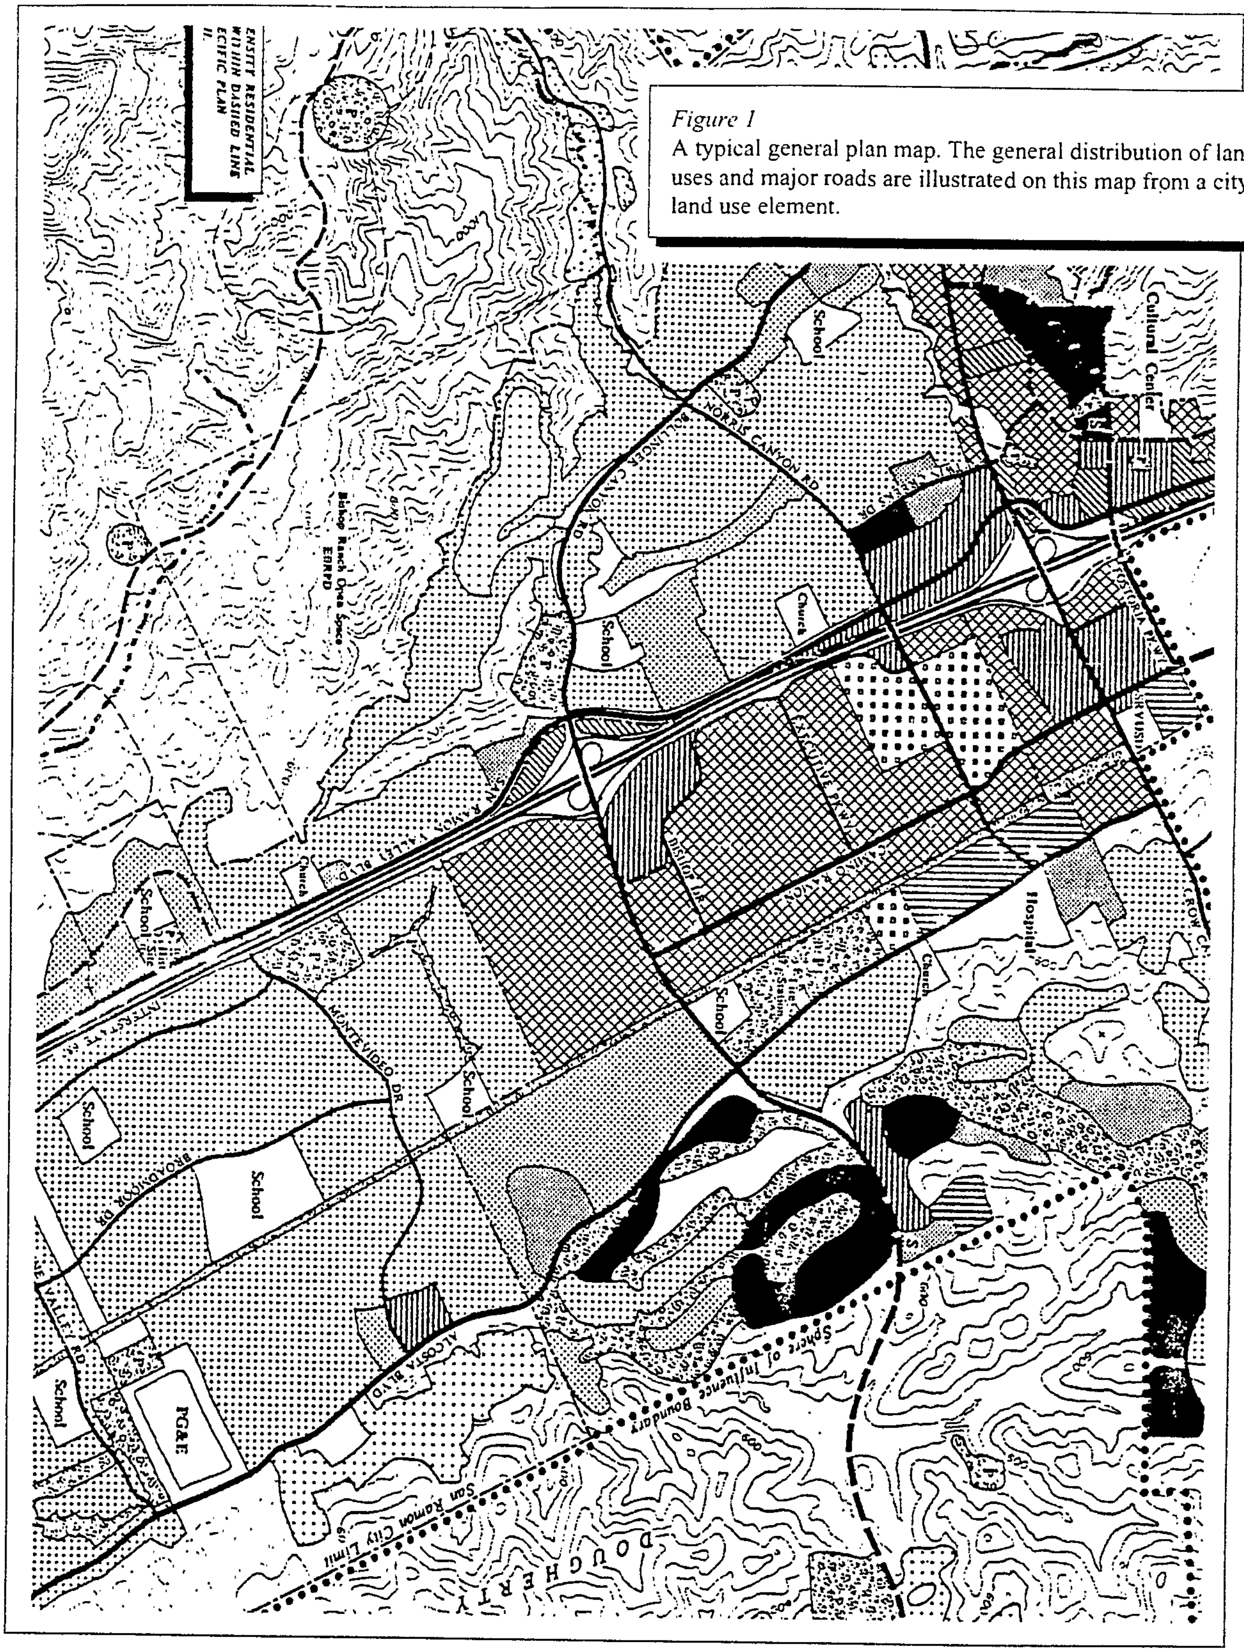

Figure 1
A typical general plan map. The general distribution of land uses and major roads are illustrated on this map from a city land use element.

R0011179

ZONING

The general plan is a long-range policy document that looks at the future of the community. A zoning ordinance is the local law that spells out the immediate, allowable uses for each piece of property within the community. In all counties, general law cities, and the city of Los Angeles, zoning must comply with the general plan. This rule does not apply to charter cities.

The purpose of zoning is to implement the policies of the general plan.

Zones

Under the concept of zoning, various kinds of land uses are grouped into general categories or "zones" such as single-family residential, multi-family residential, neighborhood commercial, light industrial, agricultural, etc. A typical zoning ordinance describes 20 or more different zones which may be applied to land within the community. Each piece of property in the community is assigned a zone listing the kinds of uses that will be allowed on that land and setting standards such as minimum lot size, maximum building height, and minimum front yard depth. The distribution of residential, commercial, industrial, and other zones will be based on the pattern of land uses established in the community's general plan. Maps are used to keep track of the zoning for each piece of land (an example of a zoning map is shown in Figure 2).

Zoning is adopted by ordinance and carries the weight of local law. Land may be put only to those uses allowed by the applicable zoning classification. For example, if a commercial zone does not allow five-story office buildings, then no such building could be built on the lands which have been assigned that zone. A zoning ordinance has two parts: (1) a precise map or maps illustrating the distribution of zones within the community; and, (2) a text which identifies the specific land uses and development standards allowed in each zone.

Rezoning

The particular zone determines the uses to which land may be put. If a landowner proposes a use that is not allowed in the zone, the city or county could approve a rezoning (change in zone) to allow that development. The local planning commission and the city council or county board of supervisors must hold public hearings before property may be rezoned. The hearings must be advertised in advance and notice mailed directly to surrounding property owners. The council or board is not obligated to approve requests for rezoning and, except in charter cities, must deny such requests when the proposed zone conflicts with the general plan.

Overlay Zones

In addition to the zoning applied to each parcel of land, many cities and counties use "overlay zones" to further regulate development in areas of special concern. Lands in historic districts, downtowns, floodplains, near earthquake faults or on steep slopes are often subject to having additional regulations "overlain" upon the basic zoning requirements. For example, a lot that is within a single-family residential zone and also subject to a steep-slope overlay zone, must meet the development requirements of both zones when it is developed.

Prezoning

Cities may "prezone" lands located within the surrounding county in the same way that they approve zoning within the city. Prezoning is done before annexation of the land to the city in order to facilitate its transition into the city boundaries. Prezoning does not change the allowable uses of the land nor the development standards until such time as the site is officially annexed to the city. Likewise, land that has been prezoned continues to be subject to county zoning regulations until annexation is completed.

Variances

A variance is a limited waiver of development standards for a use that is otherwise permitted in that zone. The city or county may grant a variance in special cases where: (1) application of the zoning regulations would deprive property of the uses enjoyed by nearby, similarly zoned lands; and (2) restrictions have been imposed to ensure that the variance will not be a grant of special privilege. A city or county may not grant a variance that would permit a use that is not otherwise allowed in that zone (for example, a commercial use could not be approved in a residential zone by variance). Typically, variances are considered when the physical characteristics of the property make it difficult to develop. For instance, in a situation where the rear half of a lot is a steep slope, a variance might be approved to allow a house to be built closer to the street than usually allowed. Variance requests require a public hearing and neighbors are given the opportunity to testify. The local hearing body then decides whether to approve or deny the variance.

Conditional Use Permits

Most zoning ordinances identify certain land uses which do not precisely fit into existing zones, but which may be allowed upon approval of a conditional use permit (sometimes called a special use permit or a CUP). These might include community facilities (such as hospitals or schools), public buildings or grounds (such as fire stations or parks), temporary or hard-to-classify uses (such as Christmas tree sales or small engine repair), or land uses with potentially significant environmental impacts (hazardous chemical storage or a house in a floodplain). The local zoning ordinance specifies those uses for which a conditional use permit may be requested, which zones they may be requested in, and the public hearing procedure.

As with rezoning and variances, a public hearing must be held to consider a CUP. If the local planning commission or zoning board approves the use, it will usually do so subject to certain conditions being met by the permit applicant. Alternatively, it may deny uses which do not meet local standards.

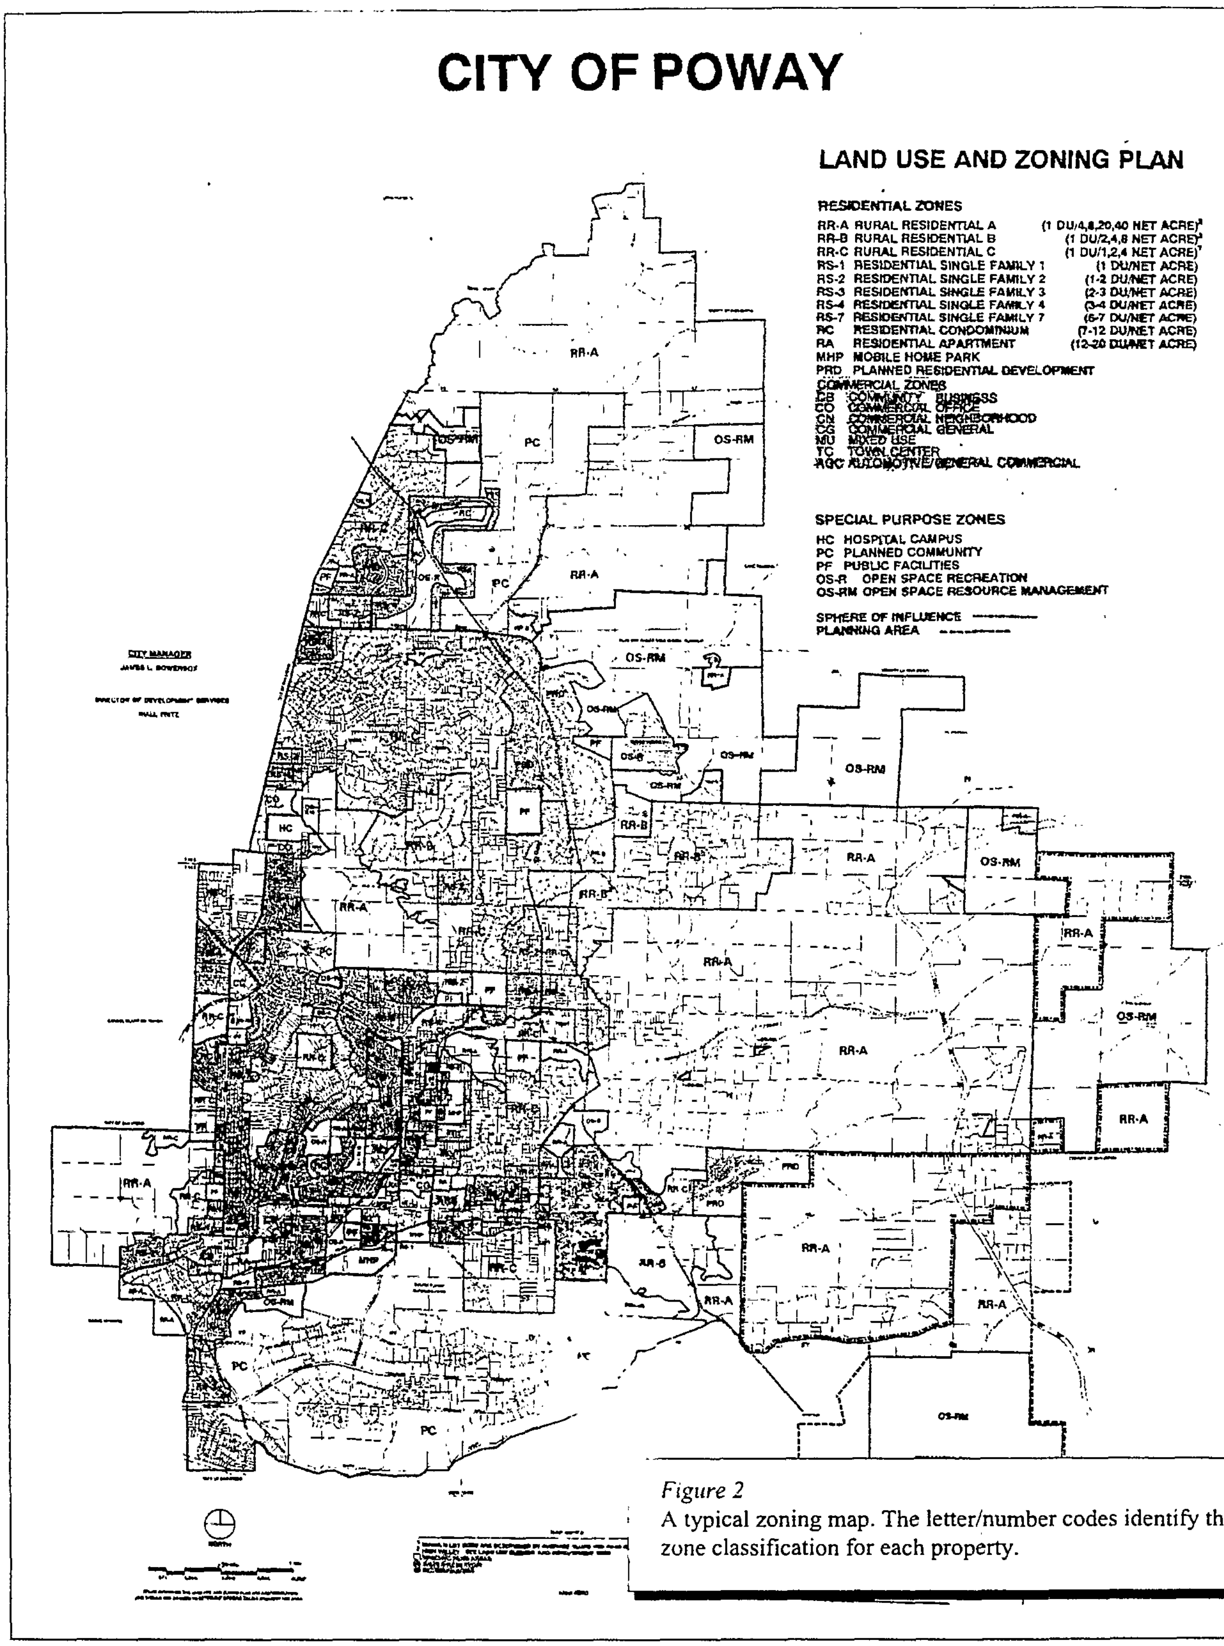

Figure 2
A typical zoning map. The letter/number codes identify the zone classification for each property.

R0011181

SUBDIVISIONS

In general, land cannot be divided in California without local government approval. Dividing land for sale, lease or financing is regulated by local ordinances based on the State Subdivision Map Act (commencing with Government Code Section 66410). The local general plan, zoning, subdivision, and other ordinances govern the design of the subdivision, the size of its lots, and the types of improvements (street construction, sewer lines, drainage facilities, etc.). In addition, the city or county may impose a variety of fees upon the subdivision, depending upon local and regional needs, such as school impact fees, park fee, etc. Contact your local planning department for information on local requirements and procedures.

Subdivision Types

There are basically two types of subdivisions: parcel maps, which are limited to divisions resulting in fewer than five lots (with certain exceptions), and subdivision maps (also called tract maps), which apply to divisions resulting in five or more lots. Applications for both types of land divisions must be submitted to the local government for consideration in accordance with the local subdivision ordinance and the Subdivision Map Act.

Processing

Upon receiving an application for a subdivision map, the city or county staff will examine the design of the subdivision to ensure that it meets the requirements of the general plan, the zoning ordinance, and the local subdivision ordinance. A public hearing must be held prior to approval of a tentative tract map. Parcel maps may also be subject to a public hearing, depending upon the requirements of the local subdivision ordinance.

Final Approval

Approval of a tentative tract map or parcel map generally means that the subdivider will be responsible for installing improvements such as streets, drainage facilities or sewer lines to serve the subdivision. These improvements must be installed or secured by bond before the city or county will grant final approval of the map and allow the subdivision to be recorded in the county recorder's office. Lots within the subdivision cannot be sold until the map has been officially recorded. The subdivider has at least two years (and depending upon local ordinance, usually more) in which to comply with the improvement requirements, gain final administrative approval, and record the final map. Parcel map requirements may vary dependent upon local ordinance requirements. Figure 3 illustrates a typical subdivision map.

OTHER ORDINANCES AND REGULATIONS

Cities and counties often adopt other ordinances besides zoning and subdivision to protect the general health, safety, and welfare of their inhabitants. Contact your local planning department for information on the particular ordinances in effect in your area. Common types include: flood protection, historic preservation, design review, hillside development control, growth management, impact fees, traffic management, and sign control.

Local ordinances may also be adopted in response to state requirements. Examples include: Local Coastal Programs (California Coastal Act); surface mining regulations (Surface Mining and Reclamation Act); earthquake hazard standards (Alquist-Priolo Special Studies Zone Act); and hazardous material disclosure requirements. These regulations are generally based on the applicable state law.

ANNEXATION AND INCORPORATION

The LAFCO

Annexation (the addition of territory to an existing city) and incorporation (creation of a new city) are controlled by the Local Agency Formation Commission (LAFCO) established in each county by the state's Cortese-Knox-Hertzberg Act (commencing with Government Code Section 56000). The commission is made up of elected officials from the county, cities, and, in some cases, special districts. LAFCO duties include: establishing the "spheres of influence" that designate the service areas of cities and special districts; studying and approving requests for city annexations; and, studying and approving proposals for city incorporations. Below is a very general discussion of annexation and incorporation procedures. For detailed information on this complex subject, contact your county LAFCO.

Annexation

When the LAFCO receives an annexation request, it will convene a hearing to determine the worthiness of the proposal and may deny or conditionally approve the request based on the policies of the LAFCO and state law. Annexation requests which

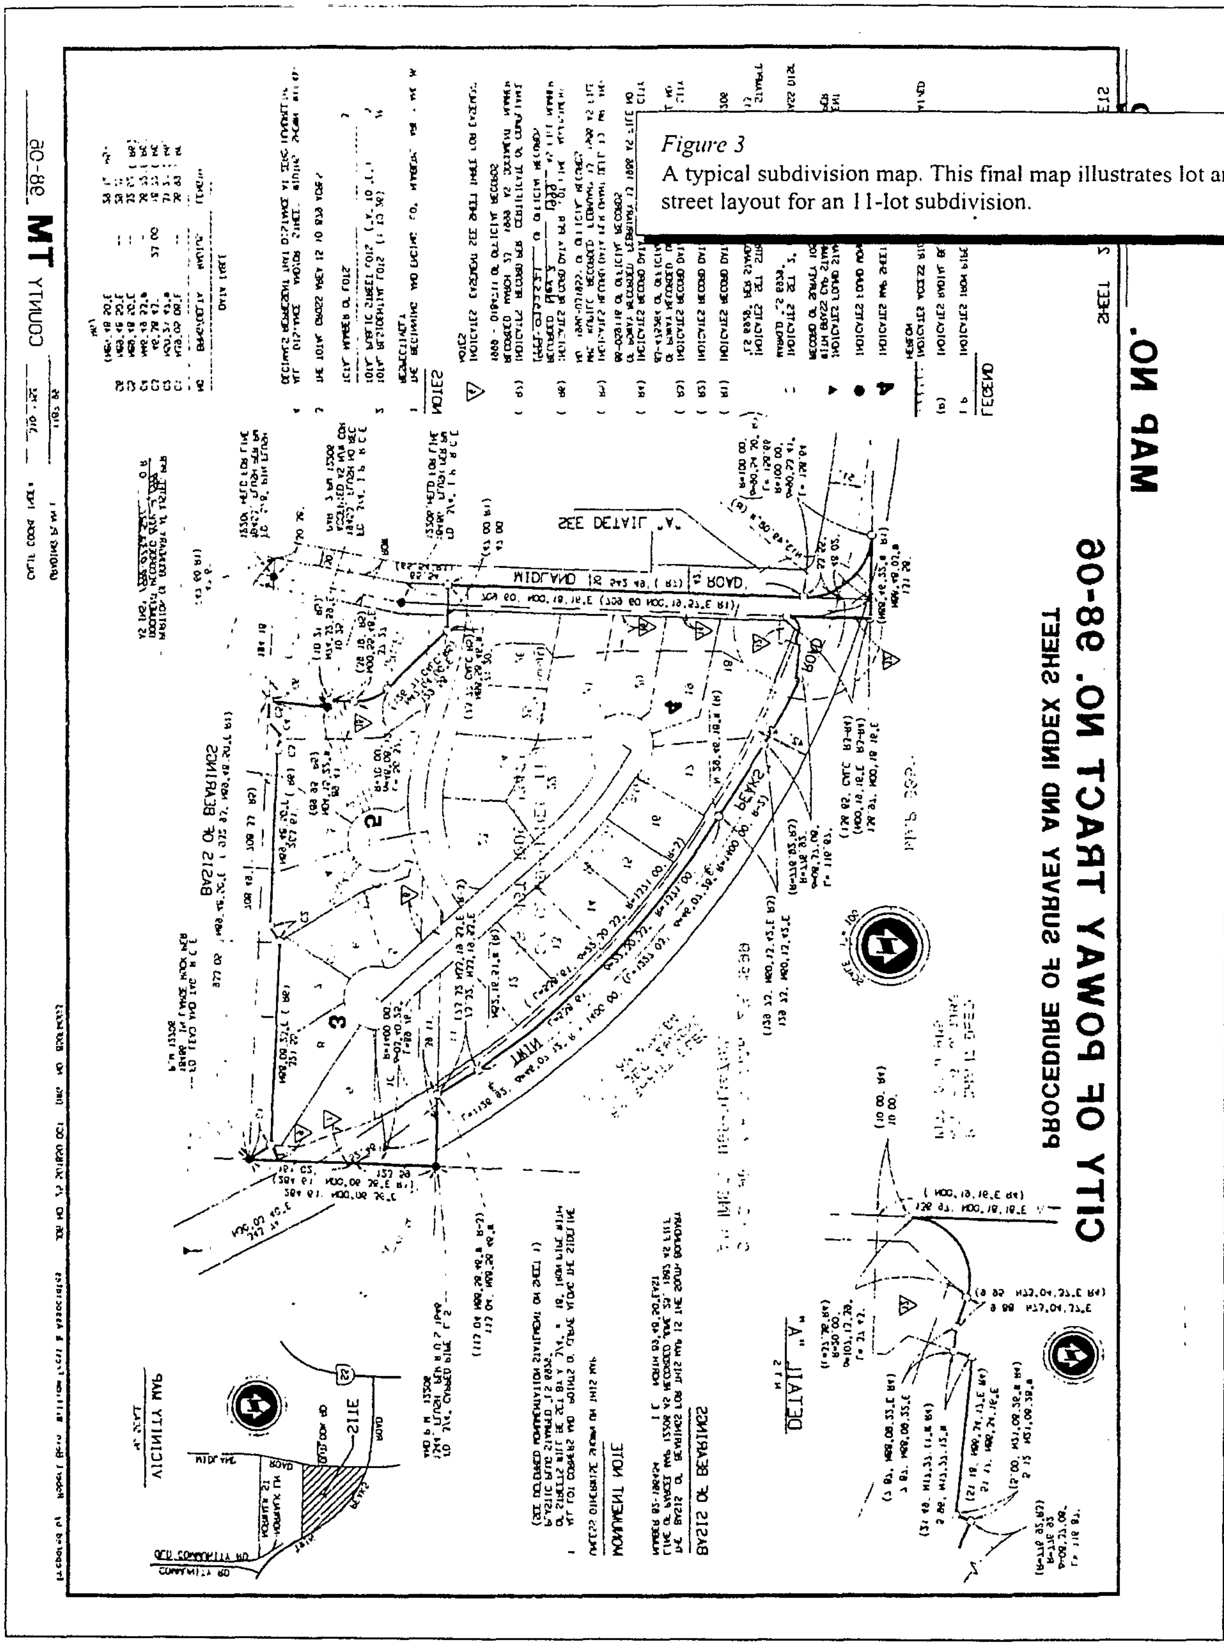

Figure 3
A typical subdivision map. This final map illustrates lot and street layout for an 11-lot subdivision.

R0011183

receive tentative LAFCO approval are delegated to the affected city for hearings and, if necessary, an election. Annexations which have been passed by vote of the inhabitants or which have not been defeated by protest (in cases where no election was required) must be certified by the LAFCO as to meeting all its conditions before they become final. It is the LAFCO, not the city, that is ultimately responsible for the annexation process.

Incorporation

When the formation of a new city is proposed, the LAFCO studies the economic feasibility of the proposed city, its impact on the county and special districts, and its ability to provide public services. A new city must be shown to be "revenue neutral" with regard to the tax revenues lost by the county as a result of incorporation and the cost of current services to the proposed city. If the feasibility of the proposed city cannot be shown, the LAFCO can terminate the proceedings. If the proposed city appears to be feasible, LAFCO will refer the proposal to the county board of supervisors for hearing along with a set of conditions to be met upon incorporation. If the supervisors do not receive protests from a majority of the involved voters, an election will be held among the voters within the proposed city boundaries to create the city. The voters elect the first council at the same election.

THE CALIFORNIA ENVIRONMENTAL QUALITY ACT (CEQA)

The California Environmental Quality Act (commencing with Public Resources Code Section 21000) requires local and state governments to consider the potential environmental effects of a project before deciding whether to approve it. CEQA's purpose is to disclose the potential impacts of a project, suggest methods to minimize those impacts, and discuss alternatives to the project so that decision makers will have full information upon which to base their decision. The term "project" is defined broadly in CEQA. It includes all of the actions discussed in this paper—from annexations to zoning.

CEQA is a complex law with a great deal of subtlety and local variation. The following discussion is *extremely* general. The basic requirements and administrative framework for local governments' CEQA responsibilities are described in the *California Environmental Quality Act: Statutes and Guidelines*. For more information, readers should contact their local planning department or refer to the CEQA listings in the bibliography.

Lead Agency

The "lead agency" is responsible for seeing that environmental review is done in accordance with CEQA and that environmental analyses are prepared when necessary. The agency with the principal responsibility for issuing permits to a project (or for carrying out the project) is deemed to be the "lead agency." As lead agency, it may prepare the environmental analysis itself or it may contract for the work to be done under its direction. In practically all local planning matters (such as rezoning, conditional use permits, and specific plans) the planning department is the lead agency.

Preliminary Review

Analyzing a project's potential environmental effect is a multistep process. Many minor projects are exempt from the CEQA requirements. Typically, these include single-family homes, remodeling, accessory structures, and minor lot divisions (for a complete list refer to *California Environmental Quality Act: Statutes and Guidelines*). No environmental review is required when a project is exempt from CEQA.

When a project is subject to review under CEQA, the lead agency prepares an "initial study" to assess the potential adverse physical impacts of the proposal.

Negative Declarations and EIRs

If the initial study shows that the project will not cause a "significant" impact on the environment or when it has been revised to eliminate all such impacts, a "negative declaration" is prepared. The negative declaration describes why the project will not have a significant impact and may require that the project incorporate a number of measures (called "mitigation measures") ensuring that there will be no such impact.

If significant environmental effects are identified, then an Environmental Impact Report (EIR) must be written before the project can be considered by decision makers. An EIR discusses the proposed project, its environmental setting, its probable impacts, realistic means of reducing or eliminating those impacts, its cumulative effects, and alternatives to the project. CEQA requires that draft Negative Declarations and EIRs be made available for review by the public and other agencies prior to consideration of the project. The review period allows concerned citizens and agencies to comment on the completeness and adequacy of the environmental review prior to its completion.

When the decision making body (the city council, board of supervisors, or other board or commission) approves a project, it must certify the adequacy of the environmental review. If its decision to approve a project will result in unavoidable significant impacts, the decision making body must not only certify the EIR, but also state, in writing, its overriding reasons for granting the approval and how the impacts are to be addressed.

A Negative Declaration or an EIR is an informational document. It does not, in itself, approve or deny a project. Environmental analysis must be done as early as possible in the process of considering a project and must address the entire project. There are several different types of EIRs that may be prepared, depending upon the project. They are described in the *California Environmental Quality Act: Statutes and Guidelines*.

GLOSSARY

These are some commonly used planning terms. This list includes several terms that are not discussed in this booklet.

Board of Supervisors
A county's legislative body. Board members are elected by popular vote and are responsible for enacting ordinances, imposing taxes, making appropriations, and establishing county policy. The board adopts the general plan, zoning, and subdivision regulations.

The "Brown Act"
The Ralph M. Brown Open Meeting Act (commencing with Government Code Section 54950) requires cities and counties to provide advance public notice of hearings and meetings of their councils, boards, and other bodies. Meetings and hearings with some exceptions must be open to the public.

CEQA
The California Environmental Quality Act (commencing with Public Resources Code Section 21000). In general, CEQA requires that all private and public projects be reviewed prior to approval for their potential adverse effects upon the environment.

Charter City
A city which has been incorporated under its own charter rather than under the general laws of the state. Charter cities have broader powers to enact land use regulations than do general law cities. All of California's largest cities are charter cities.

City Council
A city's legislative body. The popularly elected city council is responsible for enacting ordinances, imposing taxes, making appropriations, establishing policy, and hiring some city officials. The council adopts the local general plan, zoning, and subdivision ordinance.

COG
Council of Governments. There are 25 COGs in California made up of elected officials from member cities and counties. COGs are regional agencies concerned primarily with transportation planning and housing; they do not directly regulate land use.

Community Plan
A portion of the local general plan that focuses on a particular area or community within the city or county. Community plans supplement the policies of the general plan.

Conditional Use Permit
Pursuant to the zoning ordinance, a conditional use permit (CUP) may authorize uses not routinely allowed on a particular site. CUPs require a public hearing and if approval is granted, are usually subject to the fulfillment of certain conditions by the developer. Approval of a CUP is not a change in zoning.

Density Bonus
An increase in the allowable number of dwelling units granted by the city or county in return for the project's providing low- or moderate-income housing (see Government Code Section 65915).

Design Review Committee
A group appointed by the city council to consider the design and aesthetics of development within design review zoning districts.

Development Fees
Fees charged to developers or builders as a prerequisite to construction or development approval. The most common are: (1) impact fees (such as parkland acquisition fees, school facilities fees, or street construction fees) related to funding public improvements which are necessitated in part or in whole by the development; (2) connection fees (such as water line fees) to cover the cost of installing public services to the development; (3) permit fees (such as building permits, grading permits, sign permits) for the administrative costs of processing development plans; and, (4) application fees (rezoning, CUP, variance, etc.) for the administrative costs of reviewing and hearing development proposals.

Downzone
This term refers to the rezoning of land to a more restrictive or less intensive zone (for example, from multi-family residential to single-family residential or from residential to agricultural).

EIR
Environmental Impact Report. A detailed review of a proposed project, its potential adverse impacts upon the environment, measures that may avoid or reduce those impacts, and alternatives to the project.

Final Map Subdivision
Final map subdivisions (also called tract maps or major subdivisions) are land divisions which create five or more lots. They must be consistent with the general plan and are generally subject to stricter requirements than parcel maps. Such requirements may include installing road improvements, the construction of drainage and sewer facilities, parkland dedications, and more.

Floor Area Ratio
Abbreviated as FAR, this is a measure of development intensity. FAR is the ratio of the amount of floor area of a building to the amount of area of its site. For instance, a one-story building that covers an entire lot has an FAR of 1. Similarly, a one-story building that covers 1/2 of a lot has an FAR of 0.5.

General Law City
A city incorporated under and administered in accordance with the general laws of the state.

General Plan
A statement of policies, including text and diagrams setting forth objectives, principles, standards, and plan proposals, for the future physical development of the city or county (see Government Code Sections 65300 et seq.).

"Granny" Housing
Typically, this refers to a second dwelling attached to or separate from the main residence that houses one or more elderly persons. California Government Code 65852.1 enables cities and counties to approve such units in single-family neighborhoods.

Impact Fees
See Development Fees.

Infrastructure
A general term describing public and quasi-public utilities and facilities such as roads, bridges, sewers and sewer plants, water lines, power lines, fire stations, etc.

Initial Study
Pursuant to CEQA, an analysis of a project's potential environmental effects and their relative significance. An initial study is preliminary to deciding whether to prepare a negative declaration or an EIR.

Initiative
A legislative measure which has been placed on the election ballot as a result of voter signatures. At the local level, initiatives usually propose changes or additions to the general plan and zoning ordinance. The right to initiative is guaranteed by the California Constitution.

LAFCO
Local Agency Formation Commission. The Cortese-Knox Act (commencing with Government Code Section 56000) establishes a LAFCO made up of elected officials of the county, cities, and, in some cases, special districts in each county. The 57 LAFCOs establish spheres of influence for all the cities and special districts within the county. They also consider incorporation and annexation proposals.

Mitigation Measure
The California Environmental Quality Act requires that when an adverse environmental impact or potential impact is identified, measures must be proposed that will eliminate, avoid, rectify, compensate for or reduce those environmental effects.

Negative Declaration
When a project is not exempt from CEQA and will not have a significant adverse effect upon the environment a negative declaration must be prepared. The negative declaration is an informational document that describes the reasons why the project will not have a significant effect and proposes measures to completely mitigate or avoid any possible effects.

Overlay Zone
A set of zoning requirements that is superimposed upon a base zone. Overlay zones are generally used when a particular area requires special protection (as in a historic preservation district) or has a special problem (such as steep slopes, flooding or earthquake faults). Development of land subject to overlay zoning requires compliance with the regulations of both the base and overlay zones.

Parcel Map
A minor subdivision resulting in fewer than five lots. The city or county may approve a parcel map when it meets the requirements of the general plan and all applicable ordinances. The regulations governing the filing and processing of parcel maps are found in the state Subdivision Map Act and the local subdivision ordinance.

Planned Unit Development (PUD)
Land use zoning which allows the adoption of a set of development standards that are specific to the particular project being proposed. PUD zones usually do not contain detailed development standards; these are established during the process of considering the proposals and adopted by ordinance if the project is approved.

Planning Commission
A group of residents appointed by the city council or board of supervisors to consider land use planning matters. The commission's duties and powers are established by the local legislative body and might include hearing proposals to amend the general plan or rezone land, initiating planning studies (road alignments, identification of seismic hazards, etc.), and taking action on proposed subdivisions.

Referendum
A ballot measure challenging a legislative action by the city council or county board of supervisors. When sufficient voter signatures are filed before the council or board action becomes final, the council or board must either set aside its action or call an election on the matter. Use permits, variances, and subdivisions cannot be challenged by referendum.

School Impact Fees
Proposition 13 put a limit on property taxes and thereby limited the main source of funding for new school facilities. California law allows school districts to impose fees on new developments to offset their impacts on area schools.

Setback
A minimum distance required by zoning to be maintained between two structures or between a structure and property lines.

Specific Plan
A plan addressing land use distribution, open space availability, infrastructure, and infrastructure financing for a portion of the community. Specific plans put the provisions of the local general plan into action (see Government Code Sections 65450 et seq.).

Tentative Map
The map or drawing illustrating a subdivision proposal. The city or county will approve or deny the proposed subdivision based upon the design depicted by the tentative map. A subdivision is not complete until the conditions of approval imposed upon the tentative map have been satisfied and a final map has been certified by the city or county and recorded with the county recorder.

Tract Map
See final map subdivision.

Variance
A limited waiver from the property developement standards of the zoning ordinance. Variance requests are subject to public hearing, usually before a zoning administrator or board of zoning adjustment. Variances do not allow a change in land use.

Zoning
Local codes regulating the use and development of property. The zoning ordinance divides the city or county into land use districts or "zones", represented on zoning maps, and specifies the allowable uses within each of those zones. It establishes development standards for each zone, such as minimum lot size, maximum height of structures, building setbacks, and yard size.

Zoning Adjustment Board
A group appointed by the local legislative body to consider minor zoning adjustments such as conditional use permits and variances. It is empowered to conduct public hearings and to impose conditions of approval. Its decisions may be appealed to the local legislative body.

Zoning Administrator
A planning department staff member responsible for hearing minor zoning permits. Typically, the zoning administrator considers variances and conditional use permits and may interpret the provisions of the zoning ordinance when questions arise. His/her decision may be appealed to the local legislative body.

BIBLIOGRAPHY: A FEW GOOD BOOKS

The reader is encouraged to refer to the following books for a better understanding of planning in California.

California Environmental Quality Act: Statutes and Guidelines (Governor's Office of Planning and Research, Sacramento, California). *The* CEQA Guidelines *describe the requirements for evaluating environmental impacts. Out of print; check in the government documents section of your local library, or CERES website at ceres.ca.gov/ceqa.*

California Land Use and Planning Law, by Daniel J. Curtin Jr., (Solano Press, Pt. Arena, California), revised annually. *A look at the planning, zoning, subdivision, and environmental quality laws that is illustrated by references to numerous court cases.*

The General Plan Guidelines (Governor's Office of Planning and Research, Sacramento, California). *The Guidelines discuss local planning activities and how to write or revise a general plan.*

Growth Within Bounds: Report of the Commission on Local Governance for the 21st Century, 2000. *Recommendations on future local governance options, including LAFCO reform. Out of print; check in the government documents section of your local library, or the Commission website at www.clg21.ca.gov.*

A Guide to Planning in California, (League of Women Voters of California, Sacramento, California). *An excellent summary of the processes of local and state government.*

Guide to California Planning, by William J. Fulton (Solano Press, Point Arena, California). *A lively, well-written discussion of nearly every aspect of planning in the State.*

Open and Public: A User's Guide to The Ralph M. Brown Act, by the League of California Cities (League of California Cities, Sacramento, California), 1994. *An easy to read explanation of the state's open meeting laws and the responsibilities of local government with regard to public meetings.*

Subdivision Map Act Manual, by Daniel J. Curtin, Jr., (Solano Press, Pt. Arena, California), revised annually. *A practitioner's guide to the Map Act, including pertinent legal precedents.*

Illicit Discharge Detection and Elimination

Presentation at the EPA *National Storm Water Coordinator's Meeting*, Orlando, FL. May 1-3, 2001

Robert Pitt
Department of Civil and Environmental Engineering
The University of Alabama at Birmingham

Abstract
This paper describes procedures that have been used to identify sources of inappropriate ("illicit") discharges in storm drainage systems. Also included is a review of emerging techniques that may also be useful, especially in future years as they become more accessible and become proven technologies. This paper also describes a series of tests where the original methods developed previously for EPA (Pitt, *et al.* 1993), along with selected new procedures, were examined using almost 700 stormwater samples collected from telecommunication manholes from throughout the U.S. About ten percent of the samples were estimated to be contaminated with sanitary sewage using these methods, similar to what is expected for most stormwater systems. The original methods are still recommended as the most useful procedure for identifying contamination of storm drainage systems, with the possible addition of specific tests for *E. coli* and enterococci and UV absorbance at 228 nm. Most newly emerging methods require exotic equipment and unusual expertise and are therefore not very available, especially at low cost and with fast turn-around times for the analyses. These emerging methods may therefore be more useful for special research projects than for routine screening of storm drainage systems.

The Center for Watershed Protection (CWP) and Dr. Robert Pitt with the University of Alabama are currently being funded by EPA to complete a technical assessment of techniques and methods for identifying and correcting illicit and inappropriate discharges geared towards NPDES Phase II communities. The project has a two year duration. In the first year, most of our effort will be directed to collecting data. The most cost effective and efficient techniques will also be identified during this initial project period. In the second project year, the project team will develop draft guidance on methods and techniques to identify and correct illicit connections, test the efficacy of the draft guidance in four communities, complete a final "User's Manual for Identifying and Correcting Illicit and Inappropriate Discharges," and conduct training and dissemination. This project is expected to start in the summer of 2001.

Introduction
Urban stormwater runoff includes waters from many other sources which find their way into storm drainage systems, besides from precipitation. There are cases where pollutant levels in storm drainage are much higher than they would otherwise be because of excessive amounts of contaminants that are introduced into the storm drainage system by various non-stormwater discharges. Additionally, baseflows (during dry weather) are also common in storm drainage systems. Dry-weather flows and wet-weather flows have been monitored during numerous urban runoff studies. These studies have found that discharges observed at outfalls during dry weather were significantly different from wet-weather discharges and may account for the majority of the annual discharges for some pollutants of concern from the storm drainage system.

There have been numerous methods used to investigate inappropriate discharges to storm drainage systems. Pitt, *et al.* (1993) and Lalor (1994) reviewed many of these procedures and developed a system that municipalities could use for screening outfalls in residential and commercial areas. In these areas, sewage contamination, along with low rate discharges from small businesses (especially laundries, vehicle repair shops, plating shops, etc.) are of primary concern. One of the earliest methods used to identify sewage contamination utilized the ratio of fecal coliform to fecal strep. bacteria. This method is still in use, but unfortunately has proven inaccurate in most urban stormwater

R0011189

applications. The fol[illegible] methodology developed by Pitt, *et al.* (1993) and [illegible] and some new approaches [illegible] investigated.

Use of Tracers to Identify Sources of Contamination in Urban Drainage Systems

Investigations designed to determine the contribution of urban stormwater runoff to receiving water quality problems have led to a continuing interest in inappropriate connections to storm drainage systems. Urban stormwater runoff is traditionally defined as that portion of precipitation which drains from city surfaces and flows via natural or man-made drainage systems into receiving waters. In fact, urban stormwater runoff also includes waters from many other sources which find their way into storm drainage systems. Sources of some of this water can be identified and accounted for by examining current National Pollutant Discharge Elimination System (NPDES) permit records for permitted industrial wastewaters that can be legally discharged to the storm drainage system. However, most of the water comes from other sources, including illicit and/or inappropriate entries to the storm drainage system. These entries can account for a significant amount of the pollutants discharged from storm sewerage systems (Pitt and McLean 1986).

Permits for municipal separate storm sewers include a requirement to effectively prohibit problematic non-stormwater discharges, thereby placing emphasis on the elimination of inappropriate connections to urban storm drains. Section 122.26 (d)(1)(iv)(D) of the rule specifically requires an initial screening program to provide means for detecting high levels of pollutants in dry weather flows which should serve as indicators of illicit connections to the storm sewers. To facilitate the application of this rule, the EPA's Office of Research and Development's Storm and Combined Sewer Pollution Control Program and the Environmental Engineering & Technology Demonstration Branch, along with the Office of Water's Nonpoint Source Branch, supported research for the investigation of inappropriate entries to storm drainage systems (Pitt, *et al.* 1993). The approach presented in this research was based on the identification and quantification of clean baseflow and the contaminated components during dry weather. If the relative amounts of potential components are known, then the importance of the dry weather discharge can be determined.

The ideal tracer to identify major flow sources should have the following characteristics:

- Significant difference in concentrations between possible pollutant sources;
- Small variations in concentrations within each likely pollutant source category;
- A conservative behavior (i.e., no significant concentration change due to physical, chemical or biological processes); and,
- Ease of measurement with adequate detection limits, good sensitivity and repeatability.

In order to identify tracers meeting the above criteria, literature characterizing potential inappropriate entries into storm drainage systems was examined. Several case studies which identified procedures used by individual municipalities or regional agencies were also examined.

Selection of Parameters for Identifying Inappropriate Discharge Sources. Table 1 is an assessment of the usefulness of candidate field survey parameters in identifying different potential non-stormwater flow sources. Natural and domestic waters should be uncontaminated (except in the presence of contaminated groundwaters entering the drainage system, for example). Sanitary sewage, septage, and industrial waters can produce toxic or pathogenic conditions. The other source flows (wash and rinse waters and irrigation return flows) may cause nuisance conditions, or degrade the ecosystem. The parameters marked with a plus sign can probably be used to identify the specific source flows by their presence. Negative signs indicate that the potential source flow probably does not contain the listed parameter in adverse or obvious amounts, and may help confirm the presence of the source by its absence. Parameters with both positive and negative signs for a specific source category would not likely be very helpful due to likely wide variations expected.

TABLE 1 Candidate Field Survey Parameters and Associated Non-Stormwater Flow Sources

Parameter	[illegible] Water	Potable Water	Sanitary Sewage	Septage Water	Indus Water	Wash Water	Rinse Water	Irrig Water
Fluoride	-	+	+	+	+/-	+	+	+
Hardness change	-	+/-	+	+	+/-	+	+	-
Surfactants	-	-	+	-	-	+	+	-
Florescence	-	-	+	+	-	+	+	-

pH	-	-	-	-	+	-	-	-

Note: - implies relatively low concentration
\+ implies relatively high concentration
+/- implies variable conditions

Parameters Suitable for Indicators of Contamination by Sanitary Sewage
Tracer Characteristics of Local Source Flows. Table 2 is a summary of tracer parameter measurements for Birmingham, AL. This table is a summary of the "library" that describes the tracer conditions for each potential source category. The important information shown on this table includes the median and coefficient of variation (COV) values for each tracer parameter for each source category. Appropriate tracers are characterized by having significantly different concentrations in flow categories that need to be distinguished. In addition, effective tracers also need low COV values within each flow category. The study indicated that the COV values were quite low for each category, with the exception of chlorine, which had much greater COV values. Chlorine is therefore not recommended as a quantitative tracer to estimate the flow components. Similar data must be collected in each community where these procedures are to be used. Recommended field observations include color, odor, clarity, presence of floatables and deposits, and rate of flow, in addition to the selected chemical measurements.

Simple Data Evaluation Methods to Indicate Sources of Contamination
Negative Indicators Implying Contamination. Indicators of contamination (negative indicators) are clearly apparent visual or physical parameters indicating obvious problems and are readily observable at the outfall during the field screening activities. These observations are very important during the field survey because they are the simplest method of identifying grossly contaminated dry-weather outfall flows. The direct examination of outfall characteristics for unusual conditions of flow, odor, color, turbidity, floatables, deposits/stains, vegetation conditions, and damage to drainage structures is therefore an important part of these investigations. Table 3 presents a summary of these indicators, along with narratives of the descriptors to be selected in the field.

Correlation tests were conducted to identify relationships between outfalls that were known to have severe contamination problems and the negative indicators (Lalor 1994). Pearson correlation tests indicated that high turbidity and obvious odors appeared to be the most useful physical indicators of contamination when contamination was defined by toxicity and the presence of detergents. High turbidity was noted in 74% of the contaminated source flow samples. This represented a 26% false negative rate (indication of no contamination when contamination actually exists), if one relied on turbidity alone as an indicator of contamination. High turbidity was noted in only 5% of the uncontaminated source flow samples. This represents the rate of false positives (indication of contamination when none actually exists) when relying on turbidity alone. Noticeable odor was indicated in 67% of flow samples from contaminated sources, but in none of the flow samples from uncontaminated sources. This [illegible] identified include gasoline, oil, [illegible] industrial chemicals or [illegible] compounds [illegible]

False negatives are more of a concern than a reasonable number of false positives when working with a screening methodology. Screening methodologies are used to direct further, more detailed investigations. False positives would be discarded after further investigation. However, a false negative during a screening investigation results in the dismissal of a problem outfall for at least the near future. Missed contributors to stream contamination may result in unsatisfactory in-stream results following the application of costly corrective measures elsewhere.

The method of using physical characteristics to indicate contamination in outfall flows does not allow quantifiable estimates of the flow components and, if used alone, will likely result in many incorrect determinations, especially false negatives. These simple characteristics are most useful for identifying gross contamination, only the most significantly contaminated outfalls and drainage areas would therefore be recognized using this method.

Detergents as Indicators of Contamination. Results from the Mann-Whitney U tests (Lalor 1994) indicated that samples from any of the dry-weather flow sources could be correctly classified as clean or contaminated based only on the measured value of any one of the following parameters, detergents, color, or conductivity. Color and high conductivity were present in samples from clean sources as well as contaminated sources, but their levels of occurrence were significantly different between the two groups. If samples from only one source were expected to make up outfall flows, the level of color or conductivity could be used to distinguish contaminated outfalls from clean outfalls. However, since multi-source flows occur, measured levels of color or conductivity could fall within acceptable levels because of dilution, even though a contaminating source was contributing to the flow. Detergents, on the other hand, can be used to distinguish between clean and contaminated outfalls simply by their presence or absence, using a detection limit of 0.06 mg/L. All samples analyzed from contaminated sources contained detergents in excess of this amount (with the exception of three septage samples collected from homes discharging only toilet flushing water). No clean source samples were found to contain detergents. Contaminated sources would be detected in mixtures with uncontaminated waters if they made up at least 10% of the mixture.

Flow Chart for Most Significant Flow Component Identification. A further refinement is the flow chart shown on Figure 1. This flow chart describes an analysis strategy which may be used to identify the major component of dry-weather flow samples in residential and commercial areas. This method does not attempt to distinguish among all potential sources of dry-weather flows identified earlier, but rather the following four major groups of flow are identified: (1) tap waters (including domestic tap water, irrigation water and rinse water), (2) natural waters (spring water and shallow ground water), (3) sanitary wastewaters (sanitary sewage and septic tank discharge), and (4) wash waters (commercial laundry waters, commercial car wash waters, radiator flushing wastes, and plating bath wastewaters). The use of this method would not only allow outfall flows to be categorized as contaminated or uncontaminated, but would allow outfalls carrying sanitary wastewaters to be identified. These outfalls could then receive highest priority for further investigation leading to source control. This flow chart (Lalor 1994) was designed for use in residential and/or commercial areas only.

Table 2. Tracer Concentrations found in Birmingham, AL, Waters (mean, standard deviation, and coefficient of Variation, COV) (Pitt, *et al.* 1993 and Lalor 1994)

Table 3. Interpretations of Physical Observation Parameters and Likely Associated Flow Sources (Pitt, *et al.* 1993)

Odor - Most strong odors, especially gasoline, oils, and solvents, are likely associated with high responses on the toxicity screening test. Typical obvious odors include: gasoline, oil, sanitary wastewater, industrial chemicals, decomposing organic wastes, etc.

sewage: smell associated with stale sanitary wastewater, especially in pools near outfall.
sulfur ("rotten eggs"): industries that discharge sulfide compounds or organics (meat packers, canneries, dairies, etc.).
oil and gas: petroleum refineries or many facilities associated with vehicle maintenance or petroleum product storage.
rancid-sour: food preparation facilities (restaurants, hotels, etc.).

Color - Important indicator of inappropriate industrial sources. Industrial dry-weather discharges may be of any color, but dark colors, such as brown, gray, or black, are most common.

yellow: chemical plants, textile and tanning plants.
brown: meat packers, printing plants, metal works, stone and concrete, fertilizers, and petroleum refining facilities.
green: chemical plants, textile facilities.
red: meat packers.
gray: dairies, sewage.

Turbidity - Often affected by the degree of gross contamination. Dry-weather industrial flows with moderate turbidity can be cloudy, while highly turbid flows can be opaque. High turbidity is often a characteristic of undiluted dry-weather industrial discharges.

cloudy: sanitary wastewater, concrete or stone operations, fertilizer facilities, automotive dealers.
opaque: food processors, lumber mills, metal operations, pigment plants.

Floatable Matter - A contaminated flow may contain floating solids or liquids directly related to industrial or sanitary wastewater pollution. Floatables of industrial origin may include animal fats, spoiled food, oils, solvents, sawdust, foams, packing materials, or fuel.

oil sheen: petroleum refineries or storage facilities and vehicle service facilities.
sewage: sanitary wastewater.

Deposits and Stains - Refers to any type of coating near the outfall and are usually of a dark color. Deposits and stains often will contain fragments of floatable substances. These situations are illustrated by the grayish-black deposits that contain fragments of animal flesh and hair which often are produced by leather tanneries, or the white crystalline powder which commonly coats outfalls due to nitrogenous fertilizer wastes.

sediment: construction site erosion.
oily: petroleum refineries or storage facilities and vehicle service facilities.

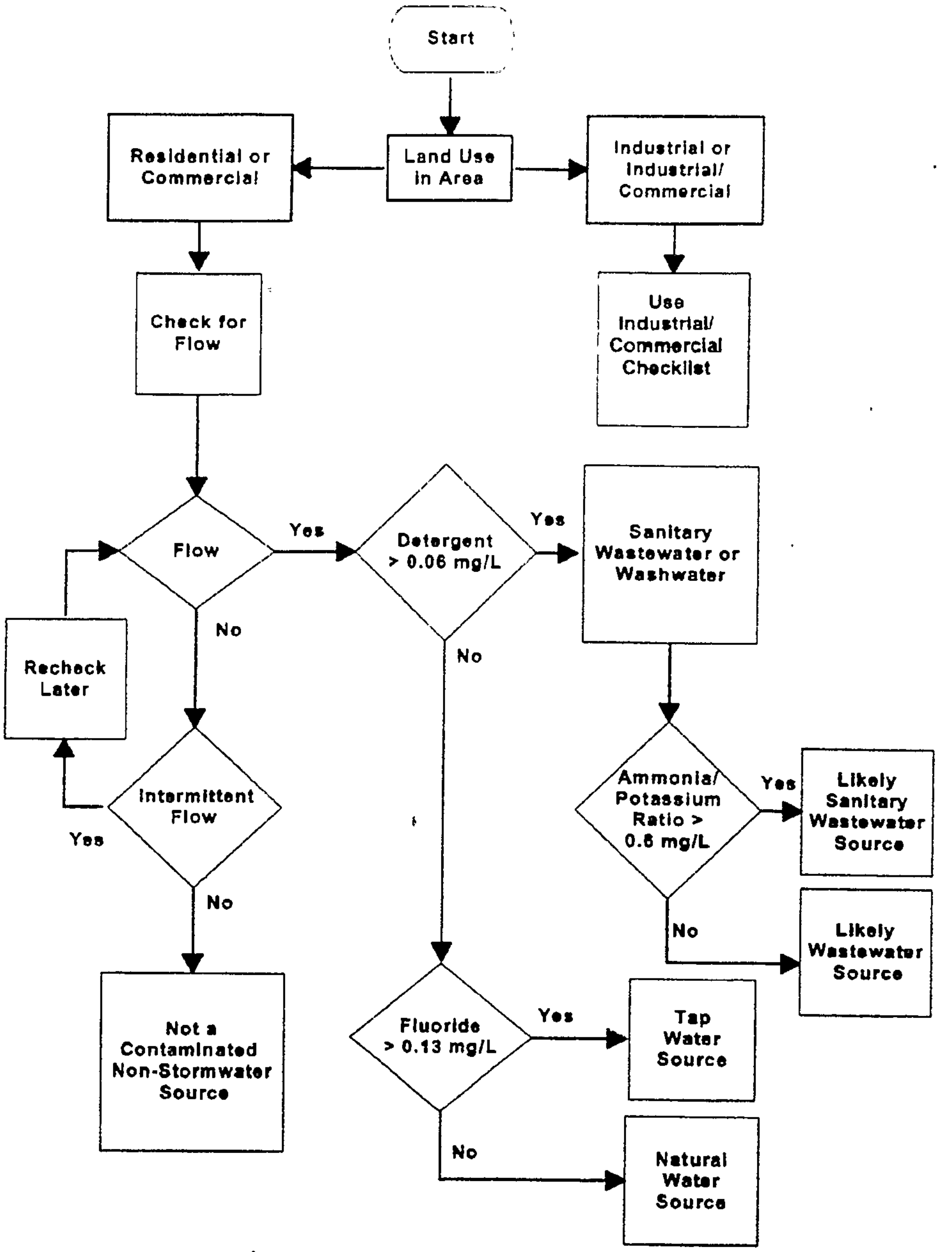
Vegetation - Vegetation surrounding an outfall may show the effects of industrial pollutants. Decaying organic materials coming from various food product wastes would cause an increase in plant life, while the discharge of chemical dyes and inorganic pigments from textile mills could noticeably decrease vegetation. It is important not to confuse the adverse effects of high stormwater flows on vegetation with highly toxic dry-weather intermittent flows.

excessive growth: food product facilities.
inhibited growth: high stormwater flows, beverage facilities, printing plants, metal product facilities, drug manufacturing, petroleum facilities, vehicle service facilities and automobile dealers.

Damage to Outfall Structures - Another readily visible indication of industrial contamination. Cracking, deterioration, and spalling of concrete or peeling of surface paint, occurring at an outfall are usually caused by severely contaminated discharges, usually of industrial origin. These contaminants are usually very acidic or basic in nature. Primary metal industries have a strong potential for causing outfall structural damage because their batch dumps are highly acidic. Poor construction, hydraulic scour, and old age may also adversely affect the condition of the outfall structure.

concrete cracking: industrial flows
concrete spalling: industrial flows
peeling paint: industrial flows
metal corrosion: industrial flows

Figure 1 Simple flow chart method to identify significant contaminating sources (Lalor 1994).



R0011195

In residential and or commercial areas, all outfalls should be located and examined. The first indicator is the presence or absence of dry-weather flow. If no dry-weather flow exists at an outfall, then indications of intermittent flows must be investigated. Specifically, stains, deposits, odors, unusual stream-side vegetation conditions, and damage to outfall structures can all indicate intermittent non-stormwater flows. However, frequent visits to outfalls over long time periods, or the use of other monitoring techniques, may be needed to confirm that only stormwater flows occur. If intermittent flow is not indicated, then the outfall probably does not have a contaminated non-stormwater source. The other points on the flow chart serve to indicate if a major contaminating source is present, or if the water is uncontaminated. Component contributions cannot be quantified using this method, and only the "most contaminated" type of source present will be identified.

If dry-weather flow exists at an outfall, then the flow should be sampled and tested for detergents. If detergents are not present, the flow is probably from a non-contaminated non-stormwater source. The lower limit of detection for detergent should be about 0.06 mg L.

If detergents are not present, fluoride levels can be used to distinguish between flows with treated water sources and flows with natural sources in communities where water supplies are fluoridated and natural fluoride levels are low. In the absence of detergents, high fluoride levels would indicate a potable water line leak, irrigation water, or wash rinse water. Low fluoride levels would indicate waters originating from springs or shallow groundwater. Based on the flow source samples tested in this research (Table 2), fluoride levels above 0.13 mg/L would most likely indicate that a tap water source was contributing to the dry-weather flow in the Birmingham, Alabama, study area.

If detergents are present, the flow is probably from a contaminated non-stormwater source, as indicated on Table 2. The ratio of ammonia to potassium can be used to indicate whether or not the source is sanitary wastewater. Ammonia/potassium ratios greater than 0.60 would indicate likely sanitary wastewater contamination. Ammonia/potassium ratios were above 0.9 for all septage and sewage samples collected in Birmingham (values ranged from 0.97 to 15.37, averaging 2.55). Ammonia/potassium ratios for all other samples containing detergents were below 0.7, ranging from 0.00 to 0.65, averaging 0.11. One radiator waste sample had an ammonia/potassium ratio of 0.65.

Non-contaminated samples collected in Birmingham had ammonia/potassium ratios ranging from 0.00 to 0.41, with a mean value of 0.06 and a median value of 0.03. Using the mean values for non-contaminated samples (0.06) and sanitary wastewaters (2.55), flows comprised of mixtures containing at least 25% sanitary wastes with the remainder of the flow from uncontaminated sources would likely be identified as sanitary wastewaters using this method. Flows containing smaller percent contributions from sanitary wastewaters might be identified as having a wash water source, but would not be identified as uncontaminated.

General Matrix Algebra Methods to Indicate Sources of Contamination Through Fingerprinting

Other approaches can also be used to calculate the source components of mixed outfall flows. One approach is the use of matrix algebra to simultaneously solve a series of chemical mass balance equations. This method can be used to predict the most likely flow source, or sources, making up an outfall sample. It is possible to estimate the outfall source flow components using a set of simultaneous equations. The number of unknowns should equal the number of equations available, resulting in a square matrix. If there are seven likely source categories, then there should be seven tracer parameters used. If there are only four possible sources, then only the four most efficient tracer parameters should be used. Only tracers that are linearly related to mixture components can be used. As an example, pH cannot be used in these equations, because it is not additive.

This method estimates flow contributions from various sources using a "receptor model", based on a set of chemical mass balance equations. Such models, which assess the contributions from various sources based on observations at sampling sites (the receptors), have been applied to the investigation of air pollutant sources for many years (Scheff and Wadden 1993; Cooper and Watson 1980). The characteristic "signatures" of the different types of sources, as identified in the library of source flow data, allows the development of a set of mass balance equations. These equations describe the measured concentrations in an outfall's flow as a linear combination of the contributions from the different potential so[illegible] requirement for this method is the physical and chemical characterization of waters collected directly from potential sources of dry-weather flows (the "library"). This allows concentration patterns (fingerprints) for the parameters of interest to be established for each type of source. Theoretically, if these patterns are different for each source, the observed concentrations at the outfall would be a linear combination of the concentration patterns from the different component sources, each weighted by a source strength term (m_n). This source strength term would indicate the fraction of outfall flow originating from each likely source. By measuring a number of parameters equal to, or greater than, the number of potential source types, the source strength term could be obtained by solving a set of chemical mass balance equations of the type:

$$C_p = \sum_n m_n x_{pn}$$

where C_p is the concentration of parameter p in the outfall flow and x_{pn} is the concentration of parameter p in source type n.

As an example of this method, consider 8 possible flow sources and 8 parameters, as presented in Table 4. The number of parameters evaluated for each outfall must equal the number of probable dry-weather flow sources in the drainage area. Mathematical methods are available which provide for the solution of over specified sets of equations (more equations than unknowns) but these are not addressed here.

The selection of parameters for measurement should reflect evaluated parameter usefulness. Evaluation of the Mann-Whitney U Test results (Lalor 1994) suggested the following groupings of parameters, ranked by their usefulness for distinguishing between all the types of flow sources sampled in Birmingham, AL:

- First set (most useful): potassium and hardness
- Second set: fluorescence, conductivity, fluoride, ammonia, detergents, and color
- Third set (least useful): chlorine

TABLE 4. Set of Chemical Mass Balance Equations

	Source 1	Source 2	Source 3	Source 4	Source 5	Source 6	Source 7	Source 8	Outfall

Emerging Tools for Identifying Sources of Discharges

Coprostanol and Other Fecal Sterol Compounds Utilized as Tracers of Contamination by Sanitary Sewage. A more likely indicator of human wastes than fecal coliforms and other "indicator" bacteria may be the use of certain molecular markers, specifically the fecal sterols such as coprostanol and epicoprostanol (Eaganhouse, *et al.* 1988). However, these compounds are also discharged by other carnivores in a drainage (especially dogs). A number of research projects have used these compounds to investigate the presence of sanitary sewage contamination. The most successful application may be associated with sediment analyses instead of water analyses. As an example, water analyses of coprostanol are difficult due to the typically very low concentrations found, although the concentrations in many sediments are quite high and much easier to quantify. Unfortunately, the long persistence of these compounds in the environment easily confuses recent contamination with historical or intermittent contamination.

Particulates and sediments collected from coastal areas in Spain and Cuba receiving municipal sewage loads were analyzed by Grimalt, *et al.* (1990) to determine the utility of coprostanol as a chemical marker of sewage contamination. Coprostanol can not by itself be attributed to fecal matter inputs. However, relative contributions of steroid components can be a useful indicator. When the relative concentrations of coprostanol and coprostanone are higher than their 5α epimers, or more realistically, other sterol components of background or natural occurrence, it can provide useful information.

Sediment cores from Santa Monica Basin, CA, and effluent from two local municipal wastewater discharges were analyzed by Venkatesan and Kaplan (1990) for coprostanol to determine the degree of sewage addition to sediment. Coprostanols were distributed throughout the basin sediments in association with fine particles. Some stations contained elevated levels, either due to their proximity to outfalls or because of preferential advection of fine-grained sediments. A noted decline of coprostanols relative to total sterols from outfalls seaward indicated dilution of sewage by biogenic sterols.

Other chemical compounds have been utilized for sewage tracer work. Saturated hydrocarbons with 16-18 carbons, and saturated hydrocarbons with 16-21 carbons, in addition to coprostanol, were chosen as markers for sewage in water, particulate, and sediment samples near the Cocoa, FL, domestic wastewater treatment plant (Holm, *et al.* 1990). The concentration of the markers was highest at points close to the outfall pipe and diminished with distance. However the concentration of C16-C21 compounds was high at a site 800 m from the outfall indicating that these compounds were unsuitable markers for locating areas exposed to the sewage plume. The concentrations for the other markers were very low at this station.

The range of concentrations of coprostanol found in sediments and mussels of Venice, Italy, were reported by Sherwin, *et al.* (1993). Raw sewage is still discharged directly into the Venice lagoon. Coprostanol concentrations were determined in sediment and mussel samples from the lagoon using gas chromatography/mass spectroscopy. Samples were collected in interior canals and compared to open-bay concentrations. Sediment concentrations ranged from 0.2-41.0 μg/g (dry weight). Interior canal sediment samples averaged 16 μg/g compared to 2 μg/g found in open bay sediment samples. Total coprostanol concentrations in mussels ranged from 80 to 620 ng/g (wet weight). No mussels were found in the four most polluted interior canal sites.

Nichols, *et al.* (1996) also examined coprostanol in stormwater and the sea-surface microlayer to distinguish human versus nonhuman sources of contamination. Other steroid compounds in sewage effluent were investigated by Routledge, *et al.* (1998) and Desbrow, *et al.* (1998) who both examined estrogenic chemicals. The most common found were 17β-Estradiol and estrone which were detected at concentrations in the tens of nanograms per liter range. These were identified as estrogenic through a toxicity identification and evaluation approach, where sequential separations and analyses identified the sample fractions causing estrogenic activity using a yeast-based estrogen screen. GC/MS was then used to identify the specific compounds.

Estimating Potential Sanitary Sewage Discharges into Storm Drainage and Receiving Waters using Detergent Tracer Compounds. As described above, detergent measurements (using methylene blue active substance, MBAS, test methods) were the most successful individual tracer to indicate contaminated water in storm sewerage dry-weather flows. Unfortunately, the MBAS method uses hazardous chloroform for an extraction step. Different detergent components, especially linear alkylbenzene sulphonates (LAS) and linear alkylbenzenes (LAB), have also been tried to indicate sewage dispersal patterns in receiving waters. Boron, a major historical ingredient of laundry chemicals, can also potentially be used. Boron has the great advantage of being relatively easy to analyze using portable field test kits, while LAS requires chromatographic equipment. LAS can be measured using HPLC with fluorescent detection, after solid phase extraction, to very low levels. Fujita, *et al.* (1998) developed an efficient enzyme-linked immunosorbent assay (ELISA) for detecting LAS at levels from 20 to 500 µg/L.

LAS from synthetic surfactants (Terzic and Ahel 1993) which degrade rapidly, as well as nonionic detergents (Terzic and Ahel 1993) which do not degrade rapidly, have been utilized as sanitary sewage markers. LAS was quickly dispersed from wastewater outfalls except in areas where wind was calm. In these areas LAS concentrations increased in freshwater but were unaffected in saline water. After time, the lower alkyl groups were mostly found, possibly as a result of degradation or settling of longer alkyl chain compounds with sediments. Chung, *et al.* (1995) also describe the distribution and fate of LAS in an urban stream in Korea. They examined different LAS compounds having carbon ratios of C12 and C13 compared to C10 and C11, plus ratios of phosphates to MBAS and the internal to external isomer ratio (I/E) as part of their research. Gonález-Mazo, *et al.* (1998) examined LAS in the Bay of Cádiz off the southwest of Spain. They found that LAS degrades rapidly (Fujita, *et al.*, 1998, found that complete biodegradation of LAS requires several days), and is also strongly sorbed to particulates. In areas close to shore and near the untreated wastewater discharges, there as significant vertical stratification of LAS: the top 3 to 5 mm of water had LAS concentrations about 100 times greater than found at 0.5 m.

Zeng and Vista (1997) and Zeng, *et al.* (1997) describe a study off of San Diego where LAB was measured, along with polycyclic aromatic hydrocarbons (PAHs) and aliphatic hydrocarbons (AHs) to indicate the relative pollutant contributions of wastewater from sanitary sewage, nonpoint sources, and hydrocarbon combustion sources. They developed and tested several indicator ratios (alkyl homologue distributions and parent compound distributions) and examined the ratio of various PAHs (such as phenanthrene to anthracene, methylphenanthrene to phenanthrene, fluoranthene to pyrene, and benzo(a)anthracene to chrysene) as tools for distinguishing these sources. They concluded that LABs are useful tracers of domestic waste inputs to the environment due to their limited sources. They also describe the use of the internal to external isomer ratio (I/E) to indicate the amount of biodegradation that may have occurred to the LABs. They observed concentrations of total LABs in sewage effluent of about 3 µg/L, although previous researchers have seen concentrations of about 150 µg/L in sewage effluent from the same area.

The fluorescent properties of detergents have also been used as a tracer by investigating the fluorescent whitening agents (FWAs), as described by Poiger, *et al.* (1996) and Kramer, *et al.* (1996). HPLC with fluorescence detection was used in these studies to quantify very low concentrations of FWAs. The two most frequently used FWAs in household detergents (DSBP and DAS 1) were found at 7 to 21 µg/L in primary sewage effluent and at 3 to 9 µg/L in secondary effluent. Raw sewage contains about 10 to 20 µg/L FWAs. The removal mechanisms in sewage treatment processes is by adsorption to activated sludge. The type of FWAs varies from laundry applications to textile finishing and paper production, making it possible to identify sewage sources. The FWAs were found in river water at 0.04 to 0.6 µg/L. The FWAs are not easily biodegradable but they are readily photodegraded. Photodegradation rates have been reported to be about 7% for DSBP and 71% for DAS 1 in river water exposed to natural sunlight, after one hour exposure. Subsequent photodegradation is quite slow.

Other Compounds Found in Sanitary Sewage that may be used for Identifying Contamination by Sewage. Halling-Sørensen, *et al.* (1998) detected numerous pharmaceutical substances in sewage effluents and in receiving waters. Their work addressed human health concerns of these low level compounds that can enter downstream drinking water supplies. However, the information can also be possibly used to help identify sewage contamination. Most of the research has focused on clofibric acid, a chemical used in cholesterol lowering drugs. It has been found in concentrations ranging from 10 to 165 ng/L in Berlin drinking water sampler. Other drugs commonly found include aspirin, caffeine, and ibuprofen. Current FDA guidance mandates that the maximum concentration of a substance or its active metabolites at the point of entry into the aquatic environment be less than 1 µg/L (Hun 1998).

Caffeine has been used as an indicator of sewage contamination by several investigators (Shuman and Strand 1996). The King County, WA, Water Quality Assessment Project is examining the impacts of CSOs on the Duwamish

River and Elliott Bay. [illegible] caffeine (representing dissolved CSO constituents) and coprostanol (representing particulate-bound CSO constituents) in connection with heavy metals and conventional analyses, to help determine the contribution of CSOs to the river. The caffeine is unique to sewage, while coprostanol is from both humans and carnivorous animals and is therefore also in stormwater. They sampled upstream of all CSOs, but with some stormwater influences, 100 m upstream of the primary CSO discharge (but downstream of other CSOs), within the primary CSO discharge line, and 100 m downriver of the CSO discharge location. The relationship between caffeine and coprostanol was fairly consistent for the four sites (coprostanol was about 0.5 to 1.5 μg/L higher than caffeine). Similar patterns were found between the three metals, chromium was always the lowest and zinc was the highest. King Co. is also using clean transported mussels placed in the Duwamish River to measure the bioconcentration potential of metal and organic toxicants and the effects of the CSOs on mussel growth rates (after 6 week exposure periods). Paired reference locations are available near the areas of deployment, but outside the areas of immediate CSO influence. *US Water News* (1998) also described a study in Boston Harbor that found caffeine at levels of about 7 μg/L in the harbor water. The caffeine content of regular coffee is about 700 mg/L, in contrast.

DNA Profiling to Measure Impacts on Receiving Water Organisms and to Identify Sources of Microorganisms in Stormwater. This rapidly emerging technique seems to have great promise in addressing a number of nonpoint source water pollution issues. Kratch (1997) summarized several investigations on cataloging the DNA of *E. coli* to identify their source in water. This rapidly emerging technique seems to have great promise in addressing a number of nonpoint source water pollution issues. The procedure, developed at the Virginia Polytechnic Institute and State University, has been used in Chesapeake Bay. In one example, it was possible to identify a large wild animal population as the source of fecal coliform contamination of a shellfish bed, instead of suspected failing septic tanks. DNA patterns in fecal coliforms vary among animals and birds, and it is relatively easy to distinguish between human and non-human sources of the bacteria. However, some wild animals have DNA patterns that are not easily distinguishable. Some researchers question the value of *E. coli* DNA fingerprinting believing that there is little direct relationship between *E. coli* and human pathogens. However, this method should be useful to identify the presence of sewage contamination in stormwater or in a receiving water.

One application of the technique, as described by Krane, *et al.* (1999) of Wright State University, used randomly amplified polymorphic DNA polymerase chain reaction (RAPD-PCR) generated profiles of naturally occurring crayfish. They found that changes in the underlying genetic diversity of these populations were significantly correlated with the extent to which they have been exposed to anthropogenic stressors. They concluded that this rapid and relatively simple technique can be used to develop a sensitive means of directly assessing the impact of stressors upon ecosystems. These Wright State University researchers have also used the RAPD-PCR techniques on populations of snails, pill bugs, violets, spiders, earthworms, herring, and some benthic macroinvertebrates, finding relatively few obstacles in its use for different organisms. As noted above, other researchers have used DNA profiling techniques to identify sources of *E. coli* bacteria found in coastal waterways. It is possible that these techniques can be expanded to enable rapid detection of many different types of pathogens in receiving waters, and the most likely sources of these pathogens.

Stable Isotope Methods for Identifying Sources of Water. Stable isotopes had been recommended as an efficient method to identify illicit connections to storm sewerage. A demonstration was conducted in Detroit as part of the Rouge River project to identify sources of dry weather flows in storm sewerage (Sangal, *et al.* 1996). Naturally occurring stable isotopes of oxygen and hydrogen can be used to identify waters originating from different geographical sources (especially along a north-south gradient). Ma and Spalding (1996) discuss this approach by using stable isotopes to investigate recharge of groundwaters by surface waters. During water vapor transport from equatorial source regions to higher latitudes, depletion of heavy isotopes occurs with rain. Deviation from a standard relationship between deuterium and ^{18}O for a specific area indicates that the water has undergone additional evaporation. The ratio is also affected by seasonal changes. As discussed by Ma and Spalding (1996), the Platte River water is normally derived in part from snowmelt from the Rocky Mountains, while the groundwater in parts of Nebraska is mainly contributed from the Gulf air stream. The origins of these waters are sufficiently different and allow good measurements of the recharge rate of the surface water to the groundwater. In Detroit, Sangal, *et al.* (1996) used differences in origin between the domestic water supply, local surface waters, and the local groundwater to identify potential sanitary sewage contributions to the separate storm sewerage. Rieley, *et al.* (1997) used stable isotopes of carbon in mar[illegible] to distinguish the primary source of carbon being consumed (sewage sludge vs. natural carbon sources) in two deep sea sewage sludge disposal areas.

Stable isotope analyses would not be able to distinguish between sanitary sewage, industrial discharges, washwaters, and domestic water, as they all have the same origin, nor would it be possible to distinguish sewage from local groundwaters if the domestic water supply was from the same local aquifer. This method works best for situations where the water supply is from a distant source and where separation of waters into separate flow components is not needed. It may be an excellent tool to study the effects of deep well injection of stormwater on deep aquifers having distant recharge sources (such as in the Phoenix area). Few laboratories can analyze for these stable isotopes, requiring shipping and a long wait for the analytical results. Sangal, *et al.* (1995) used Geochron Laboratories, in Cambridge, Massachusetts.

Dating of sediments using ^{137}Cs was described by Ma and Spalding (1996). Arsenic contaminated sediments in the Hylebos Waterway in Tacoma, WA, could have originated from numerous sources, including a pesticide manufacturing facility, a rock-wool plant, steel slags, powdered metal plant, shipbuilding facilities, marinas and arsenic boat paints, and the Tacoma Smelter. Dating the sediments, combined with knowing the history of potential discharges and conducting optical and electron microscopic studies of the sediments, was found to be a powerful tool to differentiate between the different metal sources to the sediments.

Conclusions

In almost all cases, a suite of analyses is most suitable for effective identification of inappropriate discharges. A recent example was reported by Standley, *et al.* (2000), where fecal steroids (including coprostanol), caffeine, consumer product fragrance materials, and petroleum and combustion byproducts were used to identify wastewater treatment plant effluent, agricultural and feedlot runoff, urban runoff, and wildlife sources. They studied numerous individual sources of these wastes from throughout the US. A research grade mass sperctrophotometer was used for the majority of the analyses in order to achieve the needed sensitivities, although much variability was found when using the methods in actual receiving waters affected by wastewater effluent. This sophisticated suite of analyses did yield much useful information, but the analyses are difficult to conduct and costly and may be suitable for special situations, but not for routine survey work.

Another recent series of tests examined several of these potential emerging tracer parameters, in conjunction with the previously identified parameters, during a project characterizing stormwater that had collected in telecommunication manholes, funded by Tecordia (previously Bellcore), AT&T, and eight regional telephone companies throughout the country (Pitt and Clark 1999). Numerous conventional constituents, plus major ions, and toxicants were measured, along with candidate tracers to indicate sewage contamination of this water. Boron, caffeine, coprostanol, *E. coli*, enterococci, fluorescence (using specific wavelengths for detergents), and a simpler test for detergents were evaluated, along with the use of fluoride, ammonia, potassium, and obvious odors and color. About 700 water samples were evaluated for all of these parameters, with the exception of bacteria and boron (about 250 samples), and only infrequent samples were analyzed for fluorescence. Coprostanol was found in about 25 percent of the water samples (and in about 75% of the 350 sediment samples analyzed). Caffeine was only found in very few samples, while elevated *E. coli* and enterococci (using IDEXX tests) were observed in about 10% of the samples. Strong sewage odors in water and sediment samples were also detected in about 10% of the samples. Detergents and fluoride (at >0.3 mg/L) were found in about 40% of the samples and are expected to have been contaminated with industrial activities (lubricants and cleansers) and not sewerage. Overall, about 10% of the samples were therefore expected to have been contaminated with sanitary sewage, about the same rate previously estimated for stormwater systems.

Additional related laboratory tests, funded by the University of New Orleans and the EPA (Barbe', *et al.* 2000), were conducted using many sewage and laundry detergent samples and found that the boron test was a poor indicator of sewage, possibly due to changes in formulations in modern laundry detergents. Laboratory tests did find that fluorescence was an excellent indicator of sewage, especially when using specialized "detergent whitener" filter sets, but was not very repeatable. We also examined several UV absorbance wavelengths as sewage indicators and found excellent correlations with 228 nm, a wavelength having very little background absorbance in local spring waters, but with a strong response factor with increasing strengths of sewage.

R0011202

Table 5 summarizes the different measurement parameters discussed above. We recommend that our originally developed and tested protocol, as reported by Pitt *et al.* (1993), still be used as the most efficient routine indicator of sewage contamination of stormwater drainage systems, with the possible addition of specific *E. coli* and enterococci measurements and UV absorbance at 228 nm. The numerous exotic tests requiring specialized instrumentation and expertise do not appear to warrant their expense and long analytical turn-around times, except in specialized research situations, or when special confirmation is economically justified (such as when examining sewer replacement or major repair options).

Table 5. Comparison of Measurement Parameters used for Identifying Inappropriate Discharges into Storm Drainage

Parameter Group	Comments	Recommendation
Fecal coliform bacteria and/or use of fecal coliform to fecal strep. ratio	Commonly used to indicate presence of sanitary sewage.	Not very useful as many other sources of fecal coliforms are present, and ratio not accurate for old or mixed wastes.
Physical observations (odor, color, turbidity, floatables, deposits, stains, vegetation changes, damage to outfalls)	Commonly used to indicate presence of sanitary and industrial wastewater.	Recommended due to easy public understanding and easy to evaluate, but only indicative of gross contamination, with excessive false negatives (and some false positives). Use in conjunction with chemical tracers for greater sensitivity and accuracy.
Detergents presence (anionic surfactant extractions)	Used to indicate presence of wash waters and sanitary sewage.	Recommended, but care needed during hazardous analyses (only for well-trained personnel). Accurate indicator of contamination during field tests.
Fluoride, ammonia and potassium measurements	Used to identify and distinguish between wash waters and sanitary sewage.	Recommended, especially in conjunction with detergent analyses. Accurate indicator of major contamination sources and their relative contributions.
TV surveys and source investigations	Used to identify specific locations of inappropriate discharges, especially in industrial areas.	Recommended after outfall surveys indicate contamination in drainage system.
Coprostanol and other fecal sterol compounds	Used to indicate presence of sanitary sewage.	Possibly useful. Expensive analysis with GC/MSD. Not specific to human wastes or recent contamination. Most useful when analyzing particulate fractions of wastewaters or sediments.
Specific detergent compounds (LAS, fabric whiteners, and perfumes)	Used to indicate presence of sanitary sewage.	Possibly useful. Expensive analyses with HPLC. A good and sensitive confirmatory method.
Fluorescence	Used to indicate presence of sanitary sewage and wash waters.	Likely useful, but expensive instrumentation. Rapid and easy analysis. Very sensitive.
Boron	Used to indicate presence of sanitary sewage and wash waters.	Not very useful. Easy and inexpensive analysis, but recent laundry formulations in US have minimal boron components.
Pharmaceuticals (colfibric acid, aspirin, ibuprofen, steroids, illegal drugs, etc.)	Used to indicate presence of sanitary sewage.	Possibly useful. Expensive analyses with HPLC. A good and sensitive confirmatory method.
Caffeine	Used to indicate presence of sanitary sewage.	Not very useful. Expensive analyses with GC/MSD. Numerous false negatives, as typical analytical methods not suitably sensitive.
DNA profiling of microorganisms	Used to identify sources of microorganisms	Likely useful, but currently requires extensive background information on likely sources in drainage. Could be very useful if method can be simplified, but with less specific results.
UV absorbance at 228 nm	Used to identify presence of sanitary sewage.	Possibly useful, if UV spectrophotometer available. Simple and direct analyses. Sensitive to varying levels of sanitary sewage, but may not be useful with dilute solutions. Further testing needed to investigate sensitivity in field trials.
Stable isotopes of oxygen	Used to identify major sources of water.	May be useful in area having distant domestic water sources and distant groundwater recharge areas. Expensive and time consuming procedure. Can not distinguish between wastewaters if all have common source.
E. coli and enterococci bacteria	More specific indicators of sanitary sewage than coliform tests.	Recommended in conjunction with chemical tests. Relatively inexpensive and easy analyses, especially if using the simple IDEXX methods.

I. EXECUTIVE SUMMARY

INTRODUCTION

Urban storm water is considered as one of the largest sources of pollution to the coastal waters of the United States. Storm drains convey runoff from streets, urban centers, industrial sites, and open spaces into streams, creeks, rivers, beaches, and the ocean. Industrial operations represent one contributor to storm water pollution, but they are known to be a major source of heavy metals, oily waste, and other substances. Many industrial operations involve manufacturing, storage, and shipping activities which, when conducted outside and are exposed to storm water, can be sources of pollutants in storm water.

Federal regulations issued pursuant to the 1987 amendments to the Clean Water Act mandate the regulation of point source discharges of storm water from industry and from municipal separate storm sewer systems serving 100,000 or more people. California, one of 44 states with delegated authority from the United States Environmental Protection Agency (EPA), implements its own storm water program. The State Water Resources Control Board (State Board) and the nine Regional Water Quality Control Boards (RWQCBs) are the state agencies charged with the primary responsibility for overseeing the implementation of storm water regulations in California. In 1991, State Board issued the Industrial Activities Storm Water General Permit (General Permit No. CAS000001; hereafter, GISP), subsequently reissued in 1997, to control pollutants associated with storm water runoff from industrial sources (GISP 1997). As of August 2000, approximately 9,200 industrial facilities in California were covered under the GISP, with nearly one-third of the facilities located in the Los Angeles region.

The overall goal of this study was to assess the effectiveness of the GISP program for one industrial sector, as implemented in the Los Angeles region, in reducing water quality impacts due to storm water pollution. This executive summary is divided into five sections: introduction, background, methodology, key findings, and conclusions. The background provides a general description of the objectives of the study. The methodology summarizes the approaches used in the study to fulfill the objectives. The key findings present highlights on important results. And the conclusions provide synthesis and recommendations based on the key findings.

BACKGROUND

The Los Angeles Regional Water Quality Control Board (the Los Angeles RWQCB) initiated this compliance assessment project in 1998, recognizing the need to adequately characterize the effectiveness of its industrial storm water program, as implemented at the facility level. The specific objectives of this study were: 1) to evaluate the state of compliance of one industrial sector, the auto dismantling industry, with the GISP requirements and associated water quality implications; 2) to identify limitations of the GISP program in effectively controlling pollutants in storm water runoff; and 3) to provide specific recommendations and regulatory alternatives to help guide management actions to improve water quality. This study is one of the few *comprehensive* assessments investigating the state of compliance of a particular industrial sector with storm water regulatory requirements.

This study chose to focus on the auto dismantling industry because the typical operational and material handling practices conducted by the facilities of this industry represent a potential significant source of conventional and toxic pollutants, including heavy metals and certain hydrocarbons, in storm water. Also, the industry represents a significant portion (about 15 percent) of the facilities covered in the Los Angeles RWQCB's GISP program.

For the purpose of evaluating compliance, this study categorized the GISP requirements into the following three tiers:

Initiation (Tier 1)
Facilities subject to coverage under the GISP, based on their standard industrial classification (SIC) codes or other specific conditions stated in the GISP, must file a Notice of Intent (NOI) with the State Board. (The auto dismantling industry with SIC code of 5015 has been mandated for coverage);

Documentation/Reporting (Tier 2)
Facilities must report their self-monitoring activities and results by submitting an Annual Monitoring Report by July 1st of each year. In addition, facilities must prepare an appropriate storm water document, known as Storm Water Pollution Prevention Plan (SWPPP), along with a written monitoring program to help guide their efforts in implementing appropriate storm water control measures and monitoring the quality of storm water runoff from their facilities.

On-site Implementation (Tier 3)
Facilities must implement appropriate storm water control measures known as Best Management Practices (BMPs) described in their SWPPPs and perform the required monitoring activities.

METHODOLOGY

The methods used to conduct this assessment include database analysis, in-depth document review, and onsite case study investigations.

Non-filer Identification
Auto dismantling facilities in Los Angeles County that have failed to apply for coverage under the GISP program by filing a NOI, also known as "non-filer", were characterized using the following sources of information: 1) a list obtained from the California Department of Motor Vehicles, Occupational Licensing Division (DMV) of auto dismantling facilities in Los Angeles County that maintain a current dismantling license issued from the DMV, and 2) results from the door-to-door site visits conducted

by the City of Los Angeles inspectors from January 1999 to May 2000, specifically aimed at identifying non-filers in parts of Los Angeles city. Facility names and addresses were screened using the Los Angeles RWQCB's NOI database to verify their status of coverage under the GISP.

Document review

A detailed review of SWPPPs and written Monitoring Programs was completed for a study pool of 52 auto dismantling facilities. The purpose of the review was to assess the effectiveness of these storm water documents in guiding facility operators into compliance. The 52 facilities were selected randomly from the NOI database using a systematic, replicable process and are considered to be representative of the industry.

Case study investigations

Site inspections and storm water sampling were performed on the nine selected auto dismantling facilities located in San Gabriel River and Los Angeles River watersheds. The nine facilities were selected out of the study pool of 52 facilities, based on their proximity to the San Gabriel River watershed, the Los Angeles RWQCB's priority watershed for the 1999/00 fiscal year.

The purpose of these site-specific investigations was to take a hard look at the onsite component of compliance that may not be readily observable from document review alone. Storm water analytical data were used to evaluate the quality of storm water runoff generated, impact of the BMPs implemented on water quality, and a simple load calculation for the industry. The EPA Simple Method was used to estimate load.

KEY FINDINGS

The following highlights the important findings of this study:

Initiation (Tier 1)

Non-filer Identification

The problem of non-filers among auto dismantling facilities is significant. An assessment based on the DMV list revealed that one out of every five facilities with a valid DMV license was operating as a non-filer. The site visit results indicated a more serious degree of non-compliance for certain parts of Los Angeles city, with more than one-third (37%) of the auto dismantling establishments visited operating without a NOI.

A possible explanation for such a high ratio of non-filers observed from the site visit results- almost twice as that predicted by the DMV analysis- is that some areas of Los Angeles County, including the locations targeted by the City inspectors, potentially have a disproportionately high percentage of non-filers. Also, site visits can account for non-filers that may be operating without a valid dismantling license, thus not included in the DMV database. The actual number of non-filers in Los Angeles County could be somewhat or considerably higher than that predicted by the DMV/NOI analysis (perhaps somewhere between 19% and 37%), considering an unknown number of delinquent facilities operating with neither a dismantling license nor a NOI.

Documentation/Reporting (Tier 2)

Annual (Monitoring) Reports

Since the 1995/96 permit year, the proportion of the 52 selected facilities submitting Annual Reports has been steadily rising, with a peak submittal rate of 96% observed for the two most recent years considered by this study- 1997/98 and 1998/99. This is a significant increase in compliance, considering that less than half complied with the annual reporting requirement in some of the earlier years. Accelerated efforts expended by the Los Angeles RWQCB in outreach and enforcement activities, fueled by legislation such as Assembly Bill 2019 that mandates timely enforcement actions against violators of the GISP requirements, appear to have significantly contributed to an increased compliance.

SWPPPs/Written Monitoring Program

Initially when the Los Angeles RWQCB issued letters requesting for SWPPPs, nearly a quarter of the facility operators responded with phone calls, displaying little or no knowledge of the SWPPP requirement. Following the initial responses, most facilities (50 out of the 52 requested) did submit their SWPPPs and their written monitoring programs to the RWQCB (Formal enforcement actions were taken against the two delinquent facilities for their failure to submit the requested SWPPPs and past Annual Reports.)

This study found nearly all of the SWPPPs to be deficient in more than one area. The majority were boiler-plate documents prepared by consultants that lacked sufficient site-specific and/or procedural details crucial for proper implementation of BMPs. Many SWPPPs provided sets of "ideal" or "proposed" BMPs but were vague about specifying the measures that were chosen for implementation by the facility operator. BMPs considered universally applicable and important for pollution prevention, such as employee training, site inspection, and good housekeeping programs, were missing from a considerable number of the SWPPPs reviewed.

The majority of the written monitoring programs were prepared by consultants and contained many of the deficiencies found in the SWPPPs. Most documents failed to provide sufficient procedural details necessary to ensure proper quality assurance and quality control (QA/QC), especially regarding sample collection, storage, handling, and transport procedures.

On-site Implementation

BMPs

Staff inspections of the nine case study facilities revealed that the facilities were not fully implementing the BMPs outlined in their SWPPPs, especially measures that are more cost- and/or effort– intensive. Judging from the extent of spills and leaks observed on facility ground, it was evident that the existing BMPs, at the level implemented at most of the facilities, were not adequately controlling the pollutant sources present onsite. Some BMPs such as providing an overhead coverage for dismantling areas or storing motor parts in an enclosed area were limited in their effectiveness because dismantling and storing activities were commonly conducted outside of the designated areas due to inadequate workspace or other physical constraints. One facility eliminated the exposure of vehicle parts to storm water by storing them in large autobodies. An example of an innovative, cost-effective BMP that was implemented unsuccessfully at many of the selected facilities was using truckbeds to store vehicle parts. The facilities that used truckbeds for parts storage had failed to seal the cracks in the truckbeds to prevent potential leaks.

One factor that could potentially obscure a facility operator's assessment of compliance is the lack of a clear standard of compliance in the permit; GISP specifies neither a specific set of required BMPs nor a quantifiable performance or pollutant level to be achieved. (Many of the RWQCBs' staff members use and encourage the permittees to use a set of parameter benchmark values from the USEPA's "Final National Pollutant Discharge Elimination System Storm Water Multi-Sector General Permit for Industrial Activities" (most recently reissued in 2000) for the purpose of gauging potential harm or impact on water quality. However, these benchmarks are not specified in the GISP and are typically not used for gauging compliance or for enforcement purposes.)

Facility Self-monitoring

Review of the Annual Reports submitted by 50 of the 52 selected facilities indicated that the degree of compliance with the monitoring requirements did not match the success observed with submitting the monitoring reports. Based on our review of the 1997/98 Annual Reports, less than 20% of those required successfully completed the sampling & analysis requirement. Not all facilities that collected samples analyzed for the required toxic constituents (lead, zinc, and copper). Less than half conducted the monthly visual observation of storm water runoff. Despite the deficiencies in their monitoring activities, many facility operators still self-certified their Annual Reports for compliance.

Water Quality Impacts

Storm Water Sampling and Analysis

There was a wide range in the concentrations of pollutants in storm water samples obtained from the eight (out of the nine) case study facilities. The majority of the storm water analytical data exceeded the USEPA benchmark levels, in particular, for metals and oil & grease. The general trend identified in this study is that facilities that diligently implemented BMPs, especially good housekeeping practices, and had an overall neat and organized site appearance generally had lower pollutant concentrations in their storm water samples, as expected.

Load

A simple load calculation for 1998/99 suggested the following range for pollutant loads in storm water runoff from the auto dismantling industry in Los Angeles County: 30,570 lbs. of total suspended solids, 7,460 lbs. of oil & grease, 40 lbs. of copper, 30 lbs. of lead, and 130 lbs. of zinc.

CONCLUSIONS/RECOMMENDATIONS

- There is still a substantial number of auto dismantling facilities that need to be identified and permitted under the GISP program. A combined approach using currently available databases supplemented by site visits appears to be an effective method for capturing non-filers. The existing agreement between DMV and the State Board offers a good example of interagency cooperation that helps to elucidate the non-filer identification process-- a model that could be applied to other industrial sectors, including but not limited to the transportation and recycling industries. At this time, additional information is needed to evaluate if the quality of storm water from the non-filers is significantly different, on average, from the permitted facilities.

- In general, the level of understanding among the auto dismantling facility operators of the intent and the significance of the GISP program and its requirements appeared to be low when this study was conducted.

- Compliance among many auto dismantling facilities was achieved mostly on paper, primarily reflected in the quantity of the required documents or reports submitted to the agency and perhaps less in terms of the quality. Site inspections revealed that the degree of field compliance achieved through proper implementation of appropriate BMPs is low and trails behind paper compliance.

- In light of the fact that it is only the field implementation component that substantively contributes to pollution reduction and given the high levels of oil & grease and metals found in storm water runoff from auto dismantling facilities, it may be concluded that the GISP program, as currently implemented by many auto dismantling facilities, does not appear effective in controlling storm water pollution.

- Despite an increase in compliance with the annual reporting requirement, incomplete monitoring results, especially the analytical data, limit the usefulness of the Annual Reports in developing a comprehensive data inventory needed to: fully assess the quality of runoff from regulated facilities; measure progress in pollution prevention efforts over the years; assess water quality impacts from industrial storm water runoff based on load estimates; and develop water quality standards, including total daily maximum loads (TMDLs). To improve both the compliance with monitoring requirements and the quality of the Annual Reports being submitted, the RWQCB must step up its efforts to provide timely responses, for compliance assistance and enforcement purposes, when deficiencies are noted.

- Many of the storm water documents - SWPPPs and written monitoring programs- failed to serve as useful guides for facility operators in the selection and implementation of appropriate BMPs and in monitoring activities due to the absence of sufficient procedural and site-specific details. A time-efficient solution recommended by this study is to target those the consultants (who work closely with the industry as a group monitoring leader or prepare storm water documents on behalf of the facilities) for regular training, education, and certification to ensure that SWPPPs and written monitoring programs prepared by third parties are up to par with the GISP requirements.

- One factor that potentially obscures the efforts of facility operators and regulators in assessing compliance is the lack of explicit, quantifiable standards that facilities must attain in order to demonstrate compliance with the GSIP requirements and with applicable water quality standards. Determination of compliance should not be left up to the subjective interpretation of uninformed permittees or regulators. Thus, the GISP program needs a more clear-cut standard of compliance based on a combination of a minimum set of specific BMPs and/or numerical effluent limitations. The following tiered approach is recommended for the auto dismantling industry: 1) a mandatory set of specific, baseline structural (excluding treatment) and non-structural BMPs for facilities with annual vehicle throughput less than 500 (which includes mom-and-pop and medium-sized facilities); and 2) mandatory treatment of storm water for facilities with annual vehicle throughput greater than 500. (Note: The annual volume of vehicles processed at many of the mom-and-pop facilities, which make up over three-quarters of the industry in the Los Angeles Region, is less than 300 vehicles. The threshold of 500 vehicles was chosen to include typical mom-and-pop and medium-sized facilities in the Region). Also, in lieu of requiring treatment, numerical effluent limitations could be applied to the latter group as a standard of compliance. A compliance schedule could help phase facilities into compliance over a certain specified timeframe. Facilities with less than 500 annual vehicle throughput that persistently demonstrate problems with meeting a certain water quality standard, e.g. the USEPA benchmark levels, should also be considered for inclusion in the mandatory storm water treatment category.

- The lack of sufficient resources was identified as the primary reason for the limited compliance assurance and enforcement activities performed by the RWQCB in the past and when this study was being conducted. One way to reduce the workload associated with assessing compliance of industries subject to the GISP requirements is to employ a semi-privatized certification program, such as that implemented in the State of Wisconsin, that relies on licensed, private inspectors to oversee the compliance activities of a group of facilities that voluntarily choose to participate and help fund the program. The aim of such a program is to help reduce some of the workload of the regulators and to allow facilities that diligently work toward and maintain a specified level of compliance to be certified for compliance by professional inspectors. Such certification could (partially) exempt them from certain regulatory responsibilities, such as monitoring activities, and indirectly shield them from third-party lawsuits by reducing the degree of their environmental liability. (Essential to the implementation of this type of program is regular training and (re-)certification of inspectors by the regulating agency to ensure quality assurance and quality control)

II. BACKGROUND

Storm water pollution has received steadily increasing attention from regulating agencies as well as environmental groups in the past decades. In California, efforts to better control industrial storm water pollution have resulted in legislation specifically aimed to improve the efficacy of the GISP program. Examples include Assembly Bill 2019, which mandates aggressive, mandatory enforcement actions to increase compliance with the NOI and annual reporting requirements, and Assembly Bill 1186, designed to substantially increase the funding available for the GISP program (AB 2019; AB 1186). Third-party lawsuits triggered by non-profit environmental organizations have contributed to raising the public's awareness of storm water pollution and of the importance of pollution prevention (P2).

There exist several known evaluations or reports, which have assessed the effectiveness of industrial storm water program, on both the regional and national levels. The Water Environment Federation, under a cooperative agreement with the EPA in 1994, conducted a nationwide assessment of the federal industrial storm water program implemented by USEPA (WEF 1996). The study presented the permittees' perceptions of how effective they thought the individual components of the federal industrial storm water program were in controlling and reducing storm water pollution. Two of the key findings from the study were that 1) of those companies regulated by the storm water permit program, 12.5% appeared to be out of compliance with the requirement to develop and maintain a SWPPP onsite; and that 2) small businesses spend less money on compliance and are more likely to be out of compliance because they lack environmental staff and a clear understanding of the requirements.

On a regional level, a 1998 report by Heal the Bay, a non-profit environmental organization with a primary focus on the protection of Santa Monica Bay in Southern California, criticized the lack of accomplishments of the industrial storm water program implemented by the Los Angeles Regional Water Quality Control Board (Los Angeles RWQCB), in areas of compliance assurance and enforcement activities conducted since the adoption of the GISP in 1991 (HTB 1998). In 1998 a Los Angeles RWQCB staff generated and submitted a draft report to the State Board titled, "Analysis of the Sampling Results: 1996-1997 Annual Report for Storm Water Industrial Activities General Permit". The draft document showed that a substantial fraction of the storm water data submitted for the 1992/93 and 1996/97 years exceeded the USEPA benchmark levels (RWQCB 1998). In February 2000, the National Resources Defense Council, a non-profit organization of attorneys working for environmental causes, submitted a formal written petition to EPA asking it to correct deficiencies or to withdraw from the State of California the delegated authority to implement its own storm water program, *specifically in the Los Angeles Region*. The petition documented the failure of the Los Angeles RWQCB to fully implement its storm water programs and cited the lack of sufficient funding and resources as the primary reason for the noted deficiencies (NRDC 2000). USEPA also cited similar findings in several of its annual audit summaries of the Los Angeles RWQCB's storm water programs and strongly recommended a significant augmentation in the available funding to provide the resources needed to fully implement the program (USEPA 1998; USEPA 2000a).

USEPA recognized that the RWQCB staff had achieved significant accomplishments given severely constrained resources (USEPA 1998).

Whereas many of the cited studies and analyses primarily focused on the deficiencies in the overall programmatic implementation at the RWQCB level, this study shifts the focus of its evaluation to the facility level where pollution control occurs. And by assessing the permittees' performances and compliance with the GISP requirements, this study attempts to shed light on the drawbacks and the barriers associated with the GISP program that must be addressed in order to improve the program's efficacy in controlling industrial storm water pollution. In addition, this study takes a hard look at whether the GISP requirements and its terms of compliance have been defined in such a way as to ensure adequate protection of water quality and beneficial uses of receiving waterbodies. Lastly, this study provides specific recommendations to remedy the deficiencies noted in its evaluation. To fully characterize the state of compliance achieved by the target industry, this study employed a multi-tiered assessment approach looking at the full spectrum of requirements, from initiation of coverage to field implementation.

AUTO DISMANTLING INDUSTRY

Auto dismantling industry was targeted for compliance assessment for the following reasons:

- Auto dismantling facilities, also known as auto salvage yards or auto recycling facilities, represent a significant portion (about 15%) of facilities covered in the Los Angeles RWQCB's GISP program;

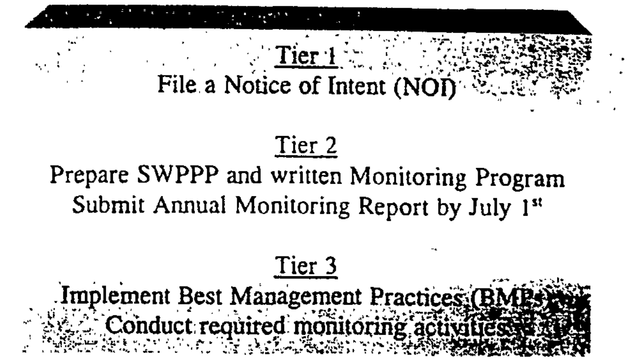
- Many of the typical operational and material handling practices conducted at auto dismantling facilities are performed outside and thus are exposed to storm water. Typical activities include dismantling vehicles and automotive parts; draining automotive fluids; storing auto parts, auto bodies and waste fluids, washing and rinsing of parts, and shipping and receiving activities;

- Spills and leaks of waste fluids and waste oil, which are common occurrences at auto dismantling facilities, contribute conventional and toxic pollutants, in particular, heavy metals and certain hydrocarbons, to storm water runoff (Swamikannu 1994); and

- The auto dismantling industry is difficult to regulate because the majority of businesses are small, mom-and-pop facilities that tend to change ownership rather quickly, posing a special challenge in outreach and compliance assurance activities for the regulating agency (approximately 70% of all auto dismantling facilities in Los Angeles County covered under the GISP are 1 acre or smaller). Economic and personnel constraints impact the ability of smaller facilities to fully comply with the GISP requirements.

MULTI-TIERED ANALYSIS

For purposes of evaluation, compliance was divided into three tiers:



Tier 1 (Initiation)

Facilities classified under certain standard industrial classification (SIC) codes specified in the GISP for coverage (including the auto dismantling industry whose SIC code is 5015) must file a NOI to apply for permit coverage. Facilities that are required but fail to file a NOI are referred to as 'non-filers'.

Tier 2 (Reporting/Documentation)

After submitting a NOI, facilities must submit an Annual Monitoring Report by July 1st of each year that summarizes both the qualitative and quantitative results from their monitoring activities. In addition to the annual reporting requirement, facilities must prepare appropriate storm water documents known as a Storm Water Pollution Prevention Plan (SWPPP) and a written Monitoring Program (MP) necessary to guide them in their P2 efforts. The purpose of a SWPPP is to serve as a "blueprint" for achieving compliance by specifying specific BMPs and a schedule of BMP implementation. Written monitoring programs must contain adequate procedural details to ensure that proper monitoring of facility condition and its storm water is provided.

Tier 3 (Implementation):

Facilities must implement BMPs provided in their SWPPP and conduct monitoring activities required by the GISP. BMPs include both non-structural and structural controls that can reduce the level of pollutants in storm water. Monitoring requirements may be broadly grouped into visual observations, storm water sampling and analysis, site inspection, and SWPPP review and update. Storm water sampling and analysis, along with the other monitoring activities, help evaluate the quality of the storm water runoff generated from the facilities and gauge the effectiveness of the facility's efforts to control storm water pollution.

The state of compliance achieved by the permittees is a reflection of how diligently facilities have been implementing the GISP requirements. Knowledge of the current state of compliance achieved and an estimate of associated load can serve many useful purposes. For example, such an understanding could help gauge if an existing program, such as the GISP, has the potential to attain further pollutant load reduction if required, for example, as part of the implementation of a Total Maximum Daily Load (TMDL). TMDL is the "amount of a specific pollutant that a waterbody can receive and still maintain water quality standard" (TWA 2000). If the majority of dischargers permitted under a given regulatory program are shown to be at the high end of a compliance curve, this implies that the program has nearly reached its maximum attainable pollutant reduction. Under such a scenario, opportunities for significant additional reduction in load would be slim. Conversely, if most dischargers are found to be at the bottom of a compliance curve, then there may be opportunities for substantial pollution reduction to be achieved through increased compliance activities.

If the GISP requirements are implemented to their maximum at the facility level, and facilities are still unable to attain the assigned load, then perhaps the standard of compliance defined in the GISP or the existing approach used to implement the GISP program may need to be re-evaluated. California has yet to allocate load associated with industrial storm water pollution. Nevertheless, an understanding of the current state of compliance under the GISP program and getting a good sense of the magnitude of load generated by industrial sectors will no doubt be useful for making critical management decisions. Also, this type of assessment will help to identify priority or high-risk industrial sectors - e.g. those with low compliance and high load contribution - to direct limited resources to the most critical areas.

LACK OF NUMERICAL EFFLUENT LIMITATIONS IN GISP

Standards for compliance can be expressed in various ways. NPDES permits may contain both qualitative and quantitative effluent limitations with which permittees must comply. Numerical effluent limitations may consist of technology- and water quality-based limits. The GISP, which falls under the NPDES framework, does not contain numerical effluent limitations for the majority of dischargers permitted under the program (Facilities among the ten industrial categories listed in USEPA regulations (40 CFR Subchapter N) must comply with the technology-based limits established by USEPA for specific pollutants. These Subchapter N facilities represent only a small portion of the facilities under the RWQCB's GISP program.)

In the absence of numerical effluent limitations, BMPs form the pillar of the GISP program. This is consistent with the "Interim Permitting Approach for Water Quality-based Effluent Limitations in Storm Water Permits" (USEPA 1996). The interim permitting approach uses BMPs in first-round storm water permits, and expanded or better-tailored BMPs in subsequent permits, where necessary, to provide for the attainment of water quality standards. While it is recognized that numeric water quality-based effluent limitations could potentially provide a greater degree of confidence that a discharger will not cause or contribute to an exceedance of the water quality standards, the variable nature of storm water discharges and the lack of information on which to base numeric water quality-based effluent limitations are the main reasons that EPA developed the interim permitting approach.

There are several standards or conditions specified in the GISP that dischargers must attain including the Best Available Technology Economically Achievable (BAT) and Best Conventional Pollutant Control Technology (BCT) levels. In addition, one of the prohibitions in the GISP states that storm water discharge shall not cause or contribute to a violation of applicable water quality standards. Specifically, the achievement of BAT and BCT levels must be demonstrated by fulfilling the requirements of the GISP, which states "compliance with the terms and conditions of this General Permit constitutes compliance with BAT/BCT requirements and with requirements to achieve water quality standards." However, as discussed in the preceding section, determining compliance based on BMP implementation and performance is complicated by the absence of clear, uniform standards for measuring compliance, and because each assessment requires site-specific considerations. Prerequisites for successful attainment or measurement of progress toward desired goals are clear and adequate definitions of expectations or goals to be achieved. The lack of quantitative or numerical targets in the GISP inevitably generates questions and confusion as to whether a facility has indeed successfully achieved compliance. And herein lies one of the major handicaps of the GISP program.

A comparison of analytical monitoring data between facilities could shed light on the relative overall effectiveness of BMPs implemented at different sites. However, the bottom-line question is "how effective is effective?" Therefore, quantitative standards of some sort must be provided in order to determine the adequacy of storm water measures provided by facilities. One set of standards that has been used by RWQCBs in California and USEPA for its national storm water program is the USEPA benchmark values provided in the Final National Pollutant Discharge Elimination System Storm Water Multi-sector General Permit for Industrial Activities (hereafter USEPA Multi-sector Permit; USEPA 1995, USEPA 2000b). The benchmarks are indicators of potential impact of discharge but are not enforceable as numerical effluent criteria through the GISP program. These benchmark values are based on several sources of information, including fresh water criteria based on the effects on aquatic species, median concentrations from the National Urban Runoff Program, and minimum levels based on detection limit. However, for these numeric water quality standards to become enforceable through the NPDES framework, they must be translated into appropriate (numeric) *effluent limitations* that typically must be met "end-of-pipe". The Discussions section, under "Case study investigations: storm water analysis," explores the situation in greater depth and recommends some specific means to address this issue of whether compliance can be adequately defined to protect water quality in the absence of numeric effluent limitations.

III. METHODS

This study used database analysis, document review, and case study evaluations consisting of site inspections and storm water sampling and analysis to assess compliance of the selected auto dismantling facilities with the requirements of the GISP program. A mathematical equation, known as the EPA Simple Method, was used to quantify pollutant load in storm water runoff from the auto dismantling industry.

NON-FILER IDENTIFICATION (TIER 1 ANALYSIS)

To assess the non-filer situation, this study used two sources of data as presented in Table 1. First, to perform a county-wide evaluation, staff enlisted the cooperation of the California Department of Motor Vehicles, Occupational License Division (DMV) to obtain a list of auto dismantlers in Los Angeles County who had applied for and maintain a current dismantling license (DMV 1999). Each facility name and address on the DMV list was queried and checked using the RWQCB's NOI database to determine if the facility had filed a NOI. Facilities on the DMV list missing from the NOI database were contacted by phone to verify their operating status and the accuracy of the facility-specific information.

The second analysis focused on a four square-mile area within the County known to have high population of auto dismantling facilities. The data used in this study has been compiled by the City of Los Angeles inspectors who conducted door-to-door site visits between December 1998 and May 2000, specifically to identify non-filers in areas within the City of Los Angeles. The site visits were conducted as a Supplemental Environmental Project (SEP) that the City undertook, as part of its penalty under an Administrative Civil Liability issued by the RWQCB for City's past sewage spill incidents. A group of University of California at Los Angeles (UCLA) professor and students led the efforts to provide data QA/QC and data analysis.

TABLE 1. Data Source and Analytical Procedures for Non-filer Assessment

	Analysis I	Analysis II
Type	Auto Dismantling License Information	Door-to-door Site-visits
Source	California DMV Occupational License Division	RWQCB (City of Los Angeles' Supplemental Environmental Project)
Target area	Los Angeles County	City of Los Angeles (four square-mile area)
Analytical Procedures	1. Cross-check information on DMV list with NOI database 2. Perform over-the-phone verification of operating status and other information 3. Compile and analyze data	1. Query site visit results for auto dismantling facilities (conducted by UCLA) 2. Confirm NOI status (City of LA/ UCLA) 3. Analyze results by area (UCLA)

DETAILED STORM WATER DOCUMENT REVIEW (TIER 2 ANALYSIS)

The next level of evaluation focused on the facilities' compliance with the reporting and documentation requirement. To obtain a smaller pool of facilities for an in-depth review of storm water documents, this study selected 52 facilities from a total of 349 auto dismantling facilities from the NOI database. To ensure a representative pool, the facilities were chosen by first alphabetically sorting the 349 facilities by business name and choosing every sixth facility (A small number of the chosen facilities were located in Ventura County. These facilities were eliminated to limit the focus to Los Angeles County.)

To evaluate permittee compliance with the annual reporting requirement, this study chose to concentrate on trends observed in Annual Report submittal rates over times, based on the 52 selected auto dismantling facilities and on the quality of the Annual Reports submitted for the 1997/98 permit year. The proportion of facilities submitting the Annual Reports, among the 52 selected facilities, was determined by electronically querying the Annual Report databases maintained at the RWQCB. Similarly, the 1997/98 Annual Report database was queried for summaries of monitoring activities conducted by facilities. In addition, Annual Reports were reviewed for more detailed information not electronically available.

SWPPPs and written Monitoring Programs were requested from the selected 52 facilities through a formal letter issued by the RWQCB to each facility operator. An in-depth review of the SWPPPs and the written Monitoring Programs was provided using a checklist (see Appendix A) outlining the requirements specified in Sections A and B of the GISP.

CASE STUDY INVESTIGATIONS (TIER 3 ANALYSIS)

To investigate the onsite component of compliance, this study selected nine out of the 52 facilities for site-specific evaluation. These nine facilities were clustered in the San Gabriel River and Los Angeles River watersheds. Staff inspected all nine sites and collected storm water samples from the eight sites that produced sufficient volume of runoff to enable sample collection. Storm water samples were collected from primary discharge locations that conveyed runoff from the areas where principal industrial activities were conducted. The purpose was to assess the extent to which facilities implemented the BMPs indicated in their SWPPPs and to study the overall effect of the BMPs implemented based on the storm water analytical data. Storm water sampling activity and analysis were carried out under conditions consistent with the requirements in the GISP. Only fully-trained staff and interns participated in the storm water sample collection, handling, storage, and transport activities to ensure adequate QA/QC. Chain of custody forms were completed for all samples. Samples were analyzed by the California Department of Health Services laboratory.

WATER QUALITY IMPACT ASSESSMENT

EPA Simple Method

To provide a perspective on the potential water quality impact(s) associated with storm water runoff generated from the auto dismantling industry, pollutant load was estimated using storm water analytical data from the case study investigations. This study used the EPA Simple Method equation for load assessment:

$$L = 0.227*P*Pj*A*C(0.05 + 0.009*I)$$

where

L = pollutant load (pounds/ per year);
C = average flow-weighted concentration of the pollutant in runoff (mg/L or ppm);

P_j = fraction of rainfall events that produce runoff;
P = annual precipitation in inches per year (inches per year);
A = area of the site (acres);
I = the percent of the site's imperviousness; and,
0.227 = conversion factor (inches/foot)* (acre-feet-ppm/pounds).

IV. DISCUSSION OF RESULTS

This chapter presents key findings on the degree of compliance achieved by auto dismantling facilities; evaluates the quality of storm water runoff generated from selected facilities; estimates the load contributed by the industry in the form of storm water pollution; and discusses water quality implications associated with the key findings of this study.

NON-FILERS

Applying for coverage under the GISP does not guarantee that a facility will actually achieve pollution abatement, but it is an important first step. Also, from the perspective of "leveling the playing field," it is necessary for regulators to characterize the extent of non-compliance with the NOI requirement and take aggressive, timely actions once non-filers are identified to bring them into compliance. Auto dismantling facilities, due to the nature of the industrial activities conducted onsite, are subject to the GISP requirements. Facilities of this industry are informed about the GISP requirements through two main channels. First, auto dismantling facilities are notified about the NOI requirement by the California DMV when they apply for a dismantling license from the DMV's Occupational License Division. The DMV auto dismantling license application includes a questionnaire about whether the facility operator has filed a NOI with the State Board. (The DMV forwards a copy of the completed application to the State Board per pre-established interagency agreement/cooperation between the two state agencies.) The second channel of information regarding the industry's duty to comply is the mass-mailing that the State Board periodically conducts as part of its effort to reach potential non-filers.

Table 2 describes the results of non-filer identification using the DMV dismantling license list. Of the 463 facilities on the list that were checked against the RWQCB's NOI database, 147 were identified as potential non-filers. Phone verification identified 77 of the 147 facilities to be actually operating without a NOI. In other words, approximately one-fifth of the facilities on the DMV list comprised of non-filers. The rest of the 147 facilities had either terminated operation or could not be reached after multiple phone attempts.

Essential to obtaining an accurate estimate of non-filers is an understanding of the total universe of facilities regulated. In screening the DMV list against the NOI database for non-filers, this study assumed that the DMV list represented a relatively thorough estimate of the total universe of auto dismantlers in Los Angeles County. To test this assumption, staff screened to see whether the auto dismantlers in the NOI database appeared on the DMV list. This screening effort yielded 72 facilities that could potentially be operating without a dismantling license. Phone verifications confirmed 35 of these to be in operation. This effort yielded a conservative estimate of 404 for the total universe of auto dismantling facilities operating in Los Angeles County, as of August 1999, when this analysis was conducted. This estimate includes facilities operating with either or both a NOI or a dismantling license. The number of facilities operating with neither a NOI nor a dismantling license is unknown and is needed to

TABLE 2. Non-filers Among Auto Dismantling Facilities, Los Angeles County: DMV Licenses vs. NOIs Filed[1]

DMV COVERAGE[3]	NOI STATUS[2]					
	Active NOI[4]	Suspended NOI	Terminated NOI	No NOI[5] (Potential Non-filers = 147): Verified Non-filers	Out of Operation	Unverifiable
DMV Licensed	292	1	23	**77**	25	45 (21)[6]
No DMV License (72)						
Verified Non-licensed[3]	**35**	-[7]	-	Unknown	-	-
Out of Operation	34	-	-	-	-	-
Unverifiable	3	-	-	-	-	-

The proportion of non-filers among auto dismantling facilities operating in Los Angeles County is estimated at 19% (77 out of 404). The total universe of auto dismantlers in Los Angeles County exceeds 400, based on the number of active NOIs and verified non-filers. For a more accurate characterization, those operating with neither a NOI nor a DMV license need to be accounted for in the total universe of facilities.

[1] Table 2 originally appeared in a doctoral dissertation (*Chang 2001*).
[2] A RWQCB's NOI database contains information on facilities with NOIs.
[3] In California, auto dismantlers are required to obtain a dismantling license from the Department of Motor Vehicles (DMV), Occupational Licensing Department prior to operation. The list of facilities in Los Angeles County with auto dismantling license was obtained from the California DMV in August 1999.
[4] Note that the total number of auto dismantlers in the NOI database with active status is 364, slightly higher than the total number (349) that was used to select the study pool of 52 facilities. The pool of facilities with active NOIs changes over time as facilities begin and terminate coverage.
[5] Facilities that did not appear on both the DMV list and the NOI database were contacted by phone to confirm their operating status. The facilities were categorized as: "verified" non-licensed (DMV); non-filers; out of operation; and unverifiable if they could not be reached by phone after numerous attempts.
[6] Of the 45 facilities in the unverifiable category, 21 did not have phone numbers listed on the DMV list nor with directory assistance. Therefore, the operating status of these facilities could not be verified. The rest did have phone numbers listed but could not be reached.
[7] Dashes mean not applicable.

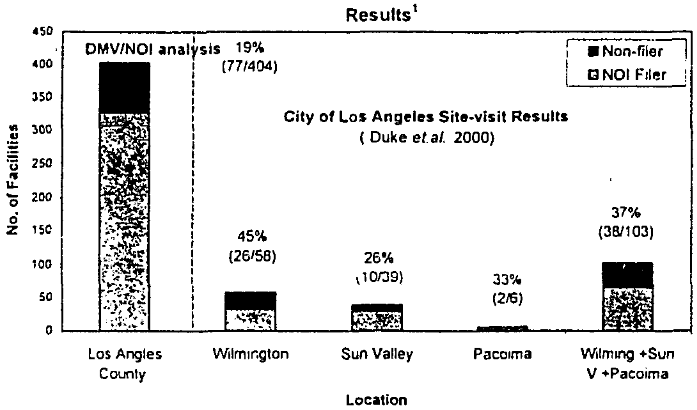
accurately characterize the total universe of facilities, is not known at this time. This estimate lies outside the realm of the objectives and methodology of this study. However, considering the potential severe consequences of violations under both regulatory requirements, the actual number of facilities in this category is probably a small percentage of the total number of auto dismantling facilities in operation.

This study further investigated the 10% (35 of the 364) of auto dismantling facilities with an active NOI that were verified to be operating without a dismantling license. The purpose was to shed some light on reasons that some facilities have apparently chosen to comply with one type of regulatory requirement over another. Each of these facilities were contacted by phone for explanations as to why the facility appeared to be in violation with a regulatory requirement so essential to its operational activities (a valid dismantling license is required for transactions at used auto auctions). It turned out that a small fraction of these facilities (less than 10% of those contacted) actually had a dismantling license, either under a slightly different address or business name, or under the name of the facility's headquarters. Facilities that knew they were in compliance cooperatively shared their dismantling license information with the

RWQCB staff. The remaining facilities, however, refrained from revealing their dismantling license number or from discussing possible reasons why the facility is not represented in the DMV dismantling license database, even after repeated assurances from staff that the information was for research purposes only and not for enforcement activities. It is highly likely that these facilities were operating without a valid dismantling license.

Figure 1 illustrates the outcome of the two non-filer analyses, showing the percentages of non-filers for the overall County and at the sub-city level. Presented to the left of the dotted line is DMV/NOI analysis, and to the right are the site visit results. The site visits performed by the City inspectors targeted three areas within the City of Los Angeles boundary-- Wilmington, Sun Valley, and Pacoima-- with the first two areas accounting for over 40% of all auto dismantlers in Los Angeles County with an active NOI. A total of six auto dismantling facilities were identified and visited in Pacoima. Overall, non-filers accounted for 37% of the auto dismantling facilities identified in the three areas. The area with the highest ratio of non-filers was Wilmington (45%), followed by Pacoima (33%) and Sun Valley (26%). Only six auto dismantling facilities were identified in Pacoima.

Figure 1. Non-filers Among Auto Dismantling Facilities in Los Angeles County, CA.: Identified from Database Analysis and Site-visit Results[1]



[1] Figure 1 originally appeared in Chang 2001.

Because the site visits did not cover all of Los Angeles County, the results obtained from the site visits cannot be directly compared with the findings from the DMV license analysis. The site visit results, though, indicate that the proportion of non-filers among auto dismantling facilities in some areas of Los Angeles County could be twice as high as the average estimated by the DMV/NOI analysis for the entire County. Three reasons potentially account for the substantial difference between the ratio of non-filers estimated for the County and at the sub-County levels. First, Wilmington and Pacoima may have disproportionately high percentages of non-filers compared to the rest of Los Angeles County (Sun Valley had a similar percentage of non-filers as estimated by the DMV/NOI analysis). Second, the number of facilities delinquent with both the NOI and the dismantling license requirements could be significant. These facilities may be reflected in the site visit results but not in the DMV database. Another possible explanation is that the areas visited by the inspectors had both disproportionately high percentages of non-filers and non-DMV-licensed facilities. (Note: The RWQCB has started to follow up with facilities, across all industries, which were identified as potential non-filers by the City inspectors. Out of about 430 facilities fully inspected, approximately 200 facilities were identified as potential non-filers and are subject to follow-up activities, including a letter notifying their potential to file a NOI and an inspection, if necessary.)

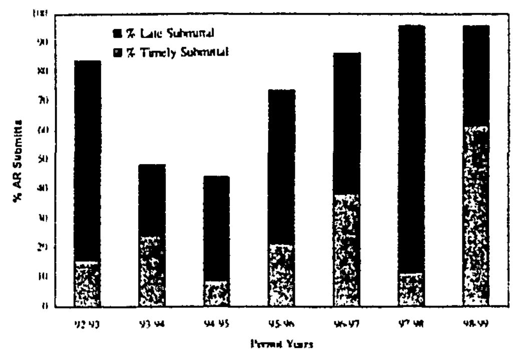
As demonstrated by the statistics, the non-filer problem is significant for the auto dismantling industry. However, to place the non-filer situation in the context of other industries, this study also looked at the City's site visit results for two other major industries mandated for coverage under the GISP- recycling and transportation sectors. Of the three sectors, the auto dismantling industry had the highest compliance rate with the NOI requirement of 63%, followed by transportation with 38%, and recycling with 13% (Duke et al 2000). The higher compliance by the auto dismantling industry could be attributed to the successful interagency coordination between the State Board and the DMV. As a way to effectively identify and reach out to potential non-filers, this study recommends that the State Board actively solicit the cooperation of other state/local agencies to enhance information sharing and to incorporate the NOI requirement by reference into other regulatory requirements, similar to the DMV dismantling application procedures. Auto dismantling licenses and construction grading permits (under the Municipal storm water requirements) are two examples where filing a storm water NOI has become a pre-requisite for license/permit issuance.

In conclusion, full compliance with the NOI requirement has not been attained by the auto dismantling industry. The DMV dismantling license analysis, which probably underestimates the number of non-filers for reasons explained revealed that, at minimum, one out of every five auto dismantling facilities in Los Angeles County is a non-filer. In some areas of Los Angeles County, such as Wilmington, the non-filer problem appears exacerbated, with approximately one out of every two facilities operating without a NOI. The recommended approach for identifying non-filers is to utilize interagency coordination and employ available databases, such as the DMV dismantling license and NOI information supplemented by site visits. Agency-generated data probably offers a higher degree of accuracy than commercially available databases. At this time, it is difficult to draw any quantifiable conclusions about the water quality implications associated with "non-filer" sites, including whether the quality of runoff from non-filers, on average, is expected to differ significantly from runoff from permitted facilities. because there are no known studies or data that specifically target the quality of storm water runoff from non-filer sites.

ANNUAL REPORTS

This sub-section describes the trend in compliance achieved by the 52 selected auto dismantling facilities with the requirement to submit Annual Reports by July 1st of each year. Also characterized are the facilities' performances in implementing the required monitoring activities for the 97-98 permit year. Both qualitative and quantitative monitoring data serve as an indicator of each facility's overall performance with BMP implementation, help build a comprehensive inventory of essential water quality data, assist in developing water quality standards, and more. For instance, analytical monitoring data provided in the Annual Reports present a potential source of information necessary to support the quantification of loads associated with storm water runoff from industrial sources, a step necessary to develop TMDLs. The types of monitoring summaries contained in the Annual Reports, if completed properly by facility operators, could reveal important facility-specific and compliance-related information such as how diligently a facility implemented the required monitoring activities, the quality of the storm water runoff generated from the facility, and whether the facility operator has reviewed and updated the facility's SWPPP, and reassessed the adequacy of existing BMPs in controlling storm water pollution.

Figure 2. Compliance with Annual Reporting Requirement among Selected Auto Dismantlers in Los Angeles County



[1] Figure 2 originally appeared in Chang 2001.

Figure 2 illustrates the trend in facilities' submittal of Annual Reports from 1992 to 1999. The overall height of a bar indicates the total percentage of Annual Reports submitted for a given permit year. The lower, lighter portion of bar indicates the proportion of facilities that submitted Annual Reports on or before July 1st. The upper, darker portion represents late submittals. Compliance is represented in percentages rather than actual number of reports submitted because the number of facilities *required* to submit Annual Reports varied over time because the facilities' coverage under the GISP program was initiated at different times (by 1996, all of the 52 selected facilities had filed a NOI).

As illustrated in Figure 2, compliance was low in the early years, with the majority of the facilities failing to submit the required Annual Reports for the 1993/94 and 1994/95 permit years, and with the majority of the reports arriving late. The lack of sound monitoring data, as a result of deficient reporting, would leave both the regulators and the dischargers in the dark about critical questions such as how successful an individual or a group of facilities' efforts have been in controlling storm water pollution at their site and their progress over the years. In addition, not having adequate analytical data substantially limits regulatory efforts to characterize the quantity of load associated with the storm water runoff from regulated communities. Without the data necessary to self-diagnose their facility's performance and a chance to address the deficiencies in a timely manner, facility operators are really placing themselves in jeopardy of increasing their environmental liability and the chances of regulatory enforcement actions and third-party lawsuits. Therefore, both the dischargers and the regulators are negatively impacted when facilities fail to monitor and report their monitoring results to the appropriate regulating agency.

Observations based on the 52 selected auto dismantling facilities revealed that starting in 1995/96, two-thirds or more of the required facilities submitted their Annual Reports. The highest Annual Report submittal rate (96%) achieved in 1997/98 and 1998/99 is an outcome of increased enforcement activities launched by the RWQCB in recent years and demonstrate the importance of and the need for aggressive, timely regulatory follow-up activities.

Several hundred enforcement letters were issued in 1997/98 to facilities across all industrial sectors that failed to submit Annual Reports on time. As apparent from Figure 2, the majority of the 1997/98 Annual Reports were received late, with most of them probably in response to the enforcement letters. The subsequent permit year had even greater success. While maintaining the Annual Report submittal rate at 96%, there was a substantial increase in the number of reports being submitted on time.

Evidently, the large-scale enforcement activities, including the issuance of formal violation letters and mandatory penalties for recalcitrant
violators, have resulted in tangible results and have demonstrated to be an effective tool for communicating to the regulated community the potential severe consequences of violating storm water regulations.

The usefulness of the Annual Reports to regulators and dischargers alike depends on the accuracy and the completeness of the reports being submitted. In the Los Angeles Region, much of the agency's limited resources have been dedicated in the past to identifying and following up with facilities that have failed to submit Annual Reports. Constrained by resources, limited regulatory attention was focused on the quality of the Annual Reports received or the monitoring results reported in the Annual Reports. This study conducted detailed reviews of the 1997/98 Annual Reports submitted by 50 of the 52 selected facilities to contribute to an increased understanding of the quality of Annual Reports and the monitoring data submitted by auto dismantling facilities.

Figure 3. Storm Water Monitoring Activities Conducted by 52 Selected Auto Dismantling Facilities (1997/98 Annual Reports)

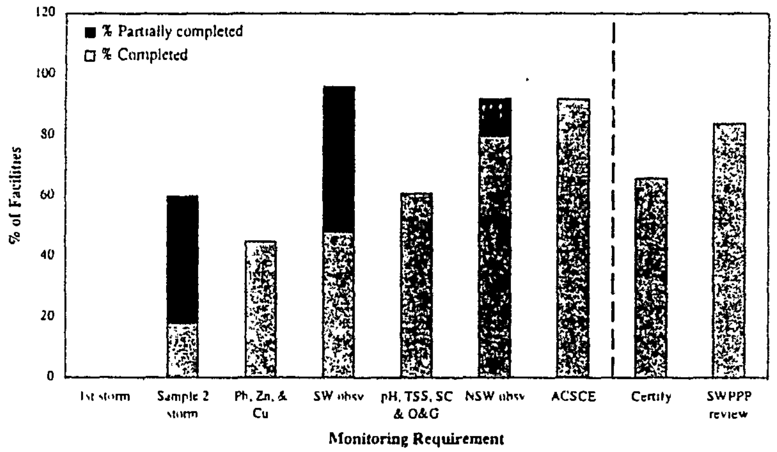


Figure 3 illustrates how successfully the 50 facilities that had submitted the Annual Reports fulfilled their required monitoring activities (two of the 52 facilities did not submit their Annual Reports). Results are presented in the order of low to high compliance, in terms of facilities that fully satisfied a monitoring requirement, as indicated by the bottom, lighter portion of a bar. The upper, darker portion represents facilities that partially completed a required monitoring activity. Bars to the left of the dashed line indicate monitoring activities and to the right are administrative requirements associated with the monitoring program. Monitoring requirements include: visual observations of storm water and non-storm water runoff, storm water sampling and analysis, and an annual comprehensive site evaluation that includes a full-scale site inspection and a SWPPP review and update. Table 3 augments the findings on the monitoring activities with detailed narrative description.

None of the individual categories of monitoring activities were completed by all 50 selected facilities. Overall, facilities were less likely to perform monitoring activities that are more cost- and effort-intensive, such as storm water sampling and analysis, than activities that are simple to perform and involve little or no cost, such as visual observations. This trend was observed even among activities such as visual observations that require minimal resources to perform. Approximately 80% of the facilities fully complied with the quarterly observation of non-storm water (a total of four observations required to be conducted under *dry* weather conditions). A

Table 3. Summary of Monitoring Activities Reported by for 50 Selected Auto Dismantling Facilities (1997/98 Annual Reports)

MONITORING REQUIREMENT	FACILITY COMPLIANCE						COMMENTS
	Completed		Partially Completed		Did Not Attempt		
1. Submit Annual Report by July 1st deadline	31	62%	19	38%	N/A	N/A	• "Completed" means facility submitted the Annual Report before or on 7/1/98. • "Partially Completed" means facility submitted Annual Report after 7/1/98. • "Did Not Attempt" means facility did not submit Annual Report.
2. Sample from two storm events	7	18%	16	42%	15	40%	• "Completed" means facility collected and analyzed sample(s) from two qualifying storm events. • "Partially Completed" means facility collected and analyzed sample(s) from one storm events. • "Did Not Attempt" means facility did not collect or analyze any sample. • Twelve out of the 50 facilities belonged to a Group Monitoring Program and were exempt from sampling during the 97-98 year. Therefore, statistics for Requirements #2-#4 reflect results for 38 facilities. • Most facilities that failed to collect samples from two storm events did not have adequate explanations. The 97-98 wet year is marked by unusually plentiful rainfall due to the El Niño phenomena.
3. Sample from the first storm	0	0%	N/A	N/A	38	100%	• The first flush occurred on a weekend. GISP does not mandate facility operators to collect storm water samples outside of their typical operating hours or under hazardous conditions. • 19 out of the 38 facilities provided inadequate reasons for not sampling from first storm; four out of the 38 facilities that failed to sample from first storm did not provide any explanation.
4. Analyze samples for pH, TSS, SC, and O&G	23	61%	0	0%	15	39%	• About 39% of the facilities failed to collect any samples • All 23 who sampled from at least one storm tested for these basic constituents.
5. Analyze samples for Cu, Pb, and Zn	17	45%	N/A	N/A	21	55%	• Seventeen facilities tested at least one set of samples for Pb, Cu, and Zn. • About 55% of the facilities either failed to sample at all or sampled from at least one storm but failed to analyze for metal.

Table 3. Summary of Monitoring Activities Reported by for 50 Selected Auto Dismantling Facilities in 1997/98 Annual Reports

(Continued)

MONITORING REQUIREMENT	FACILITY COMPLIANCE						COMMENTS
	Completed		Partially Completed		Did Not Attempt		
6. Conduct quarterly non-storm water visual observations	40	80%	6	12%	4	8%	• "Completed" means facility conducted four quarterly observations. • "Partially Completed" means facility conducted at least one but less than four quarterly observations. • Two facilities attached a narrative description of the type of authorized non-storm water discharges observed from their site. However, when asked in the Annual Report whether the facility ever had authorized non-storm water discharges, both facility operators answered negative.
7. Conduct monthly storm water visual observations during the wet season (Oct. 1st - May 30th)	24	48%	24	48%	2	4%	• "Completed" means facility conducted eight monthly observations during the wet season (October to May). • "Partially Completed" means facility conducted at least one but less than eight monthly observations during the wet season. • If a month had no storm, the facility operator must report so.
8. Conduct annual site evaluation	46	92%	N/A	N/A	4	8%	• Four facilities that failed to conduct Annual Comprehensive Site Compliance Evaluation (ACSCE) provided no explanation.
9. Review SWPPP for BMPs and compliance	42	84%	N/A	N/A	8	16%	• Eight facilities that failed to review SWPPP provided no explanation.
10. Certify for compliance	33	66%	N/A	N/A	17	34%	• Of the 17 facilities that did not certify for compliance, 16 facilities cited their failure to meet one or more of the monitoring requirements as the reason for not certifying. • One facility did not provide any explanation for not certifying for compliance.

substantially smaller proportion of facilities (less than half) completed the storm water runoff observations (a total of eight monthly observations activities during *rain* event).

None of the facilities were able to collect samples from the first storm event because the first storm event of the 1997/98 wet season occurred on a Sunday for most of the Los Angeles region (Facilities are not required to sample outside of their normal business hours or under dangerous conditions). Some facilities did not provide a valid explanation for their failure to sample from the first storm event. Less than 20% of those *required* actually sampled from two storms events, as required by the GISP (note: Some facilities that belong to a group monitoring program are subject to less frequent sampling. This study appropriately accounted for those facilities in its analysis). The 1997/98 wet season was impacted by El Niño and had unusually frequent and intense storm events, therefore ruling out the lack of sufficient rain as one of the valid excuses for not sampling. Less than half of those required actually analyzed for copper, lead, and zinc. And among the facilities that sampled from at least one storm, about a quarter did not analyze for the required metals. Failure of facilities to analyze for the designated constituents --i.e. specific pollutants determined by regulators to be of concern for a particular industry -- really hinders efforts to quantitatively evaluate a facility's performance and to gauge potential water quality impact.

Inherent to self-reported information without QA/QC procedures is the uncertainty in the accuracy of the data provided. Annual Reports are subject to similar deficiencies. Each Annual Report must contain a self-certification of compliance signed by the facility operator or equivalent. Whether self-certifications are a reliable gauge for measuring facility compliance depends on several factors including a facility operators' level of understanding and informed interpretation of the GISP requirements and their ability to appropriately assess and accurately report the facility's compliance status. To evaluate how accurately the Annual Reports reflect facility compliance, this study compared the number of Annual Reports self-certified for compliance against the number of facilities reported to have successfully complied with a particular category of monitoring requirement. We considered a monitoring activity that is required of *all* facilities- monthly visual observation of storm water discharges. According to Table 4, less than half, 48%, completed all eight monthly visual observations of storm water, which implies that an equal or smaller number should have certified for compliance, considering the fact that a facility must also satisfy all the other GISP requirements before certifying for compliance. About two-thirds of the Annual Reports were self-certified, pointing to a discrepancy of at least about 20% between those certifying for compliance and those actually complying. It should be noted that only one monitoring activity was considered here. In reality, the actual gap between the number that self-certified and the number that fully completed all required monitoring activities or all GISP requirements is expected to be considerably larger.

Whether this discrepancy is due to a flawed interpretation of compliance criteria, mere carelessness on the part of the facility operator, or unwillingness to openly expose or admit one's deficiency for fear of potential enforcement, one conclusion that can be drawn is that self-certification is not a perfect indicator of facility compliance and should be used with caution when used to estimate permittee compliance.

Storm Water Pollution Prevention Plan

A hallmark of the P2 approach, which drives the GISP program, is the reliance on the facility operators to identify potential pollutant sources and appropriate site-specific BMPs to achieve P2 at their facility. The underlying assumption is that facility operators are the ones most familiar with the facility operations and other site-specific conditions. Therefore, facility operators are considered the ideal candidates for identifying site-specific solutions for their facility.

The GISP requires each facility operator to develop a SWPPP, which is a site-specific document that lays out exactly how a facility will control storm water pollution associated with its industrial activities. Compliance with the SWPPP requirement has not been well characterized because, unlike Annual Reports, SWPPPs are not required to be submitted to the RWQCB. An in-depth review of SWPPPs that considers the site-specific nature of each facility requires a substantial amount of time. This study is one of the first attempts in California and perhaps in the nation to characterize, on a large scale, the quality of the SWPPPs prepared by and for a specific industrial sector. A detailed review was provided for the 50 SWPPPs received based on specific SWPPP-related requirements outlined in Section A of the GISP. A summary of the deficiencies found in the SWPPPs are described in Table 4.

One major deficiency noted in many of the SWPPPs was that they were boiler-plate documents that lacked specific details on the actual BMPs chosen for implementation by the facility operator. Also missing were procedural details about how the BMPs would be implemented. About 90% of the SWPPPs reviewed were prepared by one of four consulting companies. Many of the SWPPPs were written in a vague manner that made it difficult to determine exactly which measure, among a set of "ideal" or "proposed" BMPs described in the document, was chosen for implementation by the facility operator.

As indicated in italics in Table 4, these SWPPPs provided no or limited information on: 1) the name(s) of individual(s) responsible for the implementation of various monitoring activities; 2) a detailed, comprehensive site map that describes the locations of pollutant sources and where industrial activities are conducted; and 3) BMPs that are fundamental to the P2 efforts, such as employee training, site inspection, and good housekeeping programs. In essence, a SWPPP is a "blue-print" that describes specific measures and a schedule of implementation a facility will employ to achieve P2 and regulatory compliance. The SWPPP should be a "living" document that is regularly updated and reflects the actual site conditions. Given their generally poor quality, the majority of the SWPPPs reviewed fail to effectively guide facility operators in the field implementation phase. From verbal communication with facility operators, it appeared that many SWPPPs were being developed by a third party with little involvement or input from the facility operators or key personnel. About a quarter of the 52 facility operators who had called after receiving the RWQCB's formal request for SWPPPs demonstrated little or no knowledge of the SWPPP requirement, indicating

Certification and signature of facility operator	3	0

[1] SWPPPs and written monitoring programs were received from 50 and 47 of the 52 selected facilities, respectively.
[2] GISP encourages facility operators to consider structural BMPs *if* the non-structural BMPs chosen are considered insufficient to adequately address the pollutants present. Therefore, the review of structural BMPs was limited to evaluating whether the facility had considered any of the five categories of structural BMPs described in the GISP. For example, it was considered adequate for the purpose of this study if a SWPPP cited that structural BMPs were reviewed and considered but not chosen for implementation because the non-structural BMPs were considered sufficient.

how closely they were involved with preparing their facility's SWPPP. Also, discussions with facility operators during the case study investigations indicated that the facility operators were either unfamiliar or unsure about many BMPs described in their SWPPP. Some facility operators admitted to not fully understanding all aspects of the SWPPP, including the BMPs described, and expressed reservations about their ability to implement certain structural BMPs described in the SWPPP, when it was explained to them what those measures were and the potential consequences for failing to fully implement the SWPPP which they had certified to implement. The lack of or limited facility operator involvement in preparing the facility's SWPPP and in selecting the appropriate BMPs for the facility appears to be one of the main reasons for the disconnect observed between the descriptions provided in a facility's SWPPP and what is actually being implemented in the field.

WRITTEN MONITORING PROGRAMS

How does a facility measure its performance or progress in P2 efforts or gauge the effectiveness of the BMPs implemented? By monitoring. As a requirement of the GISP, facilities must prepare a written monitoring program. The purpose of a written monitoring program is to ensure that proper methods are provided so that facility operators may employ these methods consistently in monitoring their site conditions and the storm water runoff generated from their site. In turn, this would generate monitoring results - both qualitative and quantitative - that are representative of the facility's site conditions and which could provide useful information on a facility's progress over the years.

Out of the 52 requested, 47 auto dismantling facilities submitted their written monitoring programs. The majority of the monitoring programs were prepared by consultants, and had characteristically similar problems as the SWPPPs. Table 4 summarizes some of the deficiencies found in the written monitoring programs per requirements outlined in Section B of the GISP. The documents generally lacked in procedural details explaining how each monitoring activity would be performed. For example, sections on sampling and analysis requirements did not describe the type of sampling equipment to be used, QA/QC procedures, or special precautions needed to provide a well-controlled environment for collecting, storing, and transporting the samples to certified laboratories for analysis. The lack of sufficient procedural details in the written monitoring programs raises questions about the QA/QC procedures used by facilities for their monitoring activities, especially during sample collection, storage, and transport. And this deficiency limits the reliability and the credibility of the storm water analytical data reported in the Annual Reports. Thus, regulators should use the monitoring results provided in the Annual Reports with caution, keeping in mind some of the limitations discussed above. Another flaw observed in a significant number of the monitoring programs is outdated information that fails to reflect the changes included in the 1997 reissued permit. For example, the minimum period required for retaining records increased from 3 years to 5 years in the 1997 permit. However, many monitoring programs still specified 3 years for the minimum required record retention period. Also, many still used the old definition of a wet season (September to April) instead of October through May, as defined in the 1997 permit. Failure to update the SWPPP per new permit conditions affects a facility's ability to comply with the regulatory requirements.

Many of the nine case study facilities that hired consultants to prepare their storm water documents also depended entirely on them to conduct many, if not all, of their monitoring activities. It appears, from discussions with facility operators, that some consultants perform the required monitoring activities alone, unaccompanied by any facility personnel, and provide a written report, summarizing qualitative and/or quantitative monitoring results, to the facility operator at a later time. Although this type of monitoring may technically meet certain regulatory requirement(s), it tends to remove from the facility operator or other key facility personnel the opportunity to fully assess and understand the site conditions first-hand and to seek out the additional steps that may be necessary to make further progress.

Increased compliance assurance activities by regulators, including random audits and formal request of SWPPPs and monitoring programs for review, as well as timely follow-up responses, are some ways to enhance the quality of these storm water documents. In addition, since some of the major problems, including the lack of site-specificity of the documents, are due to the consultants working on these documents, a time-efficient and effective approach would be for the regulating agency to target those few consultants who prepare the documents for the majority in the industry for regular education and training them so that the SWPPPs and the monitoring programs they prepare are up to speed with the GISP requirements. Another recommendation is for the regulating agency to consider the option of requiring all SWPPPs prepared by a third party to be certified to ensure that the details of the monitoring programs selected for implementation have been fully discussed, understood, and agreed upon by facility operators, and that a key facility personnel will conduct or personally accompany the consultant(s) on all of the monitoring activities.

CASE STUDY INVESTIGATIONS: SITE INSPECTIONS

The first and second tiers of compliance establish the foundation for achieving pollution reduction and/or prevention. However, it is only the compliance with the third tier requirements, the onsite implementation, that results in actual pollution abatement and directly impacts water quality. Staff conducted field investigations of nine selected auto dismantling facilities to study their onsite performance.

The field compliance component of the industrial storm water program has generally not been well characterized for the Los Angeles region due to lack of resources available for the GISP program in the past and other competing priorities. However, the general perception is that field compliance is low especially among small facilities. Substantial staff time is required to complete a comprehensive site inspection, which includes pre-inspection preparation, the actual inspection, and post-inspection follow-up activities including completing an inspection report.

Table 5 summarizes some characteristics of the nine case study facilities, including their property size, percent of imperviousness, and the estimated annual vehicle throughput or the number of vehicles processed yearly. Percent imperviousness refers to the portion of a facility property that is paved, roofed (including buildings), or covered. As shown in Table 5, the case study facilities span a wide spectrum in terms of their annual vehicle throughput, property size, and percent imperviousness. One facility

Facility	Property Size (Acres)	Percent Imperviousness (% Paved, Roofed or Inside Building)	Annual Vehicle Throughput
A	2	60	175 - 250
B	0.7	100	80 - 120
C	2	100	180
D	1	100	50
E	1.5	100	75 - 200 (trucks)
F	0.7	100	120
G	1.5	100	150 (trucks)
H	13	100	16,800
I	0.6	32	110

Table 5. Characterization of Nine Case Study Auto Dismantling Facilities

(Facility H) offered "self-service"- i.e. it allows customers to dismantle desired parts directly from the vehicles. The rest of the Facilities, A through G and I, offered retail, "over-the-counter" service and sold already dismantled parts to customers.

Table 6 summarizes some key findings on facility BMP implementation based on staff site inspections. A more complete assessment is presented in Table 7, which provides numerical ratings (from 0 to 3) on how well individual case study facilities implemented the BMPs described in the facility's SWPPPs and other BMPs considered either universally applicable or especially effective for the auto dismantling industry. A facility's overall BMP implementation score -- the sum of individual BMP ratings -- was used to evaluate a possible correlation between a facility's performance and water quality impacts, which is presented in a subsequent section (Appendix B augments Table 7 with the information on the kinds of pollutant sources or activities conducted at each facility and the BMPs that were cited in the facility's SWPPP). The SWPPPs prepared for the nine case study facilities included very similar, overlapping BMPs, primarily consisting of non-structural measures. In general, the findings of this study concur with the trend analyzed in a previous study on the transportation industry by Duke and Chung (1996) that concluded that storm water control measures described similarly in SWPPPs at a number of case study facilities were not uniformly implemented and unequally effective at managing storm water pollutants. As shown in Table 6, some BMPs were more frequently implemented than others.

Table 6. Evaluation of BMPs Implemented at the Nine Case Study Auto Dismantling Facilities

BMP Types	Fully	Partially
Overhead cover for dismantling area	0	3
Cover parts	1	7
2° Containment for fluid-storing container	3	2
Overhead cover for fluid storage	4	3
Pave entire site	7	1
Conduct dismantling on impervious area	8	0

This study also found that BMPs that are more resource-intensive or pose physical constraints on daily operational activities are less likely to be implemented. The structural BMPs cited in the case study facilities' SWPPPs were often missing or if provided at all, were not fully implemented. The first four BMPs that appear in Table 6 (overhead coverage for dismantling and fluid storage areas, coverage for stored part, and secondary containment for fluid storage area) are examples of measures specifically designed to help eliminate or reduce the exposure of pollutant sources to storm water, but yield little apparent tangible benefits for daily operational activities. Only a few facilities successfully implemented these BMPs. More often than not, dismantling activities were conducted outside in an open space, even when a designated roofed area (with three-sided walls) was provided. Staff noticed that one deterrent was the

Table 7. BMP Performance Observed at the Nine Case Study Auto Dismantling Facilities

Activity/ Pollutant Source	Applicable BMPs	BMP Rating[a]								
		A	B	C	D	E	F	G	H	I
Dismantling (includes fluid draining)	Conduct Activity on Impervious area	3	3	3	3	3	3	3	3	0
	Provide overhead cover	1	0	2	0	0	2	0	0	0
	Use drip pan	2	2	3	N/O	N/O	3	1	0	N/O
Parts storage (batteries excluded)	Provide permanent or temporary cover	1	0	2	1	1	2	0	0	3
	Drain most fluids prior to storage	1	2	2	2	2	3	1	1	3

General	Recordkeeping (copy of GISP, SWPPP, MP, Annual Reports, monitoring records)	1	1	2	1	3	3	1	3	1
General	Storm water treatment	0	0	0	0	2	0	0	2	0
Overall BMP Score		31	27	39	35	38	48	26	34	46

[a] For BMP implementation rating, 0=Not implemented; 1= Poorly implemented; 2= Somewhat poorly implemented; 3= adequately implemented, N/A= not applicable, N/O= Not observed during site inspection.
[b] An overall BMP score is the sum of individual BMP ratings. Two BMPs that were excluded when calculating an overall BMP rating scores. The two BMPs are related to auto compaction activities and recordkeeping activities. Auto compaction-related BMP was left out because eight out of the nine case study facilities did not perform auto compaction and to consider this BMP would necessarily bias the results against the eight facilities. Recordkeeping has a definite indirect contribution toward the successful implementation of a facility's storm water program, but was not included because it is an administrative procedure and in itself does not result in pollution prevention.

insufficient overhead and work space that restricted the movement or the maneuvering of employees during dismantling activities or imposed limitations in forklift-aided transfer of vehicles to and from the designated area. These limitations could have been avoided with a more careful strategic planning of the BMP, that considers adequate work space.

Some BMPs were not implemented by many facilities because of the effort involved in consistently implementing the BMP and other factors. These BMPs include covering parts during storm events and the use of absorbents to control spills. For example, most facilities cited in their SWPPPs that plastic sheets, tarpaulins, or other types of temporary covers would be used to shield vehicle parts from rain. The use of plastic sheets or tarpaulins involves minimal cost for material acquisition but is beset by the following difficulties: (1) unless secured appropriately, tarps or plastic sheets tend to be blown away by wind and provide minimal protection from rain, if any; (2) providing temporary covers depends entirely on the effort of facility employees and are less likely to be implemented consistently and completely, especially under severe storm conditions or if a storm event starts before or after normal business hours; and (3) some facility operators cited other factors, such as tarps placed over the parts storage areas disappearing over night, most likely claimed by itinerant individuals or children in the neighborhood. Given these limitations associated with using temporary covers, facility operators should be strongly encouraged to install permanent roofs or an overhead coverage to effectively reduce exposure of stored parts to precipitation. Another BMP shown to be inconsistently implemented is the use of absorbents to control spills and leaks. Supply maintenance and timely responses are especially crucial for spill-related BMPs. Many case study facilities were deficient in implementing their spill control measures, judging by the degree of spills, leaks, and stains from past spills present on the facility ground. Failure to maintain an adequate supply of spill absorbents on site, the diligent effort required to address small frequent spills, and the lack of urgency that small spills pose compared to large-scale spills are some reasons cited by facility employees for their failure to provide spill control and response measures mentioned in the facility's SWPPPs. Instead of providing immediate attention, many facility employees delayed spill clean-up activities until the end of the business day.

Several major sources contributing oil and grease in storm water runoff were visually identified during the site inspections. Qualitatively judging from the rainbow-colored sheen floating on top of the storm water runoff, failing secondary containment, such as leaky truckbeds used to store incompletely drained parts, fluid-storage areas missing adequate secondary containment or overhead covers, unprotected dismantling areas, and auto compaction location appeared to be the principal sources introducing high levels of oil and grease into storm water from the case study facilities. All of these sources represent areas associated with principal industrial activities.

A recommendation based on these site inspection observations is to provide both an overhead coverage and an adequate (secondary) containment for areas associated with principal industrial activities. Conducting all activities inside a building or roofed, bermed (or curbed) areas would really help minimize or eliminate the introduction of pollutants into storm water runoff. To maximize the usefulness of these structural BMPs, adequate working space and overhead room are two critical factors that need to be considered in the planning stage of these BMPs. There are BMPs such as storing well-drained parts in large autobodies (as observed at Facility I) that allows facility operators to use materials readily available onsite and does not necessitate building a structure. However, this type of BMP, to be effectively implemented, requires extra effort and vigilance on the part of the facility staff (and are thus less likely to be implemented successfully) since parts must be thoroughly drained prior to being placed inside the autobodies, as opposed to parts stored in bermed areas which prevent runoff of residual fluids. Some specific measures to protect the fluid storage areas that have been shown to be effective in the field include a combination of providing an overhead roof or a clean solid board (placed on top of fluid-storing drums) along with the use of sealed, flat-bottom truckbeds, berms, or a secondary drum large enough to fit another drum inside. Secondary drums should preferably be filled with sand or other spill absorbent material, and sufficiently large and low enough so that the inner fluid-containing drum could easily be transported in and out using a forklift.

The primary cause of significant spills observed during auto compaction is incomplete draining of fluids from parts that remain on the vehicles. Facility H, the only case study facility that conducted auto compaction activities, removed most cores (unwanted parts) prior to vehicle compaction after customers had a chance to claim the desired parts. Based on the substantial spills observed during its auto compaction process, the facility apparently had neglected to completely drain residual fluids from the parts remaining on the vehicles, causing fluids to jet out well beyond the surrounding berm during the compaction process. Complete fluid draining upon vehicle arrival is crucial to preventing spills generated during vehicle staging or compaction process.

Many BMPs must be implemented in combination with other BMPs to be effective. A set of BMPs that appears to be especially effective when implemented together is secondary containment and overhead coverage as mentioned above. Overhead coverage helps to eliminate the exposure of pollutants to storm water runoff but not for spills traveling away from, for example, a roofed fluid-storage area. Similarly, severe storms could flood uncovered, bermed areas and introduce pollutants to storm water runoff. When combined, these BMPs could effectively reduce pollutant contact with storm water. Few facilities provided both of these BMPs for the same source area.

Other BMPs implemented by the case study facilities (storing parts off-ground or removing greasy parts from vehicles) by themselves offer minimal or limited pollution control. For example, mounting partially-drained parts or fluid-storing drums on wooden pallets could appear to reduce contact with storm water runoff; however, spills and leaks generated during parts or fluid transfer typically flow over the pallets and contaminate the site ground and make contact with storm water. Mounting fluid-storing drums on top of pallets does not help contain spills and leaks and is not a secondary containment measure, contrary to the claims of some facility operators. Even when parts are fully drained before being placed on pallets, they must be provided with adequate cover to minimize exposure to storm water. Site pavement, which is considered as a stand-alone solution to controlling sediment in storm water, could only offer some degree of control of solids in storm water when facilities have poor housekeeping practices. Facility B had the entire site paved, but the level of total suspended solids (TSS) in its storm water samples substantially exceeded the USEPA benchmark for this constituent. In fact, the facility's TSS level was comparable to other case study facilities with partial or almost no site pavement. A potential source of sediment in storm water generated from completely paved sites is soil from vehicle tires or customers' shoes.

Several factors were considered in identifying potential reasons for the varying degree of BMP implementation observed at the nine case study facilities. The number of employees, facility size, and annual vehicle throughput did not appear to correlate well with a facility's ability to effectively implement BMPs for facilities with five or less personnel, of two acres or less, or with yearly vehicle throughput of less than 300. The eight facilities that fell within this category demonstrated significant differences in their BMP implementation efforts. Facility H, with 16,800 annual vehicle throughput and a 13-acre site, provided several environmentally-trained personnel onsite, maintained efficient recordkeeping, offered regular training for all its employees, and provided storm water treatment, including an oil and water separator for a portion of the site's storm water runoff and an adequate supply of excelsior in the primary discharge location. However, because of the small study pool, with only one facility of this caliber, it is difficult to arrive at a conclusion as to whether facilities with greater resources are more likely to fully implement their BMPs and other storm water program requirements. The performance of this facility could very well have been compelled by an aggressive third-party lawsuit launched by a local non-profit environmental organization against the facility in the recent past.

Cultural or language barriers and the lack of public outreach were identified as two potential reasons for the deficient BMP implementation. The different ethnic backgrounds represented among auto dismantlers in Los Angeles County include Armenian, Mexican, Korean, Persian, and Caucasian, with the first two groups representing the dominant ethnic groups in some areas. From phone conversations and discussions from the site inspections, it became apparent that many of the ethnic minorities did not fully understand the GISP instructions and some had trouble following the verbal instructions of staff. This may partially explain the apparent disconnect between the consultant-prepared SWPPPs and the actual implementation of BMPs onsite. Many of the case study facility operators displayed complete ignorance and a sense of apathy about the significance of storm water pollution, and complained about having to pay for the discharge of naturally-occurring storm water, clearly missing the key point that it is the *pollution* in the storm water runoff that they are responsible for.

One of the key findings of this present study based on the staff's site-inspection experiences is that determining onsite compliance can be rather challenging and not very straightforward for both dischargers and regulators. This is especially true for facilities that are not grossly deficient or sloppy in their housekeeping or operational practices. More accurately, if compliance is to be defined to ensure protection of waterbodies and to prohibit contributing to possible excursion of all applicable water quality standards, as is stated in the GISP, the task of accurately assessing compliance becomes even more daunting because of the following three reasons.

First, the GISP does not specify a mandatory, minimum set of BMPs that must be implemented by all permittees or by each industry. The GISP basically states that facility operators should *consider* the different categories of BMPs outlined in the permit and then select and implement appropriate BMPs to attain the Best Available

Technology (BAT) level. However, the permit does not define what the BAT level is or how to demonstrate that the BAT level has been ascertained. Therefore, facility operators belonging to the same industry may choose from a range of different BMPs - either a single, highly effective BMP, such as treatment, or a combination of multiple BMPs whose cumulative impact may be equally effective. The P2 approach with its primary reliance on facility operators to identify and implement site-specific solutions offers flexibility and room for economic considerations. However, it also presents difficulties for those charged with the responsibility of assessing whether the BMPs provided and as implemented are sufficiently adequate to ensure that the facility's storm water discharges are not contributing to or causing exceedances of water quality standards. There is still limited information on the effectiveness of specific BMPs or the cumulative effects of combined BMPs. And to leave this task of compliance determination up to the individual operator's judgement seems to be questionable regulatory policy.

Secondly, there are no numerical effluent limitations in the GISP, with the exception of a small group of facilities specified under USEPA regulations (40 CFR Subchapter N), that could provide a clear, objective standard for compliance for all regulated facilities across industries. In the absence of a quantifiable measure of compliance, site inspections can, at most, point out whether certain BMPs in a facility's SWPPP are being implemented and identify evidence of pollution, including spills and leaks, that could visually indicate a facility's overall BMP effectiveness. However, to be able to link (visual) compliance with water quality impacts, one must come up with a quantifiable or numeric compliance standard based on water quality criteria.

Thirdly, not all BMPs are readily observable, in particular the non-structural ones when the activities targeted are not being performed. Thus, the implementation status of certain BMPs can be difficult to determine for individuals not part of the facility since site inspections provide only a snapshot in time of the facility's performance. Examples of such BMPs include preventative maintenance of equipment (unless records are maintained on file) or if special caution is employed for certain operating procedures.

Clearly, the overall success of a facility's BMP implementation efforts could qualitatively be judged based on the evidence of pollution, such as spills and stains. However, such qualitative assessment necessarily introduces the subjectivity of the observer and is prone to different interpretations about how well the facilities may be complying with the intent and the requirements of the GISP. As the saying goes, "how clean is clean?" Should facilities feel "safe" as long as they provide reasonably adequate housekeeping (but according to whose standard?) and maintain an overall neat appearance, or do they need to make sure their site is meticulous? Are facilities considered to be in compliance as long as the BMPs provided in the SWPPP are being implemented, or would they be penalized for choosing BMPs inadequate for their activities? Of course, the use of a "common sense" approach and close interaction with the regulating agency could help facilities to move forward. However, for all these efforts of the regulators and permittees to pay off or result in substantially improved water quality, there must be some type of clear quantifiable standards of compliance that could be enforced.

In conclusion, BMPs indicated in the SWPPPs were not fully implemented at the nine case study facilities. Some facilities performed their storm water control measures more diligently than others. Individual BMPs are unequally effective in controlling storm water pollution. As expected, areas associated with principal industrial activities appear to be the major contributors of oil and grease, and probably other pollutants as well, and should be provided with appropriate overhead coverage and secondary containment. Structural BMPs must be planned strategically-- taking into account the need for adequate work space and other conditions that would facilitate the daily operational activities-- to be utilized effectively by employees. Awareness of the significance of storm water pollution and the need for pollution controls appeared to be low among many of the facility operators. Language barriers and the lack of field presence of regulators and of timely enforcement actions in the past are some reasons for the lack of compliance observed among auto dismantling facilities. From a regulatory perspective, because each SWPPP is required to be certified by the facility operators under perjury of law, failure to implement the BMPs described in a facility's SWPPP automatically places a facility in violation of the GISP requirements; consequently, all nine facilities were out of compliance since they did not fully implement all the BMPs indicated in their SWPPP.

However, what is troubling is that, in addition to BMPs not being fully implemented, the list of BMPs drawn up by consultants or facility operators may not be sufficient to control the type and the level of pollutants generated from a site. Therefore, the need to provide a clear, verifiable standard for compliance in the permit, either in the form of (or a combination of) a set of minimum or baseline BMPs or numerical effluent limitations, is incumbent upon the regulators to make the compliance assessment process more understandable to both the regulating agency and the regulated community. Lastly, BMPs applicable to the auto dismantling industry that may be considered effective in the field, and BMPs cited in other storm water manuals, are summarized in Appendix C.

So far, we have focused on the compliance status of selected auto dismantling facilities. The next section explores the water quality implications associated with these findings.

CASE STUDY INVESTIGATIONS: STORM WATER SAMPLING & ANALYSIS

This section focuses on the quantitative measurement of P2 efforts - i.e. storm water analytical data. Storm water samples were collected from eight case study facilities between November 1998 and April 1999. (Due to storm water infiltration into the unpaved facility ground, Facility I did not generate any visible runoff during the several storm events that staff visited the site). Except for Facilities A and B where staff obtained samples from two separate storm events, one set of grab samples was collected from each facility. The goal of collecting samples from the case study facilities was to provide a small, well-controlled sampling program to evaluate the following: a) the range of pollutant concentrations in storm water runoff generated from the industry; b) the overall effect of BMPs implemented by different case study facilities; and c) comparison of the agency-monitored data with the self-reported data provided in the Annual Report for some facilities. Using the USEPA benchmark values as a reference, this study evaluated the levels of pollutants in storm water runoff from eight of the nine case study facilities. This section also provides a trend analysis of pollutant levels in storm water runoff reported over several years by one facility. The storm water analytical data for the eight case study facilities are presented in Table 8. The first column of Table 8 lists the constituents analyzed (auto dismantling facilities in the Los Angeles region must analyze for all constituents listed, except for iron and aluminum; facilities in most other regions in California are required to analyze for iron and aluminum and not copper and zinc.). The last column provides the USEPA benchmark values for the corresponding constituents for reference purposes.

Table 8. Storm Water Analytical Results for Eight Case Study Auto Dismantling Facilities[1]

(Los Angeles County, 1998/99)

CONSTITUENT	EPA Method	Reporting Limit	FACILITY										USEPA Benchmark Level[3]

[1] Grab samples of storm water runoff were collected from eight auto dismantling facilities in the San Gabriel River and the Los Angeles River watersheds
[2] For Facilities A and B, staff collected samples from two storm events.
[3] The Parameter Benchmark Values are from the USEPA Multi-sector Permit (USEPA 1995)
[4] G= graphite method, F= flame method.
[5] Indicates sample collection date.

None of the facilities successfully met the USEPA benchmarks for all constituents analyzed. This is not surprising since the median and the mean pollutant concentrations estimated based on past monitoring data submitted by auto dismantling facilities in their Annual Reports (from 1995/96 to 1997/98) generally exceeded the benchmark values (Appendix D). Shading in Table 8 represent excursions of the benchmark levels. Except for pH, benchmark values for all the other constituents analyzed were exceeded by at least one case study facility. Two constituents that appeared to present the most challenge for the case study facilities were copper and zinc, as demonstrated by the fact that none of the facilities were able to achieve the benchmark levels specified for those constituents. Benchmark levels for specific conductance, oil & grease, aluminum, and iron were exceeded by five (not necessarily the same) facilities (aluminum and iron are not required to be monitored by this industry). Three and four excursions of the benchmark levels were noted for TSS and lead, respectively. Facilities, E and F, whose analytical data indicated relatively lower pollutant concentrations overall, are two facilities which appeared more organized and had signs of good housekeeping practices.

Storm water analytical monitoring data demonstrated a substantial degree of variability between facilities, storm events, and sampling events. For the eight case study facilities, pollutant concentrations or measurements varied by more than a factor of seven for TSS, ten for specific conductance (SC), six for oil & grease (O&G), four for copper (Cu), ten for iron (Fe), eight for lead (Pb), and two for zinc (Zn). The lows and highs in the pollutant concentration range were: 6.8 and 9.0 for pH, 38 and 292 (mg/L) for TSS, 39 and 395 (μmho/com) for specific conductance, 11 and 73 (mg/L) for oil & grease, 812 and 3090 (μg/L) for aluminum, 67 and 259 (μg/L) for copper, 320 and 1170 (μg/L) for iron, 35 and 284 (μg/L) for lead, and 330 and 766 (μg/L) for zinc (some results for aluminum reported as < 1000 μg/L could be less than 812.).

Some interesting trends were observed in the self-monitored storm water analytical data (reported by the case study facilities) for samples collected over multiple years, for a given wet season, and on the same day. Figures 4 through 10, which evaluated the data reported by Facility H for the period between 1993 to 1999, clearly demonstrate the stochastic nature of storm water runoff. No clear increasing or decreasing trend in pollutant concentrations over time is recognized.

An analysis involving five sets of data generated by Facility H for the 1998/99 wet season demonstrated that the highs and the lows in pollutant concentrations of storm water from one facility could vary substantially for a given wet season: by more than a factor of seven for TSS, two for specific conductance, five for oil & grease, three for lead, twelve for aluminum, four for iron, and two for chemical oxygen demand (Facility H had submitted five sets of data for the wet year 1998/99). Again, no consistent trend of increase or decrease was observed in the data set spanning one wet season.

Table 9. Comparison of Pollutant Concentrations in Storm Water Samples Collected on Same Day by Different Individuals for Two Case Study Auto Dismantling Facilities.

Constituents	Facility B (sampled on 2/9/99)		Facility H (sampled on 3/25/99)	
	Facility	Staff	Facility	Staff
pH	9	9	7.42	8
TSS (mg/L)	100	210	183	202
SC (μmho/cm)	160	334	487	395
O&G (mg/L)	9	22	17	65
Pb (mg/L)	0.085	0.284	0.1	0.069
Cu (mg/L)	0.44	0.134	0.21	0.238
Zn (mg/L)	0.3	0.754	0.28	0.33
Al (mg/L)	N/A	N/A	0.21	3.09
Fe (mg/L)	N/A	N/A	4.8	2.8

We evaluated two sites (Facilities B and H) where the facility operator and our staff collected the storm water samples on the same day to determine the extent of variation in pollutant concentrations for samples collected on the same day. Table 9 compares the analytical data reported by the facility versus agency staff. Analytical results on Facilities B and H demonstrated that storm water samples taken on the same day by different individuals, in this case by RWQCB staff and by facility personnel, can display quite different results. Facility H's data (where staff collected samples immediately after a facility employees completed his sampling for the facility) indicated that the reported concentration for the following five constituents (TSS, specific conductance, oil & grease, lead,

copper, and zinc) differed by at least 20% and up to 1400% between the two sets of data, with the most significant differences observed for oil & grease (280%), and for aluminum (1400%). An interesting trend observed with Facility B's data was that for five out of the six constituents (TSS, specific conductance, oil & grease, lead, and zinc) agency-generated data were higher than the facility's self-reported data by at least 100% and up to 230%. This suggests that perhaps different sampling strategies -- agency staff attempted to capture storm water runoff with a visible oily sheen -- could produce substantially different results, even for a same-day sampling.

One of the goals of storm water sampling at the case study facilities was to provide a well-controlled sampling environment with an adequate QA/QC necessary to generate reliable data that could be used to relate meaningfully the effects of BMPs on water quality. Two methods were used to relate BMP implementation to pollutant concentrations in storm water runoff. The first method attempted to evaluate the overall BMP implementation scores of each facility, derived based on a systematic rating system, in the context of storm water concentrations. The second method used the overall site appearance or impression as a qualitative indicator of the relative concentration of pollutants in storm water runoff.

With the first method, we tested for both linearity (r) and causality (r^2) between BMP implementation and storm water concentration by plotting for each constituent the pollutant concentration against the overall BMP score of each facility (The overall BMP scores are presented in Table 7.) The r and r^2 values were all less than 0.5 and 0.25, respectively. This implies that a mathematical relationship of the type employed in this study may not be a suitable method for relating the effects of BMPs with the runoff quality, based on the results of our case study. Possible reasons that a clear relationship between overall BMP score and the pollutant concentrations were not observed include:

- the chosen method does not take into account the degree of effectiveness of individual BMPs (this study rated the BMPs only on how completely or satisfactorily each BMP was implemented at the facilities, and summed the ratings to obtain an overall BMP score. This is essentially equivalent to assuming that all BMPs are equally effective and assigining them equal weights);

- site-specific factors, such as annual vehicle throughput; when the last batch of vehicles arrived and were dismantled; how many storm events preceded the sampling activity; and the time lapsed between the start of a rain and a sampling event, and rainfall intensity, are not considered by the above method.

It should be noted that due to the short duration of storm events and the lack of staff to cover all eight case study facilities at the same time, sampling was collected over three separate events between February and April of 1999. The inspections were performed between November of 1998 and April of 1999.

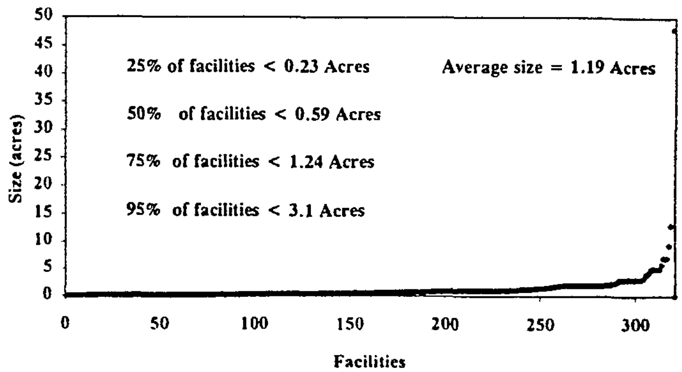
The overall site appearance or evidence of diligent implementation of good housekeeping practices seems to be a useful indicator of the relative pollutant levels between sites with similar facility size, annual throughput, and operational activities. Generally, case study facilities that were organized and clean showed relatively lower

Table 10. Geographical Distribution and Average Size of Auto Dismantling Facilities in Individual Watersheds in Los Angeles County.

Watershed	Estimated number of auto dismantling facilities	Average facility size (acres)	Estimated total source area (acres)
Los Angeles River	234 (57.8%)	1.215	284 (63%)
Dominguez Channel	103 (25.4%)	0937	96 (21%)
San Gabriel River	63 (15.6%)	1.06	67 (15%)
Santa Clara River	2 (0.6%)	1.31	3.2 (0.7%)
Santa Monica Bay	2 (0.6%)	0.2	0.4 (0.08%)
Total Source Area	404	1.12*	450

*county average

Figure 11. Size Distribution of Auto Dismantler Facilities in Los Angeles County



San Gabriel watershed; and 0.6% each in the Santa Clara River watershed and the Santa Monica Bay watershed. Figure 11 shows the size distribution of auto dismantling facilities in Los Angeles County. The County average is 1.2 acres, with 90% of the facilities under 3 acres.

Pollutant loads from the auto dismantling industry were estimated for the 1998 - 1999 storm year for the three watersheds with the highest number of auto dismantling facilities - Los Angeles River, San Gabriel River, and Dominguez Channel. Loads were calculated for TSS, oil & grease, copper, lead, and zinc. Table 11 presents the load estimates and information on parameters used to arrive at the estimates, such as average pollutant concentration, annual precipitation and runoff, and area within each watershed occupied by auto dismantling facilities. The total approximate loads for all of Los Angeles County contributed by the auto dismantling industry are: 22,400 lbs. of TSS, 4,650 lbs. of oil & grease, 35 lbs. of copper, 22 lbs. of lead, and 130 lbs. of zinc. These estimates may be slightly lower than for a typical wet season because the 1998/99 wet season was impacted by the La Niña phenomenon and had less-than-average

Table 11. Pollutant Load per Watershed Contributed by Auto Dismantling Industry in Los Angeles County based on the 1998/99 Wet Year (pounds/acre/year) [1]

Watershed	P[2] (in)	Pj[3]	TSS 116.3 mg/L[4]	O&G 28.4 mg/L	Cu 142 ug/L	Pb 103 ug/L	Zn 508 ug/L
Los Angeles River (284 Acres)	9.72[5]	0.72	22,950	5,600	30	20	100
Dominguez Channel (96 Acres)	4.71[6]	0.67	3,480	850	4	3	15
San Gabriel River (67 Acres)	7.48[7]	0.72	4,140	1,010	5	4	18
Total			30,570	7,460	40	30	130

[1] Based on average site imperviousness value of 43%. Rainfall data for the 1998/99 wet year (Oct. - Oct.) was obtained for specific reference sites within each watershed from the Los Angeles County, Department of Public Works, Hydrology Division.
[2] P is annual precipitation in inches per year.
[3] Pj is fraction of rainfall events that produce pollutants in runoff. Pj was calculated using an assumption that the threshold rainfall greater than 0.1 inches is needed to produce runoff.
[4] Average pollutant concentrations were estimated based on the storm water analytical data on the grab samples collected by RWQCB staff from the eight case study auto dismantling facilities.
[5] Rainfall data from the monitoring stations near Downtown Los Angeles and Sun Valley.
[6] Rainfall data from the monitoring station near Wilmington.
[7] Rainfall data from the monitoring station near Duarte.

R0011252

precipitation On a watershed level, the Los Angeles River was the single most impacted waterbody, receiving the majority of the load. The San Gabriel River watershed, which has a smaller total "source" area than Dominguez Channel watershed, was characterized with a higher load due to the greater total precipitation and runoff experienced in the San Gabriel watershed area. Although not presented in Table 10, the loads from the auto dismantling facilities in the Santa Monica Bay watershed and the Santa Clara River watersheds are negligible given the fact that each watershed only had two known auto dismantling businesses within its respective area.

The load introduced by the auto dismantling industry to surface waters is significant. On a weight basis, the pollutant associated with the highest load by weight is TSS, followed by oil & grease, zinc, lead and copper. The estimates presented in this study may be improved by using flow-weighted composite data for pollutant concentration, accounting for the variability in the rainfall patterns within specific watersheds, and by using a more accurate estimate of the total universe of facilities that accounts for facilities that both the RWQCB and DMV failed to capture. For a more meaningful load analysis, the estimates should be evaluated in the context of loads generated from other major industrial sources, a task that lies outside the scope of this study.

CONSIDERATION OF OTHER APPROACHES TO STORM WATER POLLUTION CONTROL

The question of how compliance should be defined to protect water quality and beneficial uses of the receiving waterbody is an important one. The pollution prevention approach, as currently designed, lacks a clear, uniform standard for measuring compliance, and may require more resources than traditional (individual) NPDES to adequately monitor for compliance. An objective quantitative or measurable standard of compliance is also necessary for equitable and consistent enforcement. Two alternatives other than the current P2 approach are considered in this section. One alternative is to define compliance in terms of numerical effluent limitations. This approach is consistent with the traditional or individual NPDES permitting approach. Establishing numerical effluent limitations would help facility operators to determine whether the facility is indeed achieving the limits, and if not, how much the facility needs to ratchet down its pollutant levels to return to compliance. This simplifies compliance assessment for both regulators and the regulated community and provides a clear basis for enforcement actions. If feasible, numerical effluent limitations should be developed based on water quality criteria that are protective of beneficial uses. This would ensure that facilities, by meeting the established limitations, are not contributing to or causing exceedances of applicable water quality standards.

Another alternative is to prescribe a set of minimum, mandatory baseline BMPs for each industry. Compliance would be determined primarily by the effective and diligent implementation of these selected BMPs. To facilitate the compliance determination process, a minimum set of BMPs should consist of measures that are readily observable. This option limits the flexibility offered by the P2 approach that allows facility operators the freedom to choose from a wide range of BMPs and to tailor the BMPs to the facility's site and economic conditions. In addition to Appendix C and the sources cited for Appendix C, the list of BMPs compiled for the cooperative compliance program of Wisconsin is another comprehensive source of information on BMPs for the auto dismantling industry (KES 1999; CCP/DNR 1999)

This study recommends the following tiered approach for the auto dismantling industry that combines the core of the two alternatives outlined above: 1) a mandatory set of specific, baseline structural and non-structural BMPs for facilities with annual vehicle throughput of less than 500 (which represent "mom-and-pop" facilities); and 2) mandatory treatment of storm water for facilities with annual vehicle throughput greater than 500. Also, in lieu of requiring treatment, numerical effluent limitations could be applied to the latter group as a standard of compliance. A compliance schedule could help phase facilities into compliance over a certain specified time frame. Facilities with less than 500 annual vehicle throughput that persistently demonstrate problems in meeting certain water quality standards, for example the USEPA benchmark levels, should also be considered for mandatory storm water treatment.

Lack of sufficient resources has been identified as the primary reason for the limited compliance assurance and enforcement activities by the RWQCB. One way to help effectively implement the above recommended strategy and at the same time, reduce the workload associated with compliance assessment and assurance activities is to employ a semi-privatized certification program, such as that implemented in the State of Wisconsin, which relies on licensed, private inspectors to oversee the compliance activities of a group of facilities that voluntarily choose to participate and help fund the program. The aim of such a program is to help reduce some of the workload of the regulators and to allow facilities that diligently work toward and maintain a specified level of compliance to be certified for compliance by professional inspectors. Such certification could potentially shield them from certain regulatory responsibilities, such as monitoring activities, and indirectly from third-party lawsuits by reducing the degree of their environmental liability. (Essential to the implementation of this type of program is regular training and (re-)certification of inspectors by the regulating agency to maintain high QA/QC for the inspection procedures.)

V. CONCLUSIONS/RECOMMENDATIONS

Several conclusions can be drawn from the findings of this study. Compliance, in general, appears to be limited or low among the auto dismantling facilities in Los Angeles County, for all three tiers of the GISP requirements. Analyses based on site visits results and DMV dismantling license information showed that about one out of every five auto dismantling facilities operating in Los Angeles County are non-filers. Compliance with the annual reporting and SWPPP and written monitoring program requirements is also limited. Review of the 1997/98 Annual Reports revealed that many of the required facilities failed to conduct the key monitoring activities, such as storm water sampling and analysis, limiting the usefulness of the Annual Reports as a tool to gauge overall permittee performance. SWPPPs and written monitoring programs, due to their generally poor quality, fail to effectively guide facility operators in their P2 efforts and in proper monitoring procedures. Accelerated enforcement activities have proven to be effective for increasing the Annual Report submittal rate. Outreach to consultants is strongly recommended to upgrade or improve the quality of SWPPPs and written monitoring programs being prepared by third parties.

The GISP program has not effectively penetrated the auto dismantling industry in terms of compelling the kinds of behavioral changes needed to effectively control storm water pollution and to improve water quality. Case study investigations indicated that the selected facilities failed to select and implement appropriate BMPs to attain the USEPA benchmark levels. Pollutant load estimates based on this industry show that the magnitude of the load could be substantial. These findings imply that the current approach based on P2 and the primary reliance on facility operators to identify and implement appropriate BMPs, without establishing enforceable numerical effluent limitations, has not been shown to be effective, at least at the level currently implemented, in controlling storm water runoff from the auto dismantling industry. Past studies on other industries, including the metal plating and transportation sectors, support some of the findings and conclusions of this study (Duke and. Shaver 1999; Duke et al 1999a; Duke et al 1999b; Duke et al 1998; Duke and Bauersachs 1998; Duke et al 1998; Duke and Beswick 1997; and Duke and Chung 1996).

The lack of a clear, objective standard for compliance could pose a special challenge to dischargers when trying to determine if the existing BMPs are sufficient or need to be upgraded or supplemented with additional BMPs. The majority of the storm water analytical data from the eight case study facilities and the self-reported data provided by auto dismantling facilities in the past substantially exceeded the USEPA benchmark values. The GISP program, as currently implemented and enforced, appears to be not attaining the potential pollution reduction achievable as envisioned. For this reason, this study considered different regulatory alternatives to control industrial storm water pollution. This study recommends a tiered approach that offers different combinations of options -- including implementation of a set of minimum required BMPs, mandatory storm water treatment, or applying numerical effluent limitations -- based on each facility's annual vehicle throughput quantity.

Until now, the GISP program at the Los Angeles RWQCB has exhausted most of its resources for determining and enforcing against violators of the first and second tier compliance. In reality, it is the onsite implementation that actually achieves pollution prevention or reduction. Therefore, more resources should be allocated to assess and verify field compliance. Increase in compliance assurance activities and timely comprehensive enforcement activities would improve overall compliance. This study suggests a possible solution -- a semi-privatized compliance certification program -- that could substantially reduce regulators' workload and allow them to focus on high-risk sectors or facilities to more effectively regulate and control storm water pollution associated with industrial activities.

MONITORING PROGRAM	Not Applicable	Included	Not Included	Incomplete	Comments
Quarterly Non-Storm Water Discharge Visual Observations (B.3)					
Observations to be conducted (B.3.c) (Jan-March, April-June, July-September, October-December)					
All drainage areas (B.3.a)					
Look for presence of unauthorized NSWDs (B.3.a)					
Observe authorized NSWDs (B.3.b)					
Maintain observation records (B.3.d)					
Storm Water Discharge Visual Observations (B.4)					
Once per month during wet season (B.4.a) (October 1-May 31)					
Observe during first hour of discharge (B.4.a)					
All drainage areas (B.4.a)					
Observe stored or contained (B.4.a) storm water at time of discharge					
Preceded by three working days dry weather (B.4.c)					
Document discharge characteristics (B.4.c)					
Sampling and Analysis					
Samples to be collected during first hour of discharge (B.5.a)					
Sample from first storm of the wet season (B.5.a)					
Sample from one additional storm during wet season (B.5.a)					
Samples collected from all discharge locations (B.5.a)					
Sampling of contained storm water (B.5.a) at time of discharge					
Sampling preceded by at least (B.5.b) three working days without storm water discharges					
Sampling for pH, TSS, SC, TOC or O&G (B.5.c.i)					
Sampling for toxic chemicals and other pollutants likely present in storm water discharges in significant quantities (B.5.c.ii)					
Other analytical parameters listed in Table D (B.5.c.iii)					
Storm Water Effluent Limitation Guidelines parameters (B.6)					
Description of sampling locations (B.7)					
Description of sampling methods (B.10)					
Identification of analytical methods (B.10.b) and method detection limits					
Retention of all records for at least five years (B.13)

Appendix C. Best Management Practices for Auto Dismantling Industry

ACTIVITY	PURPOSE	BEST MANAGEMENT PRACTICES (BMPs)
Vehicle Dismantling Dismantling Activities	Eliminate exposure	• Roof or cover to eliminate rain-in. Berm area to eliminate storm water run-on. Conduct dismantling work in this designated area. • Place a mat, plastic, or tarpaulin on the ground prior to placing parts on the ground. (Also, if no roof or cover provided over dismantling area, conduct dismantling activities on top of plastic or tarpaulin, which can be readily cleaned or replaced, and removed during storm events). • Drain all fluids (antifreeze/coolant, brake fluid, gasoline/diesel, motor oil, transmission oil) from vehicle prior to dismantling and parts removal. • Use drip pans to drain fluids. Do not overfill . • Drain oil filters before disposal/recycling. • Remove refrigerant prior to dismantling and parts removal. • Deploy airbags per guidelines or remove intact airbags for reuse and store under cover. • Dispose of greasy rags, air filters, spent coolant, and degreasers. • Remove batteries promptly after vehicle arrival. • Remove oil-bearing components prior to storage.
Fluid draining	Eliminate exposure	• Roof or cover to eliminate rain-in. Berm area to eliminate storm water run-on. Remove fluids in this designated area. • Use drip pans for draining vehicular fluid. • Use funnels, and stoppers for the containers. • Avoid discharge of vehicular fluid (as in drips or leaks) on the ground.
Parts Repair/ Wash	Eliminate exposure	• Designate contained areas for repairs and washing (curb, berm or dike area, if necessary. If not feasible, use oleophilic (oil- absorbing) boom bags to prevent washwater from running to the street / curb or other areas of facility.) • Wash parts in a wash- tray provided with secondary containment. • If area not otherwise contained, divert runoff from repair and wash areas with hydrophobic boom bags. • Transfer spent solvent or washwater into designated drums. • Recycle and reuse or release washwaters to sanitary sewer. • Use minimum amounts of solvents or detergents for parts cleaning. • Use water-based cleaning solvents and biodegradable (non-phosphate) detergents. • Wipe and sweep area regularly after activity. Dispose of greasy rags, air filters, spent coolant, and degreasers in appropriate containers.
Storage Vehicles	Eliminate exposure	• Keep vehicle engines covered with hoods or with plastic sheets secured in place. • Store vehicles on an impervious (e.g. concrete) surface (if possible). • Use drip pans under stored vehicles. • Minimize inventory during wet season. • Reduce holding time for scrap disposal.

Appendix C. Best Management Practices for Auto Dismantling Industry (Cont'd)

ACTIVITY	PURPOSE	BEST MANAGEMENT PRACTICES (BMPs)
Separated components	Eliminate exposure	• Confine to designated area. • Store indoors or under temporary or permanent cover (that sufficiently shields rainfall). • Curb, berm, or dike the area. (If not feasible, then: 1) store parts off-ground, for example on storage racks, with drip pans underneath to collect residual fluids; or 2) store parts in leak-free truck beds or plastic containers; or 3) place parts in auto bodies (intact), especially large-sized vans, which also provide an excellent storage places for parts; 4) divert runoff from scrap storage area with hydrophobic (water resistant) boom bags) • Place tires in semi-trailers, indoors, or covered area. Sell or recycle. • Store scrap parts/metals under cover and dispose of to scrap collector promptly • Divert runoff from scrap storage area with hydrophobic (water resistant) boom bags.
Batteries	Eliminate exposure	• Store batteries in covered storage area, on a paved surface that is bermed, or in plastic containers with lids.
Fluid	Eliminate exposure Improve materials management	• Store fluid containers (e.g. drums) on an impervious surface and under a roofed shed. • Provide secondary containment for the fluid-containing drums. • Keep separate (solvents, oils and fuel) and label accordingly.
Others Recycling	Waste minimization	• Recycle (or resell if possible) anti-freeze, fuel, waste oil, windshield washer and solvents. • Recycle usable recyclable parts. • Recycle tires and core/ scrap metals.
Spill Prevention & Clean-up	Minimize exposure Waste Minimization Contain/ cleanup pollutants	• Employee training (prepare for and clean up spills.) • Prepare a spill clean-up kit (absorbent sand, rags, adsorbent snakes, broom, etc.) and place in convenient readily accessible location. • Drain vehicular fluids at designated removal area. • Use the provided spill- kit to contain leaks or spills immediately. Dispose of properly. (Use oleophilic sands to absorb/contain small leaks, and boom bags for large spills.)
Employee Training	Waste minimization	• Train employees regularly in proper and environmentally safe practices.
Customer Education	Waste minimization	• Inform and require customers who remove parts to do so properly and appropriately dispose of waste (for example, posting signs that require the use of drip pans for parts removal and prohibit waste-generating activities in parking lot can be helpful).
Site Inspection	Good maintenance	• Inspect site regularly to ensure all appropriate BMPs are being implemented.
Preventative maintenance	Prevent pollution/ accidents	• Inspect to ensure integrity of tanks, containers, pipings and valves. Install safeguards against accidental release.

Appendix C. Best Management Practices for Auto Dismantling Industry (Cont'd)

ACTIVITY	PURPOSE	BEST MANAGEMENT PRACTICES (BMPs)
Site Maintenance	Minimize exposure	• Keep site clear of trash and debris. • Regularly remove and sweep sand (used to contain spills), trash or dirt from site. • Collect corrosion/ metal particles with magnet (survey the site with a forklift or small vehicle with magnet attached behind.)
Materials Inventory	Good management	• Maintain proper inventories of vehicles processed, materials stored, and wastes recycled or disposed of.
Site grading	Minimize exposure	• Repave area to direct flows to a low point (away from storage and waste areas) where leaking fluids can be collected.
Recordskeeping	Good management	• Maintain records of inspections, monitoring (including storm water sampling), Annual Reports, and training.
Storm Water Treatment Flow dissipation	Remove Pollutants	• Direct flow discharge over coarse gravel or cobblestones to facilitate settling out of particulates and sediment.
Vegetative belts	Remove Pollutants	• Direct flow discharge over vegetative belts or biofilters to enhance pollutant removal.
Sand/ gravel filters	Remove Pollutants	• Allow storm water from open parts storage areas to pass through sand-gravel filter with drain holes. Sand layer must be periodically replaced.
Detention ponds	Remove Pollutants	• Capture storm water runoff from high activity areas. Skim off surface oil and remove bottom sediment. Reuse or evaporate runoff water.
Oil-grit/ oil-water separator	Remove Pollutants	• Direct flows from high activity areas through OW separators. Off-line separators to bypass large storms are preferable. Maintain regularly.
Flotation/ coagulation	Remove Pollutants	• Store runoff flows, equalize, and provide flotation/ coagulation. High operation and maintenance costs. Inappropriate if used only intermittently.
Industrial sewer piping	Remove Pollutants offsite	• Pretreat as required and pipe to sanitary sewer if allowed (permit likely required).
Oil/grease - absorbents	Remove Pollutants	• Provide oleophilic booms or excelsior near runoff exit. Replace as needed. Dispose of properly.

COMPARISON OF BEST MANAGEMENT PRACTICES

BEST MANAGEMENT PRACTICES	Multi-Sector Permit Requires Consideration of These BMPs	Ability to Control: Sediment	Vehicle and Equipment Fluids	Metals	Solvents and Cleaners	Initial Cost	Operation and Maintenance Costs	Practicality
GOOD HOUSEKEEPING								
General Practices								
Develop a storm water management policy statement for your employees. Management can provide direction and support for pollution prevention by reviewing this policy with employees and keeping it posted.		■	■	■	■	★	★	★
An in-coming vehicle inspection inventory program should include a check for fluid leaks and for unwanted material that could have been placed in the vehicles.		■	●	■	■	★	★	★
Clean up debris and trash on a regular basis.		●	■	■	■	★	●	★
Construct fences or other physical barriers to act as visual and noise barriers, help to control dust, help prevent theft, and control the direction of runoff.		■	■	■	■	■	●	●
Maintain an organized inventory of materials used at the facility.	✔	■	■	■	■	●	●	★
Consider indoor storage of vehicles, parts, and equipment, and the use of berms and/or dikes to control storm water runoff.[1]	✔	●	★	★	●	■	●	■
Vehicle Dismantling Fluid Management								
Remove fluids from vehicles brought into the facility for processing or dismantling.	✔	■	★	■	■	■	■	★
Keep used oil separate from part cleaning solvents, antifreeze, and fuel. Engine oil, transmission fluid, brake fluid, and power steering fluid can be combined and stored together.		■	●	■	●	●	★	★
Label storage containers of all fluids and waste materials.	✔	■	■	■	■	★	★	★
Drain all parts of fluids prior to disposal.	✔	■	★	■	■	●	●	★
Confine the storage of vehicles, parts, and equipment to designated areas.	✔	■	■	■	■	●	●	●

COMMENTS

1 May interfere with operation and access. Indoor storage of vehicles is not appropriate or practical for an automotive recycling facility.

KEY TO THE TABLE

	■	●	★
Ability to Control Pollution	no significant removal	slight (<25%) removal	moderate to high (25%) removal
Initial Cost	>$5,000	$1,000 - $5,000	<$1,000
Operation and Maintenance Cost	>$1,000 / year	$500 - $1,000 / year	<$500 / year
Practicality	usually not practical	sometimes practical	practical for most facilities

COMPARISON OF BEST MANAGEMENT PRACTICES

BEST MANAGEMENT PRACTICES	Multi-Sector Permit Requires Consideration of These BMPs	Ability to Control: Sediment	Vehicle and Equipment Fluids	Metals	Solvents and Cleaners	Initial Cost	Operation and Maintenance Costs	Practicality
Use canvas or sheets of plastic to temporarily cover storage areas.[2]	✔	●	●	■	■	●	●	●
Transmission and engine cores may be stored in plastic storage boxes with leak proof tops; lugger boxes having solid bottoms and covered by a permanent roof, lugger boxes without a solid bottom stored under a permanent roof on a concrete pad with curbing; or an enclosed trailer with a steel floor to contain fluid runoff and a drain in the floor to properly remove waste fluids.		■	★	■	■	■	●	●
Engine oil should be drained and stored in labeled, doubled-walled, above ground tanks. Used oil can either be recycled for on-site use in a waste oil heater, or sent off-site for re-refining or fuel blending.		■	★	■	■	●	●	★
Antifreeze should be reclaimed and reused or properly disposed of.[3]		■	★	■	■	●	●	★
Drain window washer fluid for reuse.		■	★	■	■	★	★	★
Remove batteries as soon as possible after vehicle enters the yard. Store good batteries inside for resale. Store dead batteries inside on pallets (if your floor is gravel or dirt, put a layer of absorbent material below the pallet) or in storage containers, or store dead batteries outside in a leak proof, covered container.		■	●	●	■	●	●	★
Parts Cleaning								
Perform all parts cleaning operations indoors or cover and berm outside cleaning areas.[4]	✔	■	●	●	★	●	●	★
Clean parts by using minimal amounts of solvents or detergents.		■	●	●	★	●	●	●
Recycle and reuse cleaning fluids where practical.		■	■	■	●	★	★	●
Spent cleaning solutions should be removed by a waste hauler or recycler.		■	■	■	■	★	★	★
Use phosphate-free biodegradable detergents. Consider using detergent-based or water-based cleaning systems in place of organic solvent degreasers.		■	■	■	★	●	●	●
Vehicle Crushing Activities								
Consider providing a containment system—such as a concrete pad with berms—for vehicle crushers. Fluids and storm water runoff from such bermed areas could be discharged into a sump, oil/water separator, sanitary sewer, or other appropriate drainage system that prevents storm water contamination.		■	★	●	■	■	■	●

COMMENTS
2 May interfere with operation and access.
3 May need to check with the state to see if additional requirements are required.
4 May not be feasible or practical for all facilities.

COMPARISON OF BEST MANAGEMENT PRACTICES

BEST MANAGEMENT PRACTICES	Multi-Sector Permit Requires Consideration of These BMPs	Ability to Control: Sediment	Ability to Control: Vehicle and Equipment Fluids	Ability to Control: Metals	Ability to Control: Solvents and Cleaners	Initial Cost	Operation and Maintenance Costs	Practicality
If a gravel/geotextile fabric foundation is provided under a crusher, install a fluid collection system to capture fluids that are released during the crushing operation.		■	★	●	■	■	■	●
Capture crusher fluids to prevent spillage. Collect this mixture of fluids in a spill-proof covered container, test the fluid, and dispose of it properly. It should not be allowed to drain onto the ground. Keep the drain within the crusher clear so that the fluids do not collect and overflow from the crusher onto the ground.		■	★	●	■	●	●	●
PREVENTIVE MAINTENANCE								
Develop a preventive maintenance program that involves timely inspections and/or maintenance of the crusher and facility equipment and vehicles. The program may include • Service checklists and maintenance logs for each piece of equipment; • Employee education and instruction material; and • Review of manufacturer-recommended parts replacement and maintenance activities and frequencies.		■	●	■	■	★	●	★
Keep the crusher and other equipment clean by frequently wiping off accumulated oil and grease that may be exposed to storm water (except where needed for proper operation of the equipment) or that may hide equipment trouble spots.		■	●	■	■	★	★	★
Conduct scheduled maintenance of facility equipment and vehicles in a covered or bermed area, where practicable.		■	●	■	■	●	●	●
Schedule periodic inspections of equipment for leaks, spills and malfunctioning, worn, or corroded parts. Regularly inspect tanks, valves, hoses, and containers. Look for signs of wear or weakness.		■	●	■	■	■	●	★
On secondary containment structures, regularly inspect the valve, seals around the outlet pipe, the outlet pipe itself, and the dike for cracks, damage, or leaks.		■	■	■	■	★	★	★
When secondary containment reservoirs require pumping or release, a sample of collected water should be visually inspected or tested for pollutants. If pollutant levels are significant or there is contamination, pump the accumulated water into barrels or into a tanker truck and haul to a wastewater treatment facility.		■	■	■	■	★	●	★
Repair or replace parts before they wear out.		■	●	■	■	★	●	★
Repair malfunctioning equipment that is responsible for any leak or spill as soon as possible.		■	★	■	■	★	●	★

COMPARISON OF BEST MANAGEMENT PRACTICES

BEST MANAGEMENT PRACTICES	Multi-Sector Permit Requires Consideration of These BMPs	Ability to Control: Sediment	Vehicle and Equipment Fluids	Metals	Solvents and Cleaners	Initial Cost	Operation and Maintenance Costs	Practicality
Secure and lock above ground tank storage areas. Tanks, pumps, fittings, pipes, and containers should be inspected routinely for integrity and leaks.		■	■	■	■	★	★	★
Perform maintenance activities indoors.[5]	✔	■	●	■	■	■	●	●
Valves on secondary containment structures should be kept in the "off" position at all time, except when collected water is being removed.		■	■	■	■	★	★	★
SPILL PREVENTION AND RESPONSE								
Make available MSDS sheets and other safety materials that identify types of fluids that have the potential to spill, indicate whether these fluids are hazardous or toxic, list appropriate safety equipment to be worn, and specify correct materials and procedures to use to clean up the spill.		■	●	■	●	●	★	★
Provide spill clean-up equipment at locations where spills are most likely to occur.		■	●	■	●	●	★	★
Identify clean-up procedures, including the use of dry absorbent materials or other clean-up methods to collect, dispose of, or re-cycle spilled or leaked fluids. Maintain an adequate supply of dry absorbent material on-site. Properly dispose of used absorbent materials.		■	●	■	●	●	★	★
Contain oil or other fluids spilled during parts removal.	✔	■	●	■	■	★	★	★
Never pour liquids or dry materials down a storm drain.		■	★	■	★	★	★	★
Place drip pans, plastic sheets, or canvas tarps beneath vehicles, parts, and equipment during maintenance and dismantling activities. If any parts are removed, they should be placed in a drip pan. Drip pans should not be left unattended.	✔	■	★	■	●	★	★	★
When refueling vehicles and equipment, park as close to the pump as possible. Keep fuel nozzle upright when not in use, and replace nozzle securely in the pump.		■	●	■	■	★	★	★
Pave refueling areas to prevent contamination of the soil if a spill occurs.		■	●	■	■	■	★	●
Equip fuel pumps and tanks with overflow prevention and automatic shut-off devices.		■	★	■	■	●	★	★
Control any spills that may occur around fueling areas.		■	★	■	■	★	★	★

COMMENTS

5 May not be appropriate for certain scheduled maintenance procedures.

COMPARISON OF BEST MANAGEMENT PRACTICES

BEST MANAGEMENT PRACTICES	Multi-Sector Permit Requires Consideration of These BMPs	Ability to Control: Sediment	Vehicle and Equipment Fluids	Metals	Solvents and Cleaners	Initial Cost	Operation and Maintenance Costs	Practicality
Containers and tanks should be stored on a concrete or impermeable surface, and if feasible, under cover. All containers should be labeled according to content and hazard characteristics. Keep drums containing chemicals away from sumps and drains.[6]		■	★	■	●	■	★	●
Observed spills and leaks should be captured and cleaned up using dry absorbents, drip pans, towels, mops, pads, and booms.	✔	■	★	■	★	★	●	★

RUNOFF MANAGEMENT								
Use vegetated swales and buffer strips, catch basin filters, and/or other similar measures to facilitate settling or filtering of pollutants in runoff.[10]		★	●	●	●	■	●	●

COMMENTS

6 Secondary storage inside a building is only recommended when there is a potential for a spilled liquid to flow outside and reach a waterway.

7 This may not be feasible or practical for some facilities.

8 May be labor intensive for some facilities.

9 Filtering measures may not be practical for facilities with unpaved surfaces with large sediment loadings. Filters would become clogged, possibly causing flooding. May be damaged by heavy equipment.

10 May not be practical in many industrial facilities that are storm sewered. May be damaged by heavy equipment.

[1] Data represent grab samples of storm water from auto dismantling facilities collected by facility operators as part of the annual monitoring and reporting requirement or by the Regional Board staff as part of this study.
[2] The benchmark values are from the 1995 USEPA Multi-sector Permit (USPEA 1995).
[3] Represent samples collected by staff from the eight case study facilities.
[4] Represent samples collected by facility operators.
[5] Represent samples collected by group monitoring participants.

Appendix E. Description of Load Estimate Parameters

Each of the parameters in the EPA Simple Method equation were estimated as described below:

Average pollutant concentration, C: Ideally, Flow-weighted composites should be used to estimate load. Given the lack of flow-weighted composite storm water data on the auto dismantling industry reflective of the climatic and precipitation patterns of Southern California, grab sample data generated by staff sampling at the eight case study facilities were used. At this time, the approximate margin of error or uncertainty from using grab sample data instead of flow-weighted composite data is not known.

The total site area, A: For area, A, area occupied per watershed by auto dismantling establishments were estimated by multiplying the following three factors: a) the total number of auto dismantlers in Los Angeles County (404) estimated earlier in this study; b) the proportion of auto dismantling facilities located in each watershed area, determined based on zipcodes of all dismantlers with an active NOI; and c) the average size of auto dismantling facilities located in each watershed. It was assumed that, on average, non-filers are similar to NOI filers in size and in spatial distribution.

Annual rainfall depth, P: Rainfall records for certain parts of Los Angeles County were available from the Los Angeles County Department of Public Works, Hydrology Division (the County). This study chose reference monitoring sites chosen for each watershed with a significant number of auto dismantler establishments. Rainfall pattern could vary substantially even within a watershed. Therefore, it is important to use rainfall data as specific or closest to the source area as possible. The annual rainfall depth was calculated by adding daily rainfall (in inches) reported from October 1998 to September 1999.

Fraction of rainfall events that produce a runoff, Pj: This study used 0.1 inches as the threshold volume required to generate runoff. Pj was calculated by dividing the sum of the adjusted individual rainfall volume (i.e. minus the first 0.1 inches) for the 1998/99 wet season by the annual total rainfall volume. If Pj is known for a given geographical area for a certain wet season or for an extended period (for example 100 years), one could reasonably estimate the total annual runoff (by multiplying $P*P_j$) without the individual rain records as long as the annual total precipitation is known. Since the daily rainfall data were available from the County, we calculated the product P*Pj by simply adding the individual rainfall depth after subtracting 0.1 inch from each rainfall datum.

Site Imperviousness, I: The GISP defines percent imperviousness as the portion of a facility property that is paved, roofed (including buildings), or covered. A single value for imperviousness was derived by normalizing based on area, i.e. by dividing the sum of impervious areas calculated for each facility by the sum of facility size. An average site imperviousness of 43% was estimated for the auto dismantling facilities in Los Angeles County using the self-reported information in the NOI database (This value is significantly less than the 76% imperviousness estimated for light industrial land use in the Los Angeles County's Annual Monitoring Report submitted as a requirement under the municipal storm water program.) A source of uncertainty in this estimate is that facility operators could have misinterpreted the term "imperviousness."

Illicit Discharge Detection and Elimination

Presentation at the EPA *National Storm Water Coordinator's Meeting*, Orlando, FL, May 1-3, 2001

Robert Pitt
Department of Civil and Environmental Engineering
The University of Alabama at Birmingham

Abstract

This paper describes procedures that have been used to identify sources of inappropriate ("illicit") discharges in storm drainage systems. Also included is a review of emerging techniques that may also be useful, especially in future years as they become more accessible and become proven technologies. This paper also describes a series of tests where the original methods developed previously for EPA (Pitt, *et al* 1993), along with selected new procedures, were examined using almost 700 stormwater samples collected from telecommunication manholes from throughout the U.S. About ten percent of the samples were estimated to be contaminated with sanitary sewage using these methods, similar to what is expected for most stormwater systems. The original methods are still recommended as the most useful procedure for identifying contamination of storm drainage systems, with the possible addition of specific tests for *E coli* and enterococci and UV absorbance at 228 nm. Most newly emerging methods require exotic equipment and unusual expertise and are therefore not very available, especially at low cost and with fast turn-around times for the analyses. These emerging methods may therefore be more useful for special research projects than for routine screening of storm drainage systems.

The Center for Watershed Protection (CWP) and Dr. Robert Pitt with the University of Alabama are currently being funded by EPA to complete a technical assessment of techniques and methods for identifying and correcting illicit and inappropriate discharges geared towards NPDES Phase II communities. The project has a two year duration. In the first year, most of our effort will be directed to collecting data. The most cost effective and efficient techniques will also be identified during this initial project period. In the second project year, the project team will develop draft guidance on methods and techniques to identify and correct illicit connections, test the efficacy of the draft guidance in four communities, complete a final "User's Manual for Identifying and Correcting Illicit and Inappropriate Discharges," and conduct training and dissemination. This project is expected to start in the summer of 2001.

Introduction

Urban stormwater runoff includes waters from many other sources which find their way into storm drainage systems, besides from precipitation. There are cases where pollutant levels in storm drainage are much higher than they would otherwise be because of excessive amounts of contaminants that are introduced into the storm drainage system by various non-stormwater discharges. Additionally, baseflows (during dry weather) are also common in storm drainage systems. Dry-weather flows and wet-weather flows have been monitored during numerous urban runoff studies. These studies have found that discharges observed at outfalls during dry weather were significantly different from wet-weather discharges and may account for the majority of the annual discharges for some pollutants of concern from the storm drainage system.

There have been numerous methods used to investigate inappropriate discharges to storm drainage systems. Pitt, *et al.* (1993) and Lalor (1994) reviewed many of these procedures and developed a system that municipalities could use for screening outfalls in residential and commercial areas. In these areas, sewage contamination, along with low rate discharges from small businesses (especially laundries, vehicle repair shops, plating shops, etc.) are of primary concern. One of the earliest methods used to identify sewage contamination utilized the ratio of fecal coliform to fecal strep. bacteria. This method is still in use, but unfortunately has proven inaccurate in most urban stormwater applications. The foll[illegible] [illegible] [illegible] reviews the methodology developed by Pitt, *et al.* (1993) and Lalor (1994), and some new approaches that were investigated.

Use of Tracers to Identify Sources of Contamination in Urban Drainage Systems

Investigations designed to determine the contribution of urban stormwater runoff to receiving water quality problems have led to a continuing interest in inappropriate connections to storm drainage systems. Urban stormwater runoff is traditionally defined as that portion of precipitation which drains from city surfaces and flows via natural or man-made drainage systems into receiving waters. In fact, urban stormwater runoff also includes waters from many other sources which find their way into storm drainage systems. Sources of some of this water can be identified and accounted for by examining current National Pollutant Discharge Elimination System (NPDES) permit records for permitted industrial wastewaters that can be legally discharged to the storm drainage system. However, most of the water comes from other sources, including illicit and/or inappropriate entries to the storm drainage system. These entries can account for a significant amount of the pollutants discharged from storm sewerage systems (Pitt and McLean 1986).

Permits for municipal separate storm sewers include a requirement to effectively prohibit problematic non-stormwater discharges, thereby placing emphasis on the elimination of inappropriate connections to urban storm drains. Section 122.26 (d)(1)(iv)(D) of the rule specifically requires an initial screening program to provide means for detecting high levels of pollutants in dry weather flows which should serve as indicators of illicit connections to the storm sewers. To facilitate the application of this rule, the EPA's Office of Research and Development's Storm and Combined Sewer Pollution Control Program and the Environmental Engineering & Technology Demonstration Branch, along with the Office of Water's Nonpoint Source Branch, supported research for the investigation of inappropriate entries to storm drainage systems (Pitt, *et al.* 1993). The approach presented in this research was based on the identification and quantification of clean baseflow and the contaminated components during dry weather. If the relative amounts of potential components are known, then the importance of the dry weather discharge can be determined.

The ideal tracer to identify major flow sources should have the following characteristics:

- Significant difference in concentrations between possible pollutant sources;
- Small variations in concentrations within each likely pollutant source category;
- A conservative behavior (i.e., no significant concentration change due to physical, chemical or biological processes); and,
- Ease of measurement with adequate detection limits, good sensitivity and repeatability.

In order to identify tracers meeting the above criteria, literature characterizing potential inappropriate entries into storm drainage systems was examined. Several case studies which identified procedures used by individual municipalities or regional agencies were also examined.

Selection of Parameters for Identifying Inappropriate Discharge Sources. Table 1 is an assessment of the usefulness of candidate field survey parameters in identifying different potential non-stormwater flow sources. Natural and domestic waters should be uncontaminated (except in the presence of contaminated groundwaters entering the drainage system, for example). Sanitary sewage, septage, and industrial waters can produce toxic or pathogenic conditions. The other source flows (wash and rinse waters and irrigation return flows) may cause nuisance conditions, or degrade the ecosystem. The parameters marked with a plus sign can probably be used to identify the specific source flows by their presence. Negative signs indicate that the potential source flow probably does not contain the listed parameter in adverse or obvious amounts, and may help confirm the presence of the source by its absence. Parameters with both positive and negative signs for a specific source category would not likely be very helpful due to likely wide variations expected.

R0011274

TABLE 1. Candidate Field Survey Parameters and Associated Non-Stormwater Flow Sources

Parameter	Natural Water	Potable Water	Sanitary Sewage	Septage Water	Indus Water	Wash Water	Rinse Water	Irrig Water
Fluoride	-	+	+	+	+/-	+	+	+
Hardness change	-	+/-	+	+	+/-	+	+	-
Surfactants	-	-	+	-	-	+	+	-
Florescence	-	-	+	+	-	+	+	-
Potassium	-	-	+	+	-	-	-	-
Ammonia	-	-	+	+	-	-	-	+/-
Odor	-	-	+	+	+	+/-	-	-

pH	-	-	-	-	+	-	-	-

Note: - implies relatively low concentration
+ implies relatively high concentration
+/- implies variable conditions

Parameters Suitable for Indicators of Contamination by Sanitary Sewage

Tracer Characteristics of Local Source Flows. Table 2 is a summary of tracer parameter measurements for Birmingham, AL. This table is a summary of the "library" that describes the tracer conditions for each potential source category. The important information shown on this table includes the median and coefficient of variation (COV) values for each tracer parameter for each source category. Appropriate tracers are characterized by having significantly different concentrations in flow categories that need to be distinguished. In addition, effective tracers also need low COV values within each flow category. The study indicated that the COV values were quite low for each category, with the exception of chlorine, which had much greater COV values. Chlorine is therefore not recommended as a quantitative tracer to estimate the flow components. Similar data must be collected in each community where these procedures are to be used. Recommended field observations include color, odor, clarity, presence of floatables and deposits, and rate of flow, in addition to the selected chemical measurements.

Simple Data Evaluation Methods to Indicate Sources of Contamination

Negative Indicators Implying Contamination. Indicators of contamination (negative indicators) are clearly apparent visual or physical parameters indicating obvious problems and are readily observable at the outfall during the field screening activities. These observations are very important during the field survey because they are the simplest method of identifying grossly contaminated dry-weather outfall flows. The direct examination of outfall characteristics for unusual conditions of flow, odor, color, turbidity, floatables, deposits/stains, vegetation conditions, and damage to drainage structures is therefore an important part of these investigations. Table 3 presents a summary of these indicators, along with narratives of the descriptors to be selected in the field.

Correlation tests were conducted to identify relationships between outfalls that were known to have severe contamination problems and the negative indicators (Lalor 1994). Pearson correlation tests indicated that high turbidity and obvious odors appeared to be the most useful physical indicators of contamination when contamination was defined by toxicity and the presence of detergents. High turbidity was noted in 74% of the contaminated source flow samples. This represented a 26% false negative rate (indication of no contamination when contamination actually exists), if one relied on turbidity alone as an indicator of contamination. High turbidity was noted in only 5% of the uncontaminated source flow samples. This represents the rate of false positives (indication of contamination when none actually exists) when relying on turbidity alone. Noticeable odor was indicated in 67% of flow samples from contaminated sources, but in none of the flow samples from uncontaminated sources. This translates to 37% false [illegible] and no false positives. Obvious odors identified included gasoline, oil, sewage, industrial chemicals or detergents, decomposing organic wastes, etc.

False negatives are more of a concern than a reasonable number of false positives when working with a screening methodology. Screening methodologies are used to direct further, more detailed investigations. False positives would be discarded after further investigation. However, a false negative during a screening investigation results in the dismissal of a problem outfall for at least the near future. Missed contributors to stream contamination may result in unsatisfactory in-stream results following the application of costly corrective measures elsewhere.

The method of using physical characteristics to indicate contamination in outfall flows does not allow quantifiable estimates of the flow components and, if used alone, will likely result in many incorrect determinations, especially false negatives. These simple characteristics are most useful for identifying gross contamination: only the most significantly contaminated outfalls and drainage areas would therefore be recognized using this method.

Detergents as Indicators of Contamination. Results from the Mann-Whitney U tests (Lalor 1994) indicated that samples from any of the dry-weather flow sources could be correctly classified as clean or contaminated based only on the measured value of any one of the following parameters: detergents, color, or conductivity. Color and high conductivity were present in samples from clean sources as well as contaminated sources, but their levels of occurrence were significantly different between the two groups. If samples from only one source were expected to make up outfall flows, the level of color or conductivity could be used to distinguish contaminated outfalls from clean outfalls. However, since multi-source flows occur, measured levels of color or conductivity could fall within acceptable levels because of dilution, even though a contaminating source was contributing to the flow. Detergents, on the other hand, can be used to distinguish between clean and contaminated outfalls simply by their presence or absence, using a detection limit of 0.06 mg/L. All samples analyzed from contaminated sources contained detergents in excess of this amount (with the exception of three septage samples collected from homes discharging only toilet flushing water). No clean source samples were found to contain detergents. Contaminated sources would be detected in mixtures with uncontaminated waters if they made up at least 10% of the mixture.

Flow Chart for Most Significant Flow Component Identification. A further refinement is the flow chart shown on Figure 1. This flow chart describes an analysis strategy which may be used to identify the major component of dry-weather flow samples in residential and commercial areas. This method does not attempt to distinguish among all potential sources of dry-weather flows identified earlier, but rather the following four major groups of flow are identified: (1) tap waters (including domestic tap water, irrigation water and rinse water), (2) natural waters (spring water and shallow ground water), (3) sanitary wastewaters (sanitary sewage and septic tank discharge), and (4) wash waters (commercial laundry waters, commercial car wash waters, radiator flushing wastes, and plating bath wastewaters). The use of this method would not only allow outfall flows to be categorized as contaminated or uncontaminated, but would allow outfalls carrying sanitary wastewaters to be identified. These outfalls could then receive highest priority for further investigation leading to source control. This flow chart (Lalor 1994) was designed for use in residential and/or commercial areas only.

Table 2. Tracer Concentrations found in Birmingham, AL, Waters (mean, standard deviation, and coefficient of Variation, COV) (Pitt, *et al.* 1993 and Lalor 1994)

Table 3. Interpretations of Physical Observation Parameters and Likely Associated Flow Sources (Pitt, *et al.* 1993)

Odor - Most strong odors, especially gasoline oils and solvents, are likely associated with high responses on the toxicity screening test Typical obvious odors include gasoline oil, sanitary wastewater, industrial chemicals, decomposing organic wastes, etc

sewage smell associated with stale sanitary wastewater, especially in pools near outfall.

sulfur ("rotten eggs") industries that discharge sulfide compounds or organics (meat packers, canneries, dairies, etc.)

oil and gas petroleum refineries or many facilities associated with vehicle maintenance or petroleum product storage.

rancid-sour food preparation facilities (restaurants, hotels, etc.).

Color - Important indicator of inappropriate industrial sources Industrial dry-weather discharges may be of any color, but dark colors such as brown, gray, or black, are most common

yellow chemical plants, textile and tanning plants

brown meat packers, printing plants, metal works stone and concrete, fertilizers, and petroleum refining facilities.

green: chemical plants, textile facilities.

red: meat packers

gray: dairies, sewage.

Turbidity - Often affected by the degree of gross contamination Dry-weather industrial flows with moderate turbidity can be cloudy, while highly turbid flows can be opaque. High turbidity is often a characteristic of undiluted dry-weather industrial discharges

cloudy: sanitary wastewater, concrete or stone operations, fertilizer facilities, automotive dealers.

opaque: food processors, lumber mills, metal operations, pigment plants.

Floatable Matter - A contaminated flow may contain floating solids or liquids directly related to industrial or sanitary wastewater pollution. Floatables of industrial origin may include animal fats, spoiled food, oils, solvents, sawdust, foams, packing materials, or fuel.

oil sheen: petroleum refineries or storage facilities and vehicle service facilities

sewage: sanitary wastewater.

Deposits and Stains - Refers to any type of coating near the outfall and are usually of a dark color. Deposits and stains often will contain fragments of floatable substances. These situations are illustrated by the grayish-black deposits that contain fragments of animal flesh and hair which often are produced by leather tanneries, or the white crystalline powder which commonly coats outfalls due to nitrogenous fertilizer wastes.

sediment: construction site erosion.

oily: petroleum refineries or storage facilities and vehicle service facilities.

Vegetation - Vegetation surrounding an outfall may show the effects of industrial pollutants. Decaying organic materials coming from various food product wastes would cause an increase in plant life, while the discharge of chemical dyes and inorganic pigments from textile mills could noticeably decrease vegetation. It is important not to confuse the adverse effects of high stormwater flows on vegetation with highly toxic dry-weather intermittent flows.

excessive growth: food product facilities.

inhibited growth: high stormwater flows, beverage facilities, printing plants, metal product facilities, drug manufacturing, petroleum facilities, vehicle service facilities and automobile dealers.

Damage to Outfall Structures - Another readily visible indication of industrial contamination. Cracking, deterioration, and spalling of concrete or peeling of surface paint, occurring at an outfall are usually caused by severely contaminated discharges, usually of industrial origin. These contaminants are usually very acidic or basic in nature. Primary metal industries have a strong potential for causing outfall structural damage because their batch dumps are highly acidic. Poor construction, hydraulic scour, and old age may also adversely affect the condition of the outfall structure.

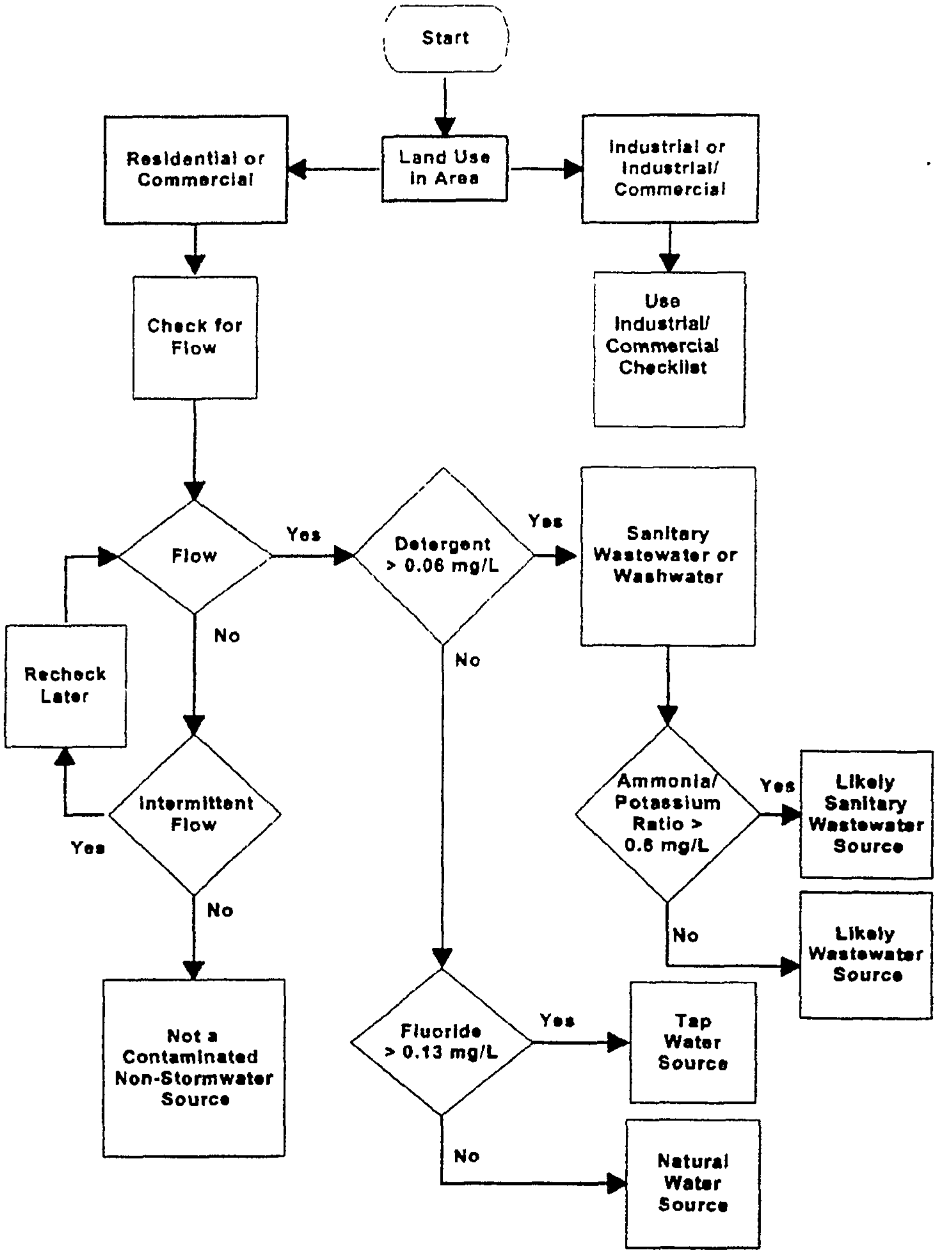
concrete cracking: industrial flows

concrete spalling: industrial flows

peeling paint: industrial flows

metal corrosion: industrial flows

Figure 1 Simple flow chart method to identify significant contaminating sources (Lalor 1994).



R0011279

In residential and/or commercial areas, all outfalls should be located and examined. The first indicator is the presence or absence of dry-weather flow. If no dry-weather flow exists at an outfall, then indications of intermittent flows must be investigated. Specifically, stains, deposits, odors, unusual stream-side vegetation conditions, and damage to outfall structures can all indicate intermittent non-stormwater flows. However, frequent visits to outfalls over long time periods, or the use of other monitoring techniques, may be needed to confirm that only stormwater flows occur. If intermittent flow is not indicated, then the outfall probably does not have a contaminated non-stormwater source. The other points on the flow chart serve to indicate if a major contaminating source is present, or if the water is uncontaminated. Component contributions cannot be quantified using this method, and only the "most contaminated" type of source present will be identified.

If dry-weather flow exists at an outfall, then the flow should be sampled and tested for detergents. If detergents are not present, the flow is probably from a non-contaminated non-stormwater source. The lower limit of detection for detergent should be about 0.06 mg/L.

If detergents are not present, fluoride levels can be used to distinguish between flows with treated water sources and flows with natural sources in communities where water supplies are fluoridated and natural fluoride levels are low. In the absence of detergents, high fluoride levels would indicate a potable water line leak, irrigation water, or wash/rinse water. Low fluoride levels would indicate waters originating from springs or shallow groundwater. Based on the flow source samples tested in this research (Table 2), fluoride levels above 0.13 mg/L would most likely indicate that a tap water source was contributing to the dry-weather flow in the Birmingham, Alabama, study area.

If detergents are present, the flow is probably from a contaminated non-stormwater source, as indicated on Table 2. The ratio of ammonia to potassium can be used to indicate whether or not the source is sanitary wastewater. Ammonia/potassium ratios greater than 0.60 would indicate likely sanitary wastewater contamination. Ammonia/potassium ratios were above 0.9 for all septage and sewage samples collected in Birmingham (values ranged from 0.97 to 15.37, averaging 2.55). Ammonia/potassium ratios for all other samples containing detergents were below 0.7, ranging from 0.00 to 0.65, averaging 0.11. One radiator waste sample had an ammonia/potassium ratio of 0.65.

Non-contaminated samples collected in Birmingham had ammonia/potassium ratios ranging from 0.00 to 0.41, with a mean value of 0.06 and a median value of 0.03. Using the mean values for non-contaminated samples (0.06) and sanitary wastewaters (2.55), flows comprised of mixtures containing at least 25% sanitary wastes with the remainder of the flow from uncontaminated sources would likely be identified as sanitary wastewaters using this method. Flows containing smaller percent contributions from sanitary wastewaters might be identified as having a wash water source, but would not be identified as uncontaminated.

General Matrix Algebra Methods to Indicate Sources of Contamination Through Fingerprinting

Other approaches can also be used to calculate the source components of mixed outfall flows. One approach is the use of matrix algebra to simultaneously solve a series of chemical mass balance equations. This method can be used to predict the most likely flow source, or sources, making up an outfall sample. It is possible to estimate the outfall source flow components using a set of simultaneous equations. The number of unknowns should equal the number of equations available, resulting in a square matrix. If there are seven likely source categories, then there should be seven tracer parameters used. If there are only four possible sources, then only the four most efficient tracer parameters should be used. Only tracers that are linearly related to mixture components can be used. As an example, pH cannot be used in these equations, because it is not additive.

This method estimates flow contributions from various sources using a "receptor model", based on a set of chemical mass balance equations. Such models, which assess the contributions from various sources based on observations at sampling sites (the receptors), have been applied to the investigation of air pollutant sources for many years (Scheff and Wadden 1993; Cooper and Watson 1980). The characteristic "signatures" of the different types of sources, as identified in the library of source flow data, allows the development of a set of mass balance equations. These equations describe the measured concentrations in an outfall's flow as a linear combination of the contributions from the different potential sources. A major requirement for this method is the physical and chemical characterization of waters collected directly from potential sources of dry-weather flows (the "library"). This allows concentration patterns (fingerprints) for the parameters of interest to be established for each type of source. Theoretically, if these patterns are different for each source, the observed concentrations at the outfall would be a linear combination of the concentration patterns from the different component sources, each weighted by a source strength term (m_n). This source strength term would indicate the fraction of outfall flow originating from each likely source. By measuring a number of parameters equal to, or greater than, the number of potential source types, the source strength term could be obtained by solving a set of chemical mass balance equations of the type:

$$C_p = \sum_n m_n x_{pn}$$

where C_p is the concentration of parameter p in the outfall flow and x_{pn} is the concentration of parameter p in source type n.

As an example of this method, consider 8 possible flow sources and 8 parameters, as presented in Table 4. The number of parameters evaluated for each outfall must equal the number of probable dry-weather flow sources in the drainage area. Mathematical methods are available which provide for the solution of over specified sets of equations (more equations than unknowns) but these are not addressed here.

The selection of parameters for measurement should reflect evaluated parameter usefulness. Evaluation of the Mann-Whitney U Test results (Lalor 1994) suggested the following groupings of parameters, ranked by their usefulness for distinguishing between all the types of flow sources sampled in Birmingham, AL:

- First set (most useful): potassium and hardness
- Second set: fluorescence, conductivity, fluoride, ammonia, detergents, and color
- Third set (least useful): chlorine

Emerging Tools for Identifying Sources of Discharges

Coprostanol and Other Fecal Sterol Compounds Utilized as Tracers of Contamination by Sanitary Sewage. A more likely indicator of human wastes than fecal coliforms and other "indicator" bacteria may be the use of certain molecular markers, specifically the fecal sterols, such as coprostanol and epicoprostanol (Eaganhouse, *et al.* 1988). However, these compounds are also discharged by other carnivores in a drainage (especially dogs). A number of research projects have used these compounds to investigate the presence of sanitary sewage contamination. The most successful application may be associated with sediment analyses instead of water analyses. As an example, water analyses of coprostanol are difficult due to the typically very low concentrations found, although the concentrations in many sediments are quite high and much easier to quantify. Unfortunately, the long persistence of these compounds in the environment easily confuses recent contamination with historical or intermittent contamination

Particulates and sediments collected from coastal areas in Spain and Cuba receiving municipal sewage loads were analyzed by Grimalt, *et al.* (1990) to determine the utility of coprostanol as a chemical marker of sewage contamination. Coprostanol can not by itself be attributed to fecal matter inputs. However, relative contributions of steroid components can be a useful indicator. When the relative concentrations of coprostanol and coprostanone are higher than their 5α epimers, or more realistically, other sterol components of background or natural occurrence, it can provide useful information.

Sediment cores from Santa Monica Basin, CA, and effluent from two local municipal wastewater discharges were analyzed by Venkatesan and Kaplan (1990) for coprostanol to determine the degree of sewage addition to sediment. Coprostanols were distributed throughout the basin sediments in association with fine particles. Some stations contained elevated levels, either due to their proximity to outfalls or because of preferential advection of fine-grained sediments. A noted decline of coprostanols relative to total sterols from outfalls seaward indicated dilution of sewage by biogenic sterols.

Other chemical compounds have been utilized for sewage tracer work. Saturated hydrocarbons with 16-18 carbons, and saturated hydrocarbons with 16-21 carbons, in addition to coprostanol, were chosen as markers for sewage in water, particulate, and sediment samples near the Cocoa, FL, domestic wastewater treatment plant (Holm, *et al.* 1990). The concentration of the markers was highest at points close to the outfall pipe and diminished with distance. However the concentration of C16-C21 compounds was high at a site 800 m from the outfall indicating that these compounds were unsuitable markers for locating areas exposed to the sewage plume. The concentrations for the other markers were very low at this station.

The range of concentrations of coprostanol found in sediments and mussels of Venice, Italy, were reported by Sherwin, *et al.* (1993). Raw sewage is still discharged directly into the Venice lagoon. Coprostanol concentrations were determined in sediment and mussel samples from the lagoon using gas chromatography/mass spectroscopy. Samples were collected in interior canals and compared to open-bay concentrations. Sediment concentrations ranged from 0.2-41.0 μg/g (dry weight). Interior canal sediment samples averaged 16 μg/g compared to 2 μg/g found in open bay sediment samples. Total coprostanol concentrations in mussels ranged from 80 to 620 ng/g (wet weight). No mussels were found in the four most polluted interior canal sites.

Nichols, *et al.* (1996) also examined coprostanol in stormwater and the sea-surface microlayer to distinguish human versus nonhuman sources of contamination. Other steroid compounds in sewage effluent were investigated by Routledge, *et al* (1998) and Desbrow, *et al.* (1998) who both examined estrogenic chemicals. The most common found were 17β-Estradiol and estrone which were detected at concentrations in the tens of nanograms per liter range. These were identified as estrogenic through a toxicity identification and evaluation approach, where sequential separations and analyses identified the sample fractions causing estrogenic activity using a yeast-based estrogen screen. GC/MS was then used to identify the specific compounds.

Estimating Potential Sanitary Sewage Discharges into Storm Drainage and Receiving Waters using Detergent Tracer Compounds. As described above, detergent measurements (using methylene blue active substance, MBAS, test methods) were the most successful individual tracer to indicate contaminated water in storm sewerage dry-weather flows. Unfortunately, the MBAS method uses hazardous chloroform for an extraction step. Different detergent components, especially linear alkylbenzene sulphonates (LAS) and linear alkylbenzenes (LAB), have also been tried to indicate sewage dispersal patterns in receiving waters. Boron, a major historical ingredient of laundry chemicals, can also potentially be used. Boron has the great advantage of being relatively easy to analyze using portable field test kits, while LAS requires chromatographic equipment. LAS can be measured using HPLC with fluorescent detection, after solid phase extraction, to very low levels. Fujita, *et al.* (1998) developed an efficient enzyme-linked immunosorbent assay (ELISA) for detecting LAS at levels from 20 to 500 μg/L.

LAS from synthetic surfactants (Terzic and Ahel 1993) which degrade rapidly, as well as nonionic detergents (Terzic and Ahel 1993) which do not degrade rapidly, have been utilized as sanitary sewage markers. LAS was quickly dispersed from wastewater outfalls except in areas where wind was calm. In these areas LAS concentrations increased in freshwater but were unaffected in saline water. After time, the lower alkyl groups were mostly found, possibly as a result of degradation or settling of longer alkyl chain compounds with sediments. Chung, *et al.* (1995) also describe the distribution and fate of LAS in an urban stream in Korea. They examined different LAS compounds having carbon ratios of C12 and C13 compared to C10 and C11, plus ratios of phosphates to MBAS and the internal to external isomer ratio (I/E) as part of their research. Gonález-Mazo, *et al* (1998) examined LAS in the Bay of Cádiz off the southwest of Spain. They found that LAS degrades rapidly (Fujita, *et al.*, 1998, found that complete biodegradation of LAS requires several days), and is also strongly sorbed to particulates. In areas close to shore and near the untreated wastewater discharges, there as significant vertical stratification of LAS: the top 3 to 5 mm of water had LAS concentrations about 100 times greater than found at 0.5 m.

Zeng and Vista (1997) and Zeng, *et al.* (1997) describe a study off of San Diego where LAB was measured, along with polycyclic aromatic hydrocarbons (PAHs) and aliphatic hydrocarbons (AHs) to indicate the relative pollutant contributions of wastewater from sanitary sewage, nonpoint sources, and hydrocarbon combustion sources. They developed and tested several indicator ratios (alkyl homologue distributions and parent compound distributions) and examined the ratio of various PAHs (such as phenanthrene to anthracene, methylphenanthrene to phenanthrene, fluoranthene to pyrene, and benzo(a)anthracene to chrysene) as tools for distinguishing these sources. They concluded that LABs are useful tracers of domestic waste inputs to the environment due to their limited sources. They also describe the use of the internal to external isomer ratio (I/E) to indicate the amount of biodegradation that may have occurred to the LABs. They observed concentrations of total LABs in sewage effluent of about 3 μg/L, although previous researchers have seen concentrations of about 150 μg/L in sewage effluent from the same area.

The fluorescent properties of detergents have also been used as a tracer by investigating the fluorescent whitening agents (FWAs), as described by Poiger, *et al.* (1996) and Kramer, *et al.* (1996). HPLC with fluorescence detection was used in these studies to quantify very low concentrations of FWAs. The two most frequently used FWAs in household detergents (DSBP and DAS 1) were found at 7 to 21 μg/L in primary sewage effluent and at 3 to 9 μg/L in secondary effluent. Raw sewage contains about 10 to 20 μg/L FWAs. The removal mechanisms in sewage treatment processes is by adsorption to activated sludge. The type of FWAs varies from laundry applications to textile finishing and paper production, making it possible to identify sewage sources. The FWAs were found in river water at 0.04 to 0.6 μg/L. The FWAs are not easily biodegradable but they are readily photodegraded. Photodegradation rates have been reported to be about 7% for DSBP and 71% for DAS 1 in river water exposed to natural sunlight, after one hour exposure. Subsequent photodegradation is quite slow.

Other Compounds Found in Sanitary Sewage that may be used for Identifying Contamination by Sewage. Halling-Sørensen, *et al.* (1998) detected numerous pharmaceutical substances in sewage effluents and in receiving waters. Their work addressed human health concerns of these low level compounds that can enter downstream drinking water supplies. However, the information can also be possibly used to help identify sewage contamination. Most of the research has focused on clofibric acid, a chemical used in cholesterol lowering drugs. It has been found in concentrations ranging from 10 to 165 ng/L in Berlin drinking water sampler. Other drugs commonly found include aspirin, caffeine, and ibuprofen. Current FDA guidance mandates that the maximum concentration of a substance or its active metabolites at the point of entry into the aquatic environment be less than 1 μg/L (Hun 1998).

Caffeine has been used as an indicator of sewage contamination by several investigators (Shuman and Strand 1996). The King County, WA, Water Quality Assessment Project is examining the impacts of CSOs on the Duwamish

River and Elliott Bay. They are using both caffeine (representing dissolved CSO constituents) and coprostanol (representing particulate bound CSO constituents) in conjunction with heavy metals and conventional analyses, to help determine the contribution of CSOs to the river. The caffeine is unique to sewage, while coprostanol is from both humans and carnivorous animals and is therefore also in stormwater. They sampled upstream of all CSOs, but with some stormwater influences, 100 m upstream of the primary CSO discharge (but downstream of other CSOs), within the primary CSO discharge line, and 100 m downriver of the CSO discharge location. The relationship between caffeine and coprostanol was fairly consistent for the four sites (coprostanol was about 0.5 to 1.5 µg/L higher than caffeine). Similar patterns were found between the three metals: chromium was always the lowest and zinc was the highest. King Co. is also using clean transported mussels placed in the Duwamish River to measure the bioconcentration potential of metal and organic toxicants and the effects of the CSOs on mussel growth rates (after 6 week exposure periods). Paired reference locations are available near the areas of deployment, but outside the areas of immediate CSO influence. *US Water News* (1998) also described a study in Boston Harbor that found caffeine at levels of about 7 µg/L in the harbor water. The caffeine content of regular coffee is about 700 mg/L, in contrast.

DNA Profiling to Measure Impacts on Receiving Water Organisms and to Identify Sources of Microorganisms in Stormwater. This rapidly emerging technique seems to have great promise in addressing a number of nonpoint source water pollution issues. Kratch (1997) summarized several investigations on cataloging the DNA of *E. coli* to identify their source in water. This rapidly emerging technique seems to have great promise in addressing a number of nonpoint source water pollution issues. The procedure, developed at the Virginia Polytechnic Institute and State University, has been used in Chesapeake Bay. In one example, it was possible to identify a large wild animal population as the source of fecal coliform contamination of a shellfish bed, instead of suspected failing septic tanks. DNA patterns in fecal coliforms vary among animals and birds, and it is relatively easy to distinguish between human and non-human sources of the bacteria. However, some wild animals have DNA patterns that are not easily distinguishable. Some researchers question the value of *E. coli* DNA fingerprinting believing that there is little direct relationship between *E. coli* and human pathogens. However, this method should be useful to identify the presence of sewage contamination in stormwater or in a receiving water.

One application of the technique, as described by Krane, *et al.* (1999) of Wright State University, used randomly amplified polymorphic DNA polymerase chain reaction (RAPD-PCR) generated profiles of naturally occurring crayfish. They found that changes in the underlying genetic diversity of these populations were significantly correlated with the extent to which they have been exposed to anthropogenic stressors. They concluded that this rapid and relatively simple technique can be used to develop a sensitive means of directly assessing the impact of stressors upon ecosystems. These Wright State University researchers have also used the RAPD-PCR techniques on populations of snails, pill bugs, violets, spiders, earthworms, herring, and some benthic macroinvertebrates, finding relatively few obstacles in its use for different organisms. As noted above, other researchers have used DNA profiling techniques to identify sources of *E. coli* bacteria found in coastal waterways. It is possible that these techniques can be expanded to enable rapid detection of many different types of pathogens in receiving waters, and the most likely sources of these pathogens.

Stable Isotope Methods for Identifying Sources of Water. Stable isotopes had been recommended as an efficient method to identify illicit connections to storm sewerage. A demonstration was conducted in Detroit as part of the Rouge River project to identify sources of dry weather flows in storm sewerage (Sangal, *et al.* 1996). Naturally occurring stable isotopes of oxygen and hydrogen can be used to identify waters originating from different geographical sources (especially along a north-south gradient). Ma and Spalding (1996) discuss this approach by using stable isotopes to investigate recharge of groundwaters by surface waters. During water vapor transport from equatorial source regions to higher latitudes, depletion of heavy isotopes occurs with rain. Deviation from a standard relationship between deuterium and ^{18}O for a specific area indicates that the water has undergone additional evaporation. The ratio is also affected by seasonal changes. As discussed by Ma and Spalding (1996), the Platte River water is normally derived in part from snowmelt from the Rocky Mountains, while the groundwater in parts of Nebraska is mainly contributed from the Gulf air stream. The origins of these waters are sufficiently different and allow good measurements of the recharge rate of the surface water to the groundwater. In Detroit, Sangal, *et al.* (1996) used differences in origin between the domestic water supply, local surface waters, and the local groundwater to identify potential sanitary sewage contributions to the separate storm sewerage. Rieley, *et al.* (1997) used stable isotopes of carbon in marine organisms to distinguish the primary source of carbon being consumed (sewage sludge vs. natural carbon sources) in two deep sea sewage sludge disposal areas.

Stable isotope analyses would not be able to distinguish between sanitary sewage, industrial discharges, washwaters, and domestic water, as they all have the same origin, nor would it be possible to distinguish sewage from local groundwaters if the domestic water supply was from the same local aquifer. This method works best for situations where the water supply is from a distant source and where separation of waters into separate flow components is not needed. It may be an excellent tool to study the effects of deep well injection of stormwater on deep aquifers having distant recharge sources (such as in the Phoenix area). Few laboratories can analyze for these stable isotopes, requiring shipping and a long wait for the analytical results. Sangal, *et al.* (1995) used Geochron Laboratories, in Cambridge, Massachusetts.

Dating of sediments using ^{137}Cs was described by Ma and Spalding (1996). Arsenic contaminated sediments in the Hylebos Waterway in Tacoma, WA, could have originated from numerous sources, including a pesticide manufacturing facility, a rock-wool plant, steel slags, powdered metal plant, shipbuilding facilities, marinas and arsenic boat paints, and the Tacoma Smelter. Dating the sediments, combined with knowing the history of potential discharges and conducting optical and electron microscopic studies of the sediments, was found to be a powerful tool to differentiate between the different metal sources to the sediments.

Conclusions

In almost all cases, a suite of analyses is most suitable for effective identification of inappropriate discharges. A recent example was reported by Standley, *et al.* (2000), where fecal steroids (including coprostanol), caffeine, consumer product fragrance materials, and petroleum and combustion byproducts were used to identify wastewater treatment plant effluent, agricultural and feedlot runoff, urban runoff, and wildlife sources. They studied numerous individual sources of these wastes from throughout the US. A research grade mass sperctrophotometer was used for the majority of the analyses in order to achieve the needed sensitivities, although much variability was found when using the methods in actual receiving waters affected by wastewater effluent. This sophisticated suite of analyses did yield much useful information, but the analyses are difficult to conduct and costly and may be suitable for special situations, but not for routine survey work.

Another recent series of tests examined several of these potential emerging tracer parameters, in conjunction with the previously identified parameters, during a project characterizing stormwater that had collected in telecommunication manholes, funded by Tecordia (previously Bellcore), AT&T, and eight regional telephone companies throughout the country (Pitt and Clark 1999). Numerous conventional constituents, plus major ions, and toxicants were measured, along with candidate tracers to indicate sewage contamination of this water. Boron, caffeine, coprostanol, *E coli*, enterococci, fluorescence (using specific wavelengths for detergents), and a simpler test for detergents were evaluated, along with the use of fluoride, ammonia, potassium, and obvious odors and color. About 700 water samples were evaluated for all of these parameters, with the exception of bacteria and boron (about 250 samples), and only infrequent samples were analyzed for fluorescence. Coprostanol was found in about 25 percent of the water samples (and in about 75% of the 350 sediment samples analyzed). Caffeine was only found in very few samples, while elevated *E. coli* and enterococci (using IDEXX tests) were observed in about 10% of the samples. Strong sewage odors in water and sediment samples were also detected in about 10% of the samples. Detergents and fluoride (at >0.3 mg/L) were found in about 40% of the samples and are expected to have been contaminated with industrial activities (lubricants and cleansers) and not sewerage. Overall, about 10% of the samples were therefore expected to have been contaminated with sanitary sewage, about the same rate previously estimated for stormwater systems.

Additional related laboratory tests, funded by the University of New Orleans and the EPA (Barbe', *et al.* 2000), were conducted using many sewage and laundry detergent samples and found that the boron test was a poor indicator of sewage, possibly due to changes in formulations in modern laundry detergents. Laboratory tests did find that fluorescence was an excellent indicator of sewage, especially when using specialized "detergent whitener" filter sets, but was not very repeatable. We also examined several UV absorbance wavelengths as sewage indicators and found excellent correlations with 228 nm, a wavelength having very little background absorbance in local spring waters, but with a strong response factor with increasing strengths of sewage.

Table 5 summarizes the different measurement parameters discussed above. We recommend that our originally developed and tested protocol, as reported by Pitt, *et al.* (1993), still be used as the most efficient routine indicator of sewage contamination of stormwater drainage systems, with the possible addition of specific *E. coli* and enterococci measurements and UV absorbance at 228 nm. The numerous exotic tests requiring specialized instrumentation and expertise do not appear to warrant their expense and long analytical turn-around times, except in specialized research situations, or when special confirmation is economically justified (such as when examining sewer replacement or major repair options).

Table 5. Comparison of Measurement Parameters used for Identifying Inappropriate Discharges into Storm Drainage

Parameter Group	Comments	Recommendation
Fecal coliform bacteria and or use of fecal coliform to fecal strep ratio	Commonly used to indicate presence of sanitary sewage	Not very useful as many other sources of fecal coliforms are present, and ratio not accurate for old or mixed wastes.
Physical observations (odor, color, turbidity, floatables, deposits, stains, vegetation changes, damage to outfalls)	Commonly used to indicate presence of sanitary and industrial wastewater	Recommended due to easy public understanding and easy to evaluate, but only indicative of gross contamination, with excessive false negatives (and some false positives). Use in conjunction with chemical tracers for greater sensitivity and accuracy
Detergents presence (anionic surfactant extractions)	Used to indicate presence of wash waters and sanitary sewage.	Recommended, but care needed during hazardous analyses (only for well-trained personnel). Accurate indicator of contamination during field tests.
Fluoride, ammonia and potassium measurements	Used to identify and distinguish between wash waters and sanitary sewage	Recommended, especially in conjunction with detergent analyses. Accurate indicator of major contamination sources and their relative contributions.
TV surveys and source investigations	Used to identify specific locations of inappropriate discharges, especially in industrial areas.	Recommended after outfall surveys indicate contamination in drainage system.
Coprostanol and other fecal sterol compounds	Used to indicate presence of sanitary sewage	Possibly useful. Expensive analysis with GC/MSD. Not specific to human wastes or recent contamination. Most useful when analyzing particulate fractions of wastewaters or sediments.
Specific detergent compounds (LAS, fabric whiteners, and perfumes)	Used to indicate presence of sanitary sewage.	Possibly useful. Expensive analyses with HPLC. A good and sensitive confirmatory method.
Fluorescence	Used to indicate presence of sanitary sewage and wash waters.	Likely useful, but expensive instrumentation. Rapid and easy analysis. Very sensitive.
Boron	Used to indicate presence of sanitary sewage and wash waters.	Not very useful. Easy and inexpensive analysis, but recent laundry formulations in US have minimal boron components.
Pharmaceuticals (colfibric acid, aspirin, ibuprofen, steroids, illegal drugs, etc.)	Used to indicate presence of sanitary sewage	Possibly useful. Expensive analyses with HPLC. A good and sensitive confirmatory method.
Caffeine	Used to indicate presence of sanitary sewage.	Not very useful. Expensive analyses with GC/MSD. Numerous false negatives, as typical analytical methods not suitably sensitive.
DNA profiling of microorganisms	Used to identify sources of microorganisms	Likely useful, but currently requires extensive background information on likely sources in drainage. Could be very useful if method can be simplified, but with less specific results.
UV absorbance at 228 nm	Used to identify presence of sanitary sewage.	Possibly useful, if UV spectrophotometer available. Simple and direct analyses. Sensitive to varying levels of sanitary sewage, but may not be useful with dilute solutions. Further testing needed to investigate sensitivity in field trials.
Stable isotopes of oxygen	Used to identify major sources of water.	May be useful in area having distant domestic water sources and distant groundwater recharge areas. Expensive and time consuming procedure. Can not distinguish between wastewaters if all have common source.
E. coli and enterococci bacteria	More specific indicators of sanitary sewage than coliform tests.	Recommended in conjunction with chemical tests. Relatively inexpensive and easy analyses, especially if using the simple IDEXX methods.

Review of Existing Stormwater Monitoring Programs for Estimating Bight-wide Mass Emissions from Urban Runoff

By Kenneth Schiff

ABSTRACT

Urban runoff is perceived as a large source of pollutant inputs to the ocean, but no mass emission monitoring programs have been established to assess this discharge. Recently, however, National Pollutant Discharge Elimination System permits for urban runoff discharges were issued to stormwater management agencies on a regional (county-wide) basis and the 1994-95 water year represents the first period in which urban runoff water quality measurements have been monitored bight-wide. The goal of this study was to use the data generated by these monitoring programs to estimate mass emissions of pollutants to the Southern California Bight from urban runoff. After documenting the sampling design of each stormwater monitoring program, then collating information on rainfall, watershed area, runoff volume, and water quality measurements, we estimated the mass emissions of total suspended solids, nutrients (ammonia, nitrate, phosphorous), and five trace metals (chromium, copper, nickel, lead, zinc). Although the mass emissions of these constituents appeared substantial relative to other sources, there was tremendous uncertainty in the load estimates. Less than 5% of the watershed areas and less than 2% of the annual runoff volumes were actually monitored during 1994-95 water year. Extrapolation of water quality data to these unmonitored channels and flows, which is necessary to develop bight-wide emission estimates, are hampered by the tremendous vaiability in contaminant concentrations among the different watersheds and storm events. This variability in water quality measurements from urban runoff are not well understood. This lack of understanding adds to our uncertainty in the load estimates we provide.

INTRODUCTION

Rivers in southern California are amongst the most extensively modified channels in the world (Brownlie and Taylor 1981). These storm drain systems, which ultimately discharge directly to the ocean, were designed to remove stormwater from streets and low-lying areas as efficiently as possible, thus reducing flooding and minimizing property damage. Most of the modification to these channels occurred prior to an era of interest or knowledge about urban runoff water quality. As a result, accumulated debris, pollutants, and pathogens from the largest metropolitan centers on the west coast are discharged along with this urban runoff. Moreover, many urban runoff discharges are augmented by inland municipal/industrial treated wastewater discharges, potentially contaminated groundwater discharges, and at times, inputs from illegal discharges and illicit connections. There is little in the way of retention and virtually no treatment of runoff from southern California urbanized watersheds. Only relatively recently has concern regarding water quality of these urban runoff discharges been examined (SMBRP 1996, Schiff and Stevenson 1996, Bay *et al.* 1996, Suffet *et al.* 1993, Gold *et al.* 1992; SCCWRP 1980).

Although urban runoff is currently perceived as a potentially large source of contaminants to our near coastal environment (Eganhouse and Kaplan 1987, RWQCB-LA 1988, USEPA 1995), there has been little monitoring for estimating contaminant mass emissions to the Southern California Bight (SCB). One reason for the lack of quantified loadings is because sampling and characterizing runoff discharges is extremely difficult. Unlike many other point sources of pollutants to the ocean, such as treated municipal or industrial wastewaters, the ubiquitous nature of urban runoff prohibits characterization from a single location or at infrequent intervals. The unpredictable rainfall in southern California further complicates runoff monitoring since the resulting flows are discontinuous and highly variable. Historically, most runoff measurements for estimating contaminant mass loadings to the ocean have been the result of special studies (SCCWRP 1973; 1990; 1992). Re-authorization of the Clean Water Act in 1987 and associated litigation sampling methodology were identified

Estimation of Runoff Mass Emissions By Collating Monitoring Data
A simplistic, watershed-based approach was used to calculate mass emissions of contaminants from urban runoff to the SCB in 1994-95 illustrated by the following equation (1):

$$(1) \quad L_{annual} = \sum_{i=1}^{n} (EMC_{median} * Volume_i)$$

Where,

L_{annual} = Annual pollutant load;

i = Watershed listed in the NPDES permit;

Volume = Annual volume of watershed$i$; and

EMC_{median} = Bightwide median event mean concentration .

Annual runoff volume for each watershed was obtained from either the ADMR's, the United States Geological Survey (USGS 1995), LA Co. - Engineering Section, Orange Co. Environmental Management Agency, San Diego Co. Flood Control District, or the International Boundary Water Commission (IBWC). Rainfall data, summarized from the National Weather Service (Nationwide Climatic Data Center, Ashville, NC), was used to complement flow data, demonstrate part of the variability responsible in flow among regions, and assess the relative discharges this water year compared to "normal" years as determined from long-term rainfall records. Additional information collated from these sources included 15 min. average flow during storm events and total volume discharged during storm events to assess volumes representatively sampled versus discharged.

Bight-wide median event mean concentrations (EMC) were calculated from the midpoint in the distribution of all the water quality data for a particular constituent reported in the 1994-95 ADMR's. The EMC is equivalent to the concentration designated as representative of each storm event by each monitoring agency. It is defined as the sum of all volume-weighted concentrations divided by the total storm volume (USEPA 1983). The only water quality data we collated for median EMC calculations were channel sites where an entire watershed was sampled. No sub-watershed, land use sites were used to calculate median EMC's. We also compared water quality results for the different region-wide permits by calculating 1994-95 median EMC's for individual SCB watersheds where the data were available.

Our watershed-based approach required pooling data to estimate water quality for channels not sampled. Because we had to extrapolate concentrations to unsampled watersheds, which adds some uncertainty to our estimates of mass emissions, we also calculated mass emissions based upon the 10th and 90 th percentile concentrations observed among watersheds. Our intention in the calculations was to capture the uncertainty in the extrapolations we have made.

Evaluation of Monitoring Data for Calculating Bightwide Mass Emissions from Runoff
The ability to calculate bightwide mass emissions from urban runoff based upon the monitoring data from 1994-95 was judged by two factors: (1) An assessment of monitoring coverage, and (2) The commonality of methods among monitoring programs. Monitoring coverage was assessed in terms of the percent of the area monitored and the percent of runoff volume representatively sampled. Commonality among programs

assessments of urban runoff including general characteristics, inorganic analytes such as trace metals, and organic constituents such as chlorinated and petroleum hydrocarbons, toxicity tests with invertebrates or vertebrates, and fecal indicator bacteria (Table 4). Since not all constituents are measured during every storm or at every station, only those analytes and detection limits routinely listed in their respective ADMR's were reported. Thirteen analytes were measured in common between the four region-wide stormwater permits in the SCB. Some individual permittees, however, measured as many as 183 analytes for a given sample.

Collating Monitoring Data and Estimation of Mass Emissions

Rainfall. Annual rainfall varied from 44 to 73 cm throughout the coastal SCB (Figure 2). As expected, precipitation patterns across the SCB were highest in the north and steadily declined moving south. Oxnard received 66% more rainfall compared to San Diego. In 1994-95, the annual rainfall was approximately double the long-term average. Although precipitation was recorded between 9 and 10 months of the year, the majority of rain fell in the months of January and March. These two months represented 69 to 80% of the rainfall for the entire year, depending upon the gage site.

Watershed Area and Runoff Volume.

The total watershed area of the rivers and creeks named in Southern California NPDES stormwater permits was roughly 26,000 km^2 (Table 5). Approximately 90% of this area was gaged for urban runoff flows by a variety of agencies; 2.9 x 10^{12} L were measured during the 1994-95 water year (Table 5). Three rivers discharged over half of the gaged volume to the SCB. Annual discharges from the Los Angeles River, Santa Clara River, and Santa Ana River cumulatively exceeded 1.7 x 10^{12} L, but their watersheds represented only 41% of the SCB area.

When examined on a region-by-region basis, the San Diego Co. NPDES permit (10,800 km_2) encompassed nearly double the watershed area of the other three permits (4,900 to 5,500 km^2). Annual discharge volume in the Los Angeles region (1.13 x 10^{12} L), however, was between 175% and 230% greater than the other three regions (0.49 to 0.65 x 10^{12} L).

Water Quality.

Suspended solids, nutrients (nitrogen and phosphorous), and five trace metals (Cr, Cu, Pb, Ni, and Zn) were consistently analyzed and reported among the various NPDES stormwater monitoring programs of the SCB that sampled channel sites (Table 6). Other water quality parameters were measured frequently by individual agencies, but not consistently among all permits or at all sites within a permit. Organic constituents such as PAH's, DDT's, and PCB's were frequently measured, but virtually all measurements for these compounds were below reported detection limits.

No single region had all the highest or all the lowest median EMC's at channel sampling sites during 1994-95 (Table 6). The range of EMC's between regions differed by a factor of 2 to 20 among the general constituents and by a factor of 1 to 15 among the trace metals. This magnitude of variability was also observed between sites within a single region (Table 6). For example, the range of median EMC's among SCB regional permits for suspended solids was 175 to 330 mg/L. The range of EMC's between different monitoring sites within the San Diego region was 148 to 485 mg/L while the EMC's from various sites within the Orange County region ranged from 41 to 2,148 mg/L.

Mass Emission Estimates from Urban Runoff to the SCB.

Bight-wide median EMC's and mass emissions from urban runoff were estimated for the 1994-95 water year (Table 7). The total load of suspended solids was estimated to be 598 x 10^3 metric tons (mt). Using the 10^{th} and 90^{th} percentile of the distribution of EMC's within the SCB, low and high load estimates tremendous variability among watersheds. For example, suspended solids flow-weighted mean concentrations ranged from 283 to 4,313 mg/L among the eight largest rivers and creeks in southern California during 1986-88. In 1994-95, only one of these eight channels was actually monitored by the stormwater management agencies. Since the corresponding data were not available from all channels, we are unable to assess the bias associated with our extrapolation to unmonitored watersheds.

A second assumption we used was that the temporal periods sampled within a watershed were representative of other periods which were not sampled. Assumptions based upon extrapolations to unsampled storms introduces uncertainty because of flow-related variability. Studies on the Los Angeles River and other channels of the SCB observed significant correlations between flow and pollutant concentrations (SCCWRP 1990). Consequently, mass emission estimates for specific runoff events differ between large and small storms as a result of changing constituent concentrations as well as discharge volumes. Therefore, missing or capturing significant events can result in potential bias depending upon the magnitude of the storm size. Capturing the largest storm of the year may result in the largest EMC's and will likely overestimate the unsampled, but smaller-sized storms. Alternatively, capturing the smallest storms may underestimate the true annual discharge (if substantially large storms are not sampled). Moreover, 1994-95 was a very wet year. Rainfall was approximately double the long-term annual average which generated some of the largest peak flows in recent history (USGS 1995). The magnitude of bias associated with unsampled storm events cannot be assessed because none of the SCB monitoring programs have sufficient temporal sampling regimes to address this question.

Other temporal assumptions relative to this study that can introduce uncertainty are even less understood than flow-related correlations. Assumptions which are not well understood for southern California watersheds include relationships of water quality to antecedent dry periods (pollutant build-up) and rainfall intensity or duration (pollutant transport). Examples of the interactions between these two important parameters include concepts such as "first flush" (initial storm flows) or "seasonal flushing" (initial storms of the water year). Although several investigators have demonstrated portions of these concepts in other regions (Herricks 1995), they are not well-quantified in southern California. In some cases they appear significant (OCEMA 1996, RWQCB-LA 1988); in others, they do not (SCCWRP 1989).

Temporal variability within and among runoff events is compounded in the SCB by the different sampling strategies utilized by stormwater monitoring agencies. Our data set was comprised of individual grab, single and multiple weighted-composite samples. Grab and composite samples however, represent very different portions of a storm event. Grab samples represent a single snapshot of water quality during a storm event and, for the most part in 1994-95, were taken independently of flow regime or time since start of flow. Composite samples were actually multiple grab samples which, when combined together, were used to represent the mean water quality for an entire storm event. Composite samples, however, were weighted differently among the agencies. Some were weighted by storm flow (e.g., sampling every set volume interval); others were weighted by time (e.g. every hour, every 15 minutes, etc.). Flow-weighted composites sample more frequently during high flows than low flows, while time-weighted samples are distributed evenly throughout the storm event. Moreover, the number of samples per composite varied substantially among agencies (4 to 40+), or even within an agency (12 to 40+). The degree to which sampling strategies influence water quality results has not been quantified in terms of bias to the true EMC or the relative effect on seasonal loading estimates.

One reason we needed to rely on so many assumptions is that the monitoring programs are not entirely designed to estimate mass emissions to the ocean. Most monitoring programs have multiple purposes, all of which are important. Multiple information needs from urban runoff monitoring include regulatory compliance, identifying sources of pollutants and developing runoff models, as well as evaluating management actions such as effectiveness of best management practices (Dixon and Chiswell 1996). The Southern California Bight Pilot Project: Sampling Design

Mary Bergen

A general description of the Southern California Bight Pilot Project (SCBPP) is provided in the *Southern California Bight Pilot Project: An Overview* (in this annual report). It describes the justification for the Project, the basic elements of the sampling design, and the project management used to implement the program. This paper will provide a detailed description of the sampling design used for the SCBPP.

SAMPLING DESIGN

The Steering Committee used the conceptual framework of the United States Environmental Protection Agency's (USEPA) Environmental Monitoring and Assessment Program (EMAP) (Overton *et al.* 1990, Stevens 1994) to design the SCBPP survey. EMAP sampling is based on a randomly-placed, triangular grid of points covering the contiguous United States and associated coastal waters. The interpoint distance for the EMAP grid is approximately 27 km (White *et al.* 1992); however, the grid spacing can be adjusted as needed for a particular sampling design. Use of the triangular grid ensures that sample points are well-distributed over the study area. Moreover, the explicit spatial basis of the design ensures that each sampling point represents a known area, so that it is possible to estimate the amount of area with a particular characteristic, e.g., the area with total organic carbon (TOC) greater than 2%. Random placement of the grid and random selection of sampling points provides randomness needed for statistical inference.

To assure a sufficient sample size, the Southern California Bight (SCB) was divided into subpopulations of interest (Figure 1, Table 1), including three geographic zones; three depth zones; the areas around the four largest municipal wastewater outfalls, treated cumulatively; the areas within 3 km of the 11 largest rivers (excluding the Los Angeles River which discharges into Long Beach Harbor) and stormdrains, treated cumulatively; Santa Monica Bay; and the area around the Hyperion Treatment Plant (HTP) outfall. The goal was to have at least 40 samples per subpopulation.

The areas around the municipal wastewater outfalls and the rivers and storm drains were chosen as subpopulations to allow assessment of ecological changes near point and nonpoint discharges, respectively. The geographic and depth subpopulations were chosen because nonpoint sources are more likely to affect shallow areas and point sources are more likely to affect deeper areas in the central Bight. In addition, the Steering Committee expected benthic infaunal and demersal fish assemblages to vary with latitude and depth. Santa Monica Bay and the area around the HTP 5-mile outfall were chosen to enhance sampling density so that data from the SCBPP could be compared to data collected by the City of Los Angeles in their fixed-station monitoring.

The dividing lines for the geographic and depth zones were chosen using the Committee's collective knowledge of invertebrate and fish distributions in the SCB. The circles around the rivers and storm drains were drawn using a 3-km radius. Since there is no information about the impacts of nonpoint discharges on demersal fish or benthic infaunal asssemblages in Southern California, this distance was chosen arbitrarily.

Except for the HTP outfall, the areas around the outfalls were delineated by drawing a line around the sampling grid that is currently used to monitor each outfall. Since the monitoring program includes all of Santa Monica Bay, the HTP sampling grid was not used to delineate the HTP outfall area. This was because the Steering Committee wanted to distinguish between the outfall area and the rest of Santa Monica Bay. In addition they wanted to enhance the sampling effort around the outfall to allow for a comparison between the SCBPP data and HTP monitoring data. Therefore, monitoring data was used to delineate an area that included stations that were shown to be impacted by the HTP outfall in the winter of 1989 (CLAEMD 1990).

For the assessment, the Committee chose 12 indicators of ecological health, including four measures of water quality (dissolved oxygen, temperature, salinity, and transmissivity), benthic infauna, epibenthic macroinvertebrate and demersal fish assemblages, sediment characteristics, including contamination, sediment toxicity, external fish pathology and bioaccumulation, and marine debris.

The assessment period was targeted for summer (July-August) since populations of demersal fish and benthic infauna are expected to be more stable in summer than in winter or spring, and sampling is less likely to be interrupted by bad weather. In addition summer sampling corresponds to the "index period" used in the EMAP program.

Due to financial and logistical constraints, it was not possible to collect enough samples to characterize all indicators in all subpopulations. Given available resources, it was possible to take enough trawls to characterize fish assemblages, fish pathology, and marine debris in the three geographic zones, three depth zones, and cumulative outfall areas. Sediment toxicity and fish tissue contamination were characterized for the cumulative outfall areas and for the SCB as a whole. Water quality, sediment characteristics and benthic invertebrate assemblages were characterized for all subpopulations.

STATION SELECTION

The stations to be sampled were chosen using a modification of the sampling protocol used by EMAP for estuaries in the Louisianan province (Summers *et al.* 1993). First, to have enough grid points to produce approximately 40 stations per subpopulation, the EMAP grid was enhanced 7x7x7 fold. Then, stations were selected by a process that involved (1) randomization of the grid points, (2) random selection of grid points, and (3) random placement of a sampling point around each grid point. The grid points were randomized using a process that produced an optimum spatial spread of samples, while retaining the randomness needed for statistical evaluation. To do this, each point in the grid was given a number and spatial address. The spatial address preserved information about the original location of the point. The numbering was in groups of seven and of powers of seven. Grid points were then completely randomized within the smallest group, and the groups were randomized within the next larger group. In this way the order of points was randomized but geographically adjacent points remained close to each other during randomization.

To select grid points for benthic and water quality sampling from the total population of grid points, each grid point (in random order) was assigned an inclusion probability based on the number of samples needed in the area in which the point was located. For instance, grid points in the river discharge areas were given larger inclusion probabilities than points in nondischarge areas because more samples per unit area were needed. To choose the first grid point, the inclusion probabilities were sequentially summed, starting with the first point, until the cumulative probability was greater than or equal to one. Then a point was randomly chosen from the group of points with a cumulative probability of one or less. Subsequent grid points were chosen by adding 1 to the first randomly chosen probability (= r) and the number of points selected (i.e., grid points were selected at r + 1, r + 2, etc.).

To select grid points for the trawl sampling, which would only be analyzed for depth, geographic, and outfall subpopulations, the same procedure was used; however, the selection process included only the grid points selected for benthic and water quality sampling. Finally, the stations to be sampled for sediment toxicity and tissue analysis were selected from the grid points chosen for trawling.

SAMPLING LOGISTICS

Five organizations were responsible for collecting samples: City of Los Angeles, Environmental Monitoring Division; City of San Diego, Metropolitan Wastewater Department, County Sanitation Districts

R0011298

For toxicity, the threshold can be set at the point where there is a statistically significant change in an experimental endpoint. For some sediment contaminants (e.g., silver), the thresholds can be chosen from estimates of the concentration of the compound expected to cause toxicity (Long and Morgan 1990). However, for a compound such as TOC, there is no definitive method to determine a threshold between natural and unnatural values. Regression analysis can be used to identify stations with higher than expected concentrations (Bergen *et al.* 1995, Daskalakis and O'Connor 1995). Then the sediment chemistry data along with data from other sources can be used to determine if increased concentrations are associated with anthropogenic activities. For demersal fish and benthic infaunal assemblages, the threshold will be based on an index (one for fish and one for infauna) that summarizes changes in community parameters, such as number of species and number of individuals. If the absolute value of the threshold is not clear, the Steering Committee will use all the available information to select a threshold.

SUMMARY

The SCBPP is a cooperative sampling effort intended to provide synoptic information about the ecological condition of the mainland shelf of Southern California.

The sampling design was based on a design developed by USEPA EMAP. Sampling points were chosen by random placement of a grid of points over the sampling area, followed by random selection of grid points and random placement of stations around the grid points. The grid ensured that the sampling effort was well distributed over the study area while the random placement of the grid and random selection of sampling stations provided randomness needed for statistical inference. Moreover, since the interpoint distance of the grid was known, each sampling point represents a known area so that the amount of area with a particular characteristic, e.g., the area with total organic carbon greater than 2%, can be estimated.

The sampling was designed for assessing ecological conditions in three geographic zones, three depth zones, the areas around the four largest municipal wastewater outfalls (treated cumulatively), the areas within 3 km of 11 rivers and stormdrains (treated cumulatively), Santa Monica Bay, and the area around the HTP outfall. The assessment of ecological condition will be based on measures of water quality, demersal fish and benthic infaunal assemblages, sediment characteristics, sediment toxicity, fish pathology and bioaccumulation, and marine debris.

The extent and magnitude of change between subpopulations will be measured by (1) developing a cumulative distribution function for a parameter and (2) selecting a threshold value to divide natural from changed. Then the percent area that has been changed will be estimated.

Analysis of data is in progress. Survey results will be presented in a series of reports, including an assessment of ecological conditions on the Southern California mainland shelf and an evaluation of the SCBPP survey design.

the percent of the area of the SCB or of one of the subpopulations for the category of the variable; for instance, it is the percent of area with DDE of 10 ppb, 20 ppb, ... up to the maximum measured. The CDF shows the percent of area with DDE equal to or less than 10 ppb, 20 ppb, etc. In the SCBPP survey, because some areas (e.g., around the HTP outfall) were more intensively sampled than others, the number of points per unit area and the amount of area that the points represent varies. Therefore, the area weight, (i.e., the amount of area represented by the point) must be used to calculate the CDF. The CDF for parameter value x (e.g., DDE = 30 ppb) is the sum of the area weights for observations with values equal to or less than x divided by the sum of all the area weights in the population or:

$$cdfx = \text{Total } x\ (areawt_i) / \text{Total } (n)\ areawt_i)$$

where: *cdfx* = estimate of CDF for parameter value x
(e.g., DDE = 40 ppb)
$areawt_i$ = area weight for parameter value x
n = total number of observations
x = parameter value

Identifying Illicit Connections

Illicit Discharge Detection and Elimination

Description

Illicit connections are defined as "illegal and/or improper connections to storm drainage systems and receiving waters" (CWP, 1998). A discharge of industrial wastewater to a storm sewer is "illicit" because it would ordinarily require a permit under the Clean Water Act. Many building owners or operators are not aware that improper connections exist in their facilities. Identifying and removing illicit connections is a measure for reducing storm water pollution. In extreme cases of illicit dumping, legal action is necessary.

One of the ways to identify illicit connections is by inspecting storm drain system using video equipment (Source: Drain Patrol, no date)

From 1987 to 1998, Wayne County, Michigan, investigated 3,851 businesses and industries for illicit connections to the county's storm sewer system. Of those investigated, about 8 percent had illicit connections, and where one illicit connection was found, there was an average of 2.4 improper connects at that business. To prioritize the investigation, the county relied on Standard Industrial Classification (SIC) codes of the businesses. The prioritization system was found to be successful in locating illicit discharges (Johnson and Tuomari, no date; Tuomari, no date). The City of Hialeah, Florida, uses its storm water management plan to emphasize illicit discharge detection and removal as part of its overall monitoring activities. There are at least 252 outfalls in the city, 72 of which drain into city rights-of-way. After considering the costs associated with removing illicit discharges, the city chose a proactive field screening program approach to remove these discharges (City of Hialeah, 1999).

Applicability

Identifying illicit and improper connections are necessary for all sewer systems, especially in areas where pollutants with unknown sources have been detected in receiving waters. The level and types of industrial activities and the surrounding land uses and ordinances will affect the methods used to identify illicit connections.

Implementation

Some practices used to discover and prevent illicit connections are

- Instituting building and plumbing codes to prevent connections of potentially hazardous pollutants to storm drains.
- Organizing structures to be inspected by building age, with older buildings identified as priorities. Buildings whose processes have the potential to affect water quality also should be given priority.
- Mapping each area to be surveyed and indicating the route of the sewer system and the locations of storm drains on the map. This enables planners to estimate the likely locations of illicit connections. A Geographic Information System (GIS) is an appropriate tool for identifying illicit discharges. The location of illicit discharges can be maintained by a geo-coded address. The attributes for illicit discharges are SIC code, owner/occupant information, inspection schedule, inspection dates, and comments (Huey, 2000).

To help municipalities detect illicit connections to storm sewers, the North Central Texas Council of Governments (NCTCOG) used GIS to develop a 1/4-mile grid cell overlay for the entire 16-county NCTCOG region. The initial report suggested that illicit connections were not as prevalent in the North Central Texas area, and sewage material was observed in about 10 percent of the sites (NCTCOG, 2000).

The City of Greensboro, North Carolina, is using GIS technology as part of its storm water management program. This GIS system is used to in conjunction with the program's monitoring aspect to identify illicit connections. More information on this program can be found at *www.ci.greensboro.nc.us/stormwater/dynamic%5Fwatershed%5F management%5Fpro.htm* (Bryant et al., 1999 and City of Greensboro, 2000).

- Survey individual buildings to discover where connections to storm drains exist.
- Inspect sewer lines with television equipment to visually identify all physical connections.
- Compare the results of the field tests and the video inspection with the known connections on the map. Suspicious areas should be further investigated.
- Institute mandatory inspections for new developments or remodeling to identify illicit connections to the storm sewer system.
- Remove and test sediment from the catch basins or equivalent structures.
- Inspect connections in question to determine whether they should be connected to the storm drain system or to the sanitary sewer. Use methods of identification such as dye testing, visual inspection, smoke testing, or flow monitoring, as described below.
  - *Dye Testing.* Flushing fluorometric dye into suspicious

R0011303

downspouts can be useful to identify illicit connections. Once the dye has been introduced into the storm system via the connection in question, the water in the collection system is monitored to determine whether an illicit connection is present.

- *Visual Inspection.* Remotely guiding television cameras through sewer lines is another way to identify physical connections.
- *Smoke Testing.* Smoke testing is another method used to discover illicit connections. Zinc chloride smoke is injected into the sewer line and emerges via vents on connected buildings or through cracks or leaks in the sewer line. Monitoring and recording where the smoke emerges, crews can identify all connections, legal and illegal, to the sewer system. Mechanisms on drains should prevent the smoke from entering buildings; however, in some instances, this will occur. It is important to notify the public that the smoke is non-toxic, though it should be avoided as it can cause irritation of the nose and throat for some people.
- *Flow Monitoring.* Monitoring increases in storm sewer flows during dry periods can also lead investigators to sources of infiltration due to improper connections.
- *Infrared, Aerial, and Thermal Photography.* Researchers are experimenting with the use of aerial, infrared, and thermal photography to locate dischargers by studying the temperature of the stream water in areas where algae might be concentrated and in soils. It also examines land surface moisture and vegetative growth. This technique assumes that a failing OSDS, for example, would have more moisture in the surface soil, the area would be warmer, and the vegetation would grow faster than in the surrounding area (Johnson and Tuomari, no date).

On November 17 and 30, 1999, the Arkansas Department of Health used infrared technology to identify illicit discharges from septic systems into Lake Conway, Arkansas. Lake Conway, located in Faulkner County, Arkansas, is a man-made lake used mostly for recreational fishing. Approximately 90 percent of the residents within 1 mile of the lakefront have onsite wastewater treatment systems. Of the 2,500 to 3,500 residents who living within 300 feet of the shoreline, only 250 are connected to the public sewer system. Most of these systems are more than 30 years old and were installed before state regulations. The inspector used a state policy helicopter that was equipped with a Forward Looking Infrared imaging system, video equipment, and a global positioning system. The results of this two-day survey indicated that there are approximately 380 malfunctioning and improperly constructed septic systems within 300 feet of the lakefront (Eddie, 2000). Facility owners should be required to correct the problem by eliminating the discharge and connecting to the sanitary sewer system

Some agencies use a priority system for identifying illicit discharges. According to the Southeast Michigan Council of Governments (1987, cited in Tuomari, no date), a priority scheme for detecting illicit discharges from businesses should be as follows:

1. Automobile-related businesses/facilities and heavy manufacturing
2. Printers, dry cleaners/laundries, photo processors, utilities, paint stores, water conditioners, chemical laboratories, construction companies, and medium light manufacturing
3. Institutional facilities, private service agencies, retail establishments, and schools

Limitations

There are several limitations to programs to detect illicit connections. First, a local ordinance is necessary to provide investigators with access to private property in order to perform field tests (Ferguson et al. 1997). Second, rain fall can hamper efforts to monitor flows and visual inspections. In addition, smoke testing and dye testing may become more difficult, depending on the severity of the storm event. Smoke testing has roughly the same efficiency as door-to-door investigation, and both smoke and dye testing are more accurate than visual inspection.

Despite the difficulty in identifying these connections due to budget and staff restraints, it is important to understand that these connections are illegal and should be identified and reported regardless of cost. Jurisdictions can offset some of these costs by encouraging the reporting of illicit discharges by employees, thereby saving expense on inspectors and directing resources more efficiently.

Maintenance Considerations

Identifying illicit discharges requires teams of at least two people (volunteers can be used), plus administrative personnel, depending on the complexity of the storm sewer system. To help identify illicit discharges, the City of Raleigh, North Carolina, has illicit discharge regulations and dry weather screening for illicit discharges and connections. By taking baseline samples throughout the city, pollution control efforts can be better established for future identification of illicit discharges. This inventory, combined with the city's mapping effort, will be added to the city's GIS to allow for improved tracking of illicit discharges and spills (City of Raleigh, 1998).

Effectiveness An illicit discharge detection program can be an effective method to reduce the quantity of industrial or commercial pollutants that enter the storm drain system. For example, the Department of Environmental Protection in Montgomery County, Maryland, has an illicit discharge detection and elimination program called "Pipe Detectives," which uses volunteer monitoring and community hotlines to identify suspicious discharges (MCDEP, 1997). When discharges are reported, DEP consults maps of the surrounding areas and targets those areas for additional monitoring to narrow the search for the illicit connection. In one instance, a "milky white" discharge was reported in an area with many small businesses and large apartment buildings. Businesses were sent informational letters advising them of the illegal discharge and requesting their assistance in identifying it by allowing DEP to survey the properties. Through this cooperative effort, three illicit connections were detected and removed, including a sink that was used to wash paintbrushes (the source of the milky white discharge).

The City of Denver Urban Drainage and Flood Control District (UDFCD) in an independent agency whose functions include master planning, design and construction, maintenance, floodplain management, and management of the South Platte River. The master planning aspect includes major drainageway master planning, outfall systems planning, preparation of drainage criteria manuals for local governments and the district, support of special projects, and wetland projects. The City of Denver has a Storm Drainage Master Plan, which identified $100 million in necessary drainage improvements. The district uses pollutants and education materials to limit illicit discharges to storm drains (City of Indianapolis and Marion County, 2000).

As part of the Rogue River National Wet Weather Demonstration Project, Wayne County, Michigan, offers training for illicit discharge elimination. Four training courses are offered: Overview, Basic Investigations, Advanced Investigations, and Prevention of Construction-Related Illicit Discharges. More information on these training opportunities can be found at *http://www.wcdoc.org/rougeriver/techtop/index.html*.

EPA's Surf Your Watershed (*http://www.epa.gov/surf*) can help citizens and business/industry owners identify into which watershed their storm drains flow.

The Conservation Technology Information Center (CTIC), a non-profit data and technology information transfer center, has created *Know Your Watershed* (*www.ctic.purdue.edu/KYW*). This web site allows individuals to learn their watershed address by entering their city, county, or river name, or their ZIP code.

Cost Considerations

The cost of smoke testing, dye testing, visual inspection, and flow monitoring can be significant and time-consuming. Site-specific factors, such as the level of impervious area, the density and ages of buildings, and type of land use will determine the level of investigation necessary. Case studies in Michigan have estimated the cost of two field staff and required support at $182,000 to $187,000 annually (Ferguson et al., 1997). Wayne County's budget for illicit detection investigations was $735,151 from 1996 to 1997 and $599,041 for 1997 through 1998 (Johnson and Tuomari, no date).

Many programs offset some of their cost by encouraging the reporting of illicit discharges by employees, thereby saving expense on inspectors and directing resources more efficiently. Programs have also saved money by using student interns to locate and map dry weather flows from outfalls, or by contracting with academic institutions to perform outfall monitoring.

Some programs have used funds available from "environmental fees" or special assessment districts to fund their illicit connection elimination programs. The Huron River Pollution Abatement Project used annual assessments of the city of Ann Arbor and a per parcel basis for the rest of the district to fund the costs of illicit connection removal efforts. The project provided Washtenaw County with a total of $1.7 million over the life of the program to finance their efforts. Fort Worth, Texas, charges an "environmental fee" to local residents and businesses to fund storm water-related efforts, including illicit connection detection. Approximately $2.5 million dollars a year is raised through these fees.

Review of Existing Stormwater Monitoring Programs for Estimating Bight-wide Mass Emissions from Urban Runoff

By Kenneth Schiff

ABSTRACT

Urban runoff is perceived as a large source of pollutant inputs to the ocean, but no mass emission monitoring programs have been established to assess this discharge. Recently, however, National Pollutant Discharge Elimination System permits for urban runoff discharges were issued to stormwater management agencies on a regional (county-wide) basis and the 1994-95 water year represents the first period in which urban runoff water quality measurements have been monitored bight-wide. The goal of this study was to use the data generated by these monitoring programs to estimate mass emissions of pollutants to the Southern California Bight from urban runoff. After documenting the sampling design of each stormwater monitoring program, then collating information on rainfall, watershed area, runoff volume, and water quality measurements, we estimated the mass emissions of total suspended solids, nutrients (ammonia, nitrate, phosphorous), and five trace metals (chromium, copper, nickel, lead, zinc). Although the mass emissions of these constituents appeared substantial relative to other sources, there was tremendous uncertainty in the load estimates. Less than 5% of the watershed areas and less than 2% of the annual runoff volumes were actually monitored during 1994-95 water year. Extrapolation of water quality data to these unmonitored channels and flows, which is necessary to develop bight-wide emission estimates, are hampered by the tremendous vaiability in contaminant concentrations among the different watersheds and storm events. This variability in water quality measurements from urban runoff are not well understood. This lack of understanding adds to our uncertainty in the load estimates we provide.

INTRODUCTION

Rivers in southern California are amongst the most extensively modified channels in the world (Brownlie and Taylor 1981). These storm drain systems, which ultimately discharge directly to the ocean, were designed to remove stormwater from streets and low-lying areas as efficiently as possible, thus reducing flooding and minimizing property damage. Most of the modification to these channels occurred prior to an era of interest or knowledge about urban runoff water quality. As a result, accumulated debris, pollutants, and pathogens from the largest metropolitan centers on the west coast are discharged along with this urban runoff. Moreover, many urban runoff discharges are augmented by inland municipal/industrial treated wastewater discharges, potentially contaminated groundwater discharges, and at times, inputs from illegal discharges and illicit connections. There is little in the way of retention and virtually no treatment of runoff from southern California urbanized watersheds. Only relatively recently has concern regarding water quality of these urban runoff discharges been examined (SMBRP 1996, Schiff and Stevenson 1996, Bay *et al.* 1996, Suffet *et al.* 1993, Gold *et al.* 1992; SCCWRP 1980).

Although urban runoff is currently perceived as a potentially large source of contaminants to our near coastal environment (Eganhouse and Kaplan 1987, RWQCB-LA 1988, USEPA 1995), there has been little monitoring for estimating contaminant mass emissions to the Southern California Bight (SCB). One reason for the lack of quantified loadings is because sampling and characterizing runoff discharges is extremely difficult. Unlike many other point sources of pollutants to the ocean, such as treated municipal or industrial wastewaters, the ubiquitous nature of urban runoff prohibits characterization from a single location or at infrequent intervals. The unpredictable rainfall in southern California further complicates runoff monitoring since the resulting flows are discontinuous and highly variable. Historically, most runoff measurements for estimating contaminant mass loadings to the ocean have been the result of special studies (SCCWRP 1973; 1990; 1992). Re-authorization of the Clean Water Act in 1987 and associated litigation have now required regulatory permitting of stormwater discharges. Most of this regulatory burden, both technical and fiscal, has been tasked to the stormwater management agencies, whose mission has traditionally been building and maintaining our flood control channels.

The State of California, through it's Regional Water Quality Control Boards, issued four region-wide National Pollutant Discharge Elimination System (NPDES) Permits between 1990 and 1993 for urban stormwater discharges to the SCB (Table 1; Figure 1). Each permit has many co-permittees including counties, incorporated cities within the counties, and special districts (e.g., Port District). The principal permittees are the Ventura County Flood Control District (Ventura Co.) for the Ventura County Region-wide Permit, Los Angeles County Department of Public Works (LA Co.) for the Los Angeles County Region-wide Permit, Orange County Flood Control District (Orange Co.) for the Orange County Region-wide Permit, and the City of San Diego (San Diego Co.) for the San Diego Region-wide Permit. All permittees are mandated to create a stormwater management plan (SWMP), part of which is water quality monitoring. Although monitoring programs are mandated by each NPDES Permit, they have not been standardized within the SCB.

The objectives of this study were three-fold. For each of the urban runoff water quality monitoring programs in the SCB during the 1994-95 water year, we attempted to:

1) Document the sampling designs of each water quality monitoring program;

2) Collate rainfall, watershed area, runoff volume, and water quality information from each of the monitoring programs and use this information to estimate bightwide mass emissions; and

3) Evaluate our ability to calculate mass emission estimates based upon the current monitoring programs.

MATERIALS AND METHODS

Each stormwater management agency's Annual Discharge Monitoring Report (ADMR) was reviewed to document sampling designs, collate data for water quality and flow measurements, and evaluate monitoring programs for estimating bight-wide mass emissions from urban runoff (VCFCD 1995; LACDPW 1996; OCEMA 1996; KLI 1995). The most recent year for which an ADMR was available for all permittees was the 1994-95 water year (October 1994 through September 1995). Each ADMR was obtained from the RWQCB files or from the permittee.

For the purposes of this article, several assumptions were required. First, only watersheds listed in the NPDES permits were considered, including areas beyond the urban limit line. Where watersheds were split between permits (i.e., Santa Clara, Santa Ana, and Santa Margarita Rivers), the region for which the discharge entered the ocean was chosen as the area encompassed in permitted discharge. Significant impoundments exist on most rivers of the SCB, but no attempt was made to remove upstream portions of watersheds from the estimated discharge area. However, only flows downstream of dams were considered for discharges to the ocean. No runoff factors were used to estimate unmonitored flows; only gaged flows to the SCB were utilized. It was assumed that flow and analytical chemistry measurements were conducted (and recorded) without error.

Documentation of Existing Monitoring Programs

Documentation of the existing monitoring programs focused on three areas: (1) Station selection, (2) Storm sampling criteria, and (3) Target analytes and detection limits. For station selection, the general strategy for site selection, the number of sites sampled, and the watershed area encompassed by that site were identified. For storm sampling criteria, the minimum storm size, total number of storms sampled, and sampling methodology were identified.

Estimation of Runoff Mass Emissions By Collating Monitoring Data
A simplistic, watershed-based approach was used to calculate mass emissions of contaminants from urban runoff to the SCB in 1994-95 illustrated by the following equation (1):

$$(1) \qquad L_{annual} = \sum_{i=1}^{n} (EMC_{median} * Volume_i)$$

Where,

L_{annual} = Annual pollutant load;

i = Watershed listed in the NPDES permit;

Volume = Annual volume of watershed i; and

EMC_{median} = Bightwide median event mean concentration .

Annual runoff volume for each watershed was obtained from either the ADMR's, the United States Geological Survey (USGS 1995), LA Co. - Engineering Section, Orange Co. Environmental Management Agency, San Diego Co. Flood Control District, or the International Boundary Water Commission (IBWC). Rainfall data, summarized from the National Weather Service (Nationwide Climatic Data Center, Ashville, NC), was used to complement flow data, demonstrate part of the variability responsible in flow among regions, and assess the relative discharges this water year compared to "normal" years as determined from long-term rainfall records. Additional information collated from these sources included 15 min. average flow during storm events and total volume discharged during storm events to assess volumes representatively sampled versus discharged.

Bight-wide median event mean concentrations (EMC) were calculated from the midpoint in the distribution of all the water quality data for a particular constituent reported in the 1994-95 ADMR's. The EMC is equivalent to the concentration designated as representative of each storm event by each monitoring agency. It is defined as the sum of all volume-weighted concentrations divided by the total storm volume (USEPA 1983). The only water quality data we collated for median EMC calculations were channel sites where an entire watershed was sampled. No sub-watershed, land use sites were used to calculate median EMC's. We also compared water quality results for the different region-wide permits by calculating 1994-95 median EMC's for individual SCB watersheds where the data were available.

Our watershed-based approach required pooling data to estimate water quality for channels not sampled. Because we had to extrapolate concentrations to unsampled watersheds, which adds some uncertainty to our estimates of mass emissions, we also calculated mass emissions based upon the 10th and 90 th percentile concentrations observed among watersheds. Our intention in the calculations was to capture the uncertainty in the extrapolations we have made.

Evaluation of Monitoring Data for Calculating Bightwide Mass Emissions from Runoff
The ability to calculate bightwide mass emissions from urban runoff based upon the monitoring data from 1994-95 was judged by two factors: (1) An assessment of monitoring coverage, and (2) The commonality of methods among monitoring programs. Monitoring coverage was assessed in terms of the percent of the area monitored and the percent of runoff volume representatively sampled. Commonality among programs

R0011311

included such factors as numbers and types of storms captured, sampling methodology and frequency, and comparability of analytical chemistry.

RESULTS

Documentation of Existing Monitoring Programs
Two general types of monitoring sites are currently being used by the stormwater management agencies in the SCB. The first type of monitoring site samples an entire watershed composed of large areas (10^1 to 10^3 km^2) and a diverse mix of land use types by sampling water quality at or near the end of a river or creek. The goal of this monitoring design is to characterize the cumulative discharges from all sources within the entire watershed. We refer to these as "channel sites";. The second type of monitoring site samples sub-watersheds composed of small areas (10^{-2} to 10^0 km^2) and a single homogeneous land use. The goal of this monitoring design is to characterize particular runoff sources (e.g. residential, commercial, industrial, etc.). We refer to these as "land use sites".

Fifteen of the 36 sites monitored by stormwater management agencies in 1994-95 were channel sites (Table 2). Orange Co. sampled channel sites exclusively (eight total, including the only unlined earthen channels). In contrast, Ventura Co. sampled only land use sites (seven total, including the only agricultural land use monitored). San Diego Co. sampled more sites in 1994-95 than any other stormwater management agency in the SCB (nine land use and three channel sites).

All of the stormwater monitoring programs in the SCB used storm mobilization criteria to trigger crews into action (Table 3). The first criterion was minimum storm size, as estimated from predicted rainfall quantities, which ranged from 0.10 to 0.25 inches among monitoring programs. The second criterion was antecedent dry period between storms, which ranged from three to four days among monitoring programs. Only the San Diego Co. NPDES permit specified the individual storms that must be captured, including the first two significant storms of the season and one late season storm (after February 1). Except for Los Angeles Co., monitoring programs in the SCB were required to sample a minimum of three storms per site each year; Los Angeles Co. was required to sample five storms per site each year.

Two types of samples were collected by the monitoring agencies (Table 3). The first type was a grab sample consisting of a bottle or bucket lowered into the channel or manhole. The second type was a composite sample, typically collected using a peristaltic pump with an intake strainer mounted in the bottom of channels or pipes. Composite samples, however, were weighted differently among agencies (Table 3). Ventura Co., Los Angeles Co., and San Diego Co. used a single composite sample per event weighted by storm flow (e.g., sampling every set volume interval). In contrast, Orange Co. measured two to three composite samples per event, each weighted by time (e.g. every hour, every 15 minutes, etc.). Although sampling frequency within a composite can vary as a result of storm duration or volume, automated samplers were programmed differently among monitoring agencies. Actual sampling frequencies varied from four to over 40 per storm event (Table 3).

Minimum flow requirements were defined by each monitoring agency to identify when to end sampling and evaluate the acceptability of a storm event (Table 3). Typically two trigger levels were used to conclude sampling. First, peak flows needed to recede to 120%, or less, of baseline pre-storm flow. Alternatively, the time since rainfall concluded needed to exceed a minimum interval (typically 96 hr.). Three of the four agencies reported the storm capture percentage which is equivalent to the volume representatively sampled compared to the total storm volume discharged. For those agencies that reported storm capture criteria, most events were greater than 75%.

Each of the stormwater management agencies analyzed a variety of constituents for their water quality assessments of urban runoff including general characteristics, inorganic analytes such as trace metals, and organic constituents such as chlorinated and petroleum hydrocarbons, toxicity tests with invertebrates or vertebrates, and fecal indicator bacteria (Table 4). Since not all constituents are measured during every storm or at every station, only those analytes and detection limits routinely listed in their respective ADMR's were reported. Thirteen analytes were measured in common between the four region-wide stormwater permits in the SCB. Some individual permittees, however, measured as many as 183 analytes for a given sample.

Collating Monitoring Data and Estimation of Mass Emissions

Rainfall. Annual rainfall varied from 44 to 73 cm throughout the coastal SCB (Figure 2). As expected, precipitation patterns across the SCB were highest in the north and steadily declined moving south. Oxnard received 66% more rainfall compared to San Diego. In 1994-95, the annual rainfall was approximately double the long-term average. Although precipitation was recorded between 9 and 10 months of the year, the majority of rain fell in the months of January and March. These two months represented 69 to 80% of the rainfall for the entire year, depending upon the gage site.

Watershed Area and Runoff Volume.

The total watershed area of the rivers and creeks named in Southern California NPDES stormwater permits was roughly 26,000 km^2 (Table 5). Approximately 90% of this area was gaged for urban runoff flows by a variety of agencies; 2.9 x 10^{12} L were measured during the 1994-95 water year (Table 5). Three rivers discharged over half of the gaged volume to the SCB. Annual discharges from the Los Angeles River, Santa Clara River, and Santa Ana River cumulatively exceeded 1.7 x 10^{12} L, but their watersheds represented only 41% of the SCB area.

When examined on a region-by-region basis, the San Diego Co. NPDES permit (10,800 km_2) encompassed nearly double the watershed area of the other three permits (4,900 to 5,500 km^2). Annual discharge volume in the Los Angeles region (1.13 x 10^{12} L), however, was between 175% and 230% greater than the other three regions (0.49 to 0.65 x 10^{12} L).

Water Quality.

Suspended solids, nutrients (nitrogen and phosphorous), and five trace metals (Cr, Cu, Pb, Ni, and Zn) were consistently analyzed and reported among the various NPDES stormwater monitoring programs of the SCB that sampled channel sites (Table 6). Other water quality parameters were measured frequently by individual agencies, but not consistently among all permits or at all sites within a permit. Organic constituents such as PAH's, DDT's, and PCB's were frequently measured, but virtually all measurements for these compounds were below reported detection limits.

No single region had all the highest or all the lowest median EMC's at channel sampling sites during 1994-95 (Table 6). The range of EMC's between regions differed by a factor of 2 to 20 among the general constituents and by a factor of 1 to 15 among the trace metals. This magnitude of variability was also observed between sites within a single region (Table 6). For example, the range of median EMC's among SCB regional permits for suspended solids was 175 to 330 mg/L. The range of EMC's between different monitoring sites within the San Diego region was 148 to 485 mg/L while the EMC's from various sites within the Orange County region ranged from 41 to 2,148 mg/L.

Mass Emission Estimates from Urban Runoff to the SCB.

Bight-wide median EMC's and mass emissions from urban runoff were estimated for the 1994-95 water year (Table 7). The total load of suspended solids was estimated to be 598 x 10^3 metric tons (mt). Using the 10^{th} and 90^{th} percentile of the distribution of EMC's within the SCB, low and high load estimates

R0011313

varied from 199 x [illegible] to 2,874 x 10^3 mt. The combined load of five trace metals (chromium, copper, lead, nickel, and zinc) was estimated to be 531 mt, although estimates varied from 236 to 1,807 mt.

Evaluation of Monitoring Data for Calculating Bightwide Mass Emissions from Runoff

Calculating mass emissions from urban runoff to the SCB from the current monitoring data was constrained by missing data from unmonitored watersheds (i.e., unsampled channels) and unmonitored flows (i.e., unsampled storms) (Figure 3). The watershed area sampled by stormwater monitoring agencies during the 1994-95 water year was approximately 1,162 km2 or 4.5% of the entire area discharging to the SCB which are listed in NPDES permits. Likewise, a very low percentage of the annual discharge volume was monitored. Approximately 0.06 x 1012 L was representatively sampled for analysis during the 1994-95 water year; Less than 2% of the annual volume. Of the SCB's largest watersheds (Los Angeles, San Gabriel, and Santa Clara Rivers), only 0.5 km^2 and 0.15 x 10^9 L was sampled.

Although the four stormwater monitoring programs targeted similar numbers, sizes, and types of storms, each sampled its storms differently. The data set used for this study consisted of grab, single and multiple-weighted composite samples. Furthermore, some agencies used time-weighted and others flow-weighted composites. Finally the sampling frequency within composites varied from 4 to 40+. Not all agencies used storm capture criteria, but those that did met expectations of $\geq$ 75% or more of the storm volume representatively sampled.

Each of the stormwater monitoring agencies analyzed at least nine constituents in common for which bight-wide mass emissions could be calculated (TSS, nutrients, and five trace metals). One agency measured as many as 183 constituents per sample. The methods cited in each of the ADMR's were comparable to Environmental Protection Agency (EPA) protocols. However, many organic compounds were non-detectable using these methods. Detection limits for trace metals were generally not problematic (i.e., usually detected), except for those agencies attempting to measure dissolved fractions.

DISCUSSION

Two approaches are generally used to calculate mass emissions from runoff to the SCB. There is a watershed-based approach which is empirical; concentrations and volumes are measured directly at the terminus of a channel prior to entering the receiving waters. The other approach employs a land use model which estimates runoff volumes based upon quantity of rainfall (from rain gages), watershed area, and coefficients of runoff (based upon imperviouseness). Typically, runoff models also rely upon representative land use sites for water quality data. The watershed-based approach was chosen for this study because channel sites required fewer assumptions to estimate mass emissions to receiving waters. A land use model was not applied because the ADMR's we reviewed lacked the water quality data for some land uses that may contribute substantial quantities of constituents to the SCB. Moreover, we lacked the necessary data to sufficiently calibrate and validate a land use model which would require a combination of both land use and channel site monitoring.

Although the watershed-based approach requires fewer assumptions than the land use model, it was not completely empirical. The watershed-based approach is most effective on a channel-by-channel and storm-by-storm basis. However, the stormwater monitoring agencies are not mandated by the RWQCB to monitor every channel or every storm. As a result, the data set was incomplete and a number of assumptions were required that introduced considerable uncertainty in the quality of our mass emissions estimates. First, it was necessary to assume that water quality measurements in monitored channels were equivalent to those from unmonitored channels. Based upon water quality results from monitored channels, 1994-95 median EMC's for channels within a county and between counties fluctuated widely, often ranging an order of magnitude or more for most constituents. Studies by SCCWRP (1992) also demonstrated tremendous variability among watersheds. For example, suspended solids flow-weighted mean concentrations ranged from 283 to 4,313 mg/L among the eight largest rivers and creeks in southern California during 1986-88. In 1994-95, only one of these eight channels was actually monitored by the stormwater management agencies. Since the corresponding data were not available from all channels, we are unable to assess the bias associated with our extrapolation to unmonitored watersheds.

A second assumption we used was that the temporal periods sampled within a watershed were representative of other periods which were not sampled. Assumptions based upon extrapolations to unsampled storms introduces uncertainty because of flow-related variability. Studies on the Los Angeles River and other channels of the SCB observed significant correlations between flow and pollutant concentrations (SCCWRP 1990). Consequently, mass emission estimates for specific runoff events differ between large and small storms as a result of changing constituent concentrations as well as discharge volumes. Therefore, missing or capturing significant events can result in potential bias depending upon the magnitude of the storm size. Capturing the largest storm of the year may result in the largest EMC's and will likely overestimate the unsampled, but smaller-sized storms. Alternatively, capturing the smallest storms may underestimate the true annual discharge (if substantially large storms are not sampled). Moreover, 1994-95 was a very wet year. Rainfall was approximately double the long-term annual average which generated some of the largest peak flows in recent history (USGS 1995). The magnitude of bias associated with unsampled storm events cannot be assessed because none of the SCB monitoring programs have sufficient temporal sampling regimes to address this question.

Other temporal assumptions relative to this study that can introduce uncertainty are even less understood than flow-related correlations. Assumptions which are not well understood for southern California watersheds include relationships of water quality to antecedent dry periods (pollutant build-up) and rainfall intensity or duration (pollutant transport). Examples of the interactions between these two important parameters include concepts such as "first flush" (initial storm flows) or "seasonal flushing" (initial storms of the water year). Although several investigators have demonstrated portions of these concepts in other regions (Herricks 1995), they are not well-quantified in southern California. In some cases they appear significant (OCEMA 1996, RWQCB-LA 1988); in others, they do not (SCCWRP 1989).

Temporal variability within and among runoff events is compounded in the SCB by the different sampling strategies utilized by stormwater monitoring agencies. Our data set was comprised of individual grab, single and multiple weighted-composite samples. Grab and composite samples however, represent very different portions of a storm event. Grab samples represent a single snapshot of water quality during a storm event and, for the most part in 1994-95, were taken independently of flow regime or time since start of flow. Composite samples were actually multiple grab samples which, when combined together, were used to represent the mean water quality for an entire storm event. Composite samples, however, were weighted differently among the agencies. Some were weighted by storm flow (e.g., sampling every set volume interval); others were weighted by time (e.g. every hour, every 15 minutes, etc.). Flow-weighted composites sample more frequently during high flows than low flows, while time-weighted samples are distributed evenly throughout the storm event. Moreover, the number of samples per composite varied substantially among agencies (4 to 40+), or even within an agency (12 to 40+). The degree to which sampling strategies influence water quality results has not been quantified in terms of bias to the true EMC or the relative effect on seasonal loading estimates.

One reason we needed to rely on so many assumptions is that the monitoring programs are not entirely designed to estimate mass emissions to the ocean. Most monitoring programs have multiple purposes, all of which are important. Multiple information needs from urban runoff monitoring include regulatory compliance, identifying sources of pollutants and developing runoff models, as well as evaluating management actions such as effectiveness of best management practices (Dixon and Chiswell 1996). Even if calculating total pollutant loads to the marine environment were not the primary goal of urban runoff monitoring, we suggest that the same assumptions we had to make will also inhibit the use of current monitoring data for other purposes. For example, evaluating the effectiveness of a specific management action, would be very difficult with the degree of variation observed. If a load reduction of 30% is targeted but variability in mass emission estimates are only accurate to within a factor of five to 10, true load reductions will be obscured and may not be detected. The effect of large variability would also hinder attempts to assess differences between sources and the variance added to a mass emissions computer modeling program would limit its utility as a management tool.

Estimating pollutant mass emissions from urban runoff discharges is the only way to gain perspective relative to the magnitude of inputs from other sources. Even when using the lower end of the mass emission estimates provided in this article, based upon monitoring data compiled from the 1994-95 NPDES permitted stormwater programs, inputs from urban runoff are substantial relative to other sources (See *Characteristics of Effluents from Power Generating Stations in 1995* and *Characteristics of Effluents from Large Municipal Wastewater Treatment Facilities in 1995* in this volume). Mass-based comparisons among various sources are preferred because large temporal and/or spatial changes in concentrations or flow can mislead scientists and resource managers when assessing the extent of potential impact. Of course, mass emission estimates are just one factor in the overall impact assessment process. Other important elements need to be considered including pollutant transport, contaminant fate, and biological impairment (See *Impacts of Stormwater Discharges on Santa Monica Bay* and *Toxicity of Stormwater Discharges from Ballona and Malibu Creeks* in this volume).

We suggest that estimating mass emissions is one of the greatest reasons to monitor because this is the only way in which stormwater management agencies can assess their relative contribution of pollutants to the marine environment. In southern California, marine environments are habitats of great concern since little freshwater habitat exists in our ephemeral streams and most channels are already highly modified. Currently, urban runoff is estimated to be a substantial source of pollutant inputs; However, this study has shown that mass emission calculations required numerous assumptions and the quality of load estimates are uncertain. If urban runoff is in fact a large source of pollutants, then quality load estimates will be required so that stormwater managers can leverage appropriate funding from their respective legislative bodies for controlling these inputs. If urban runoff is not a significant source of pollutant inputs, then quality load estimates will serve to alleviate the regulatory pressure and public perception that this source of inputs represents an unresolved environmental problem. At this point in time, the "true load" from creeks and rivers of the SCB is unknown. Furthermore, without adequate mass emission estimates and reliable confidence limits we will be unable to quantify with certainty whether mass emissions from urban runoff are increasing, decreasing, or staying the same with time, or whether they are changing as a result of management action.

The Southern California Bight Pilot Project: Sampling Design

9 Field Manual

Mary Bergen

A general description of the Southern California Bight Pilot Project (SCBPP) is provided in the *Southern California Bight Pilot Project: An Overview* (in this annual report). It describes the justification for the Project, the basic elements of the sampling design, and the project management used to implement the program. This paper will provide a detailed description of the sampling design used for the SCBPP.

SAMPLING DESIGN

The Steering Committee used the conceptual framework of the United States Environmental Protection Agency's (USEPA) Environmental Monitoring and Assessment Program (EMAP) (Overton *et al.* 1990, Stevens 1994) to design the SCBPP survey. EMAP sampling is based on a randomly-placed, triangular grid of points covering the contiguous United States and associated coastal waters. The interpoint distance for the EMAP grid is approximately 27 km (White *et al.* 1992); however, the grid spacing can be adjusted as needed for a particular sampling design. Use of the triangular grid ensures that sample points are well-distributed over the study area. Moreover, the explicit spatial basis of the design ensures that each sampling point represents a known area, so that it is possible to estimate the amount of area with a particular characteristic, e.g., the area with total organic carbon (TOC) greater than 2%. Random placement of the grid and random selection of sampling points provides randomness needed for statistical inference.

To assure a sufficient sample size, the Southern California Bight (SCB) was divided into subpopulations of interest (Figure 1, Table 1), including three geographic zones; three depth zones; the areas around the four largest municipal wastewater outfalls, treated cumulatively; the areas within 3 km of the 11 largest rivers (excluding the Los Angeles River which discharges into Long Beach Harbor) and stormdrains, treated cumulatively; Santa Monica Bay; and the area around the Hyperion Treatment Plant (HTP) outfall. The goal was to have at least 40 samples per subpopulation.

The areas around the municipal wastewater outfalls and the rivers and storm drains were chosen as subpopulations to allow assessment of ecological changes near point and nonpoint discharges, respectively. The geographic and depth subpopulations were chosen because nonpoint sources are more likely to affect shallow areas and point sources are more likely to affect deeper areas in the central Bight. In addition, the Steering Committee expected benthic infaunal and demersal fish assemblages to vary with latitude and depth. Santa Monica Bay and the area around the HTP 5-mile outfall were chosen to enhance sampling density so that data from the SCBPP could be compared to data collected by the City of Los Angeles in their fixed-station monitoring.

The dividing lines for the geographic and depth zones were chosen using the Committee's collective knowledge of invertebrate and fish distributions in the SCB. The circles around the rivers and storm drains were drawn using a 3-km radius. Since there is no information about the impacts of nonpoint discharges on demersal fish or benthic infaunal asssemblages in Southern California, this distance was chosen arbitrarily.

Except for the HTP outfall, the areas around the outfalls were delineated by drawing a line around the sampling grid that is currently used to monitor each outfall. Since the monitoring program includes all of Santa Monica Bay, the HTP sampling grid was not used to delineate the HTP outfall area. This was because the Steering Committee wanted to distinguish between the outfall area and the rest of Santa Monica Bay. In addition they wanted to enhance the sampling effort around the outfall to allow for a comparison between the SCBPP data and HTP monitoring data. Therefore, monitoring data was used to delineate an area that

Project Management

More than 100 people from thirteen different organizations were involved in the management of the 1994 Pilot Project. Effective management was a critical component of the success of the project since it required coordinating the efforts of many groups to produce data that are reliable and comparable. Management was based on a three-tier structure, with each tier performing a different function.

At the center of the management structure was the Steering Committee, composed of scientist/managers from each of the participating agencies. The Steering Committee was responsible for the overall planning of regional monitoring activities, focusing largely on program design. During the design process, the Steering Committee identified the questions to be addressed in the survey, selected sample sites to achieve these objectives and identified the indicators to be measured.

The Steering Committee was also responsible for project coordination among the different organizations involved. To achieve this, selected members of the Steering Committee were appointed as Quality Assurance (QA) Officer (who directed the QA components of the project), Field Coordinator (who directed the administrative and technical components of field operations), Laboratory Coordinator (who directed the administrative and technical components of laboratory analyses), and Information Management Officer (who coordinated data reporting and management).

The Steering Committee was supported by five technical subcommittees, which were responsible for addressing the technical details associated with each indicator group. These groups prepared sections of the methods and QA manuals specific to their areas of expertise. They also conducted data analysis of their indicators, with their reports subject to Steering Committee review.

The Steering Committee reported to the SCCWRP Commission, which is composed of the highest level of management from each of the largest municipal dischargers to Southern California Bight and from each of the agencies responsible for regulating discharge to the Bight. The Commission, which meets on a quarterly basis, ensured that the questions we were addressing stayed relevant to current management issues. Reporting to the Commission also ensured that the results would be used for management action.

Steering Committee Members
SCCWRP Commission

included stations that were shown to be impacted by the HTP outfall in the winter of 1989 (CLAEMD 1990).

For the assessment, the Committee chose 12 indicators of ecological health, including four measures of water quality (dissolved oxygen, temperature, salinity, and transmissivity), benthic infauna, epibenthic macroinvertebrate and demersal fish assemblages, sediment characteristics, including contamination, sediment toxicity, external fish pathology and bioaccumulation, and marine debris.

The assessment period was targeted for summer (July-August) since populations of demersal fish and benthic infauna are expected to be more stable in summer than in winter or spring, and sampling is less likely to be interrupted by bad weather. In addition summer sampling corresponds to the "index period" used in the EMAP program.

Due to financial and logistical constraints, it was not possible to collect enough samples to characterize all indicators in all subpopulations. Given available resources, it was possible to take enough trawls to characterize fish assemblages, fish pathology, and marine debris in the three geographic zones, three depth zones, and cumulative outfall areas. Sediment toxicity and fish tissue contamination were characterized for the cumulative outfall areas and for the SCB as a whole. Water quality, sediment characteristics and benthic invertebrate assemblages were characterized for all subpopulations.

STATION SELECTION

The stations to be sampled were chosen using a modification of the sampling protocol used by EMAP for estuaries in the Louisianan province (Summers *et al.* 1993). First, to have enough grid points to produce approximately 40 stations per subpopulation, the EMAP grid was enhanced 7x7x7 fold. Then, stations were selected by a process that involved (1) randomization of the grid points, (2) random selection of grid points, and (3) random placement of a sampling point around each grid point. The grid points were randomized using a process that produced an optimum spatial spread of samples, while retaining the randomness needed for statistical evaluation. To do this, each point in the grid was given a number and spatial address. The spatial address preserved information about the original location of the point. The numbering was in groups of seven and of powers of seven. Grid points were then completely randomized within the smallest group, and the groups were randomized within the next larger group. In this way the order of points was randomized but geographically adjacent points remained close to each other during randomization.

To select grid points for benthic and water quality sampling from the total population of grid points, each grid point (in random order) was assigned an inclusion probability based on the number of samples needed in the area in which the point was located. For instance, grid points in the river discharge areas were given larger inclusion probabilities than points in nondischarge areas because more samples per unit area were needed. To choose the first grid point, the inclusion probabilities were sequentially summed, starting with the first point, until the cumulative probability was greater than or equal to one. Then a point was randomly chosen from the group of points with a cumulative probability of one or less. Subsequent grid points were chosen by adding 1 to the first randomly chosen probability (= r) and the number of points selected (i.e., grid points were selected at r + 1, r + 2, etc.).

To select grid points for the trawl sampling, which would only be analyzed for depth, geographic, and outfall subpopulations, the same procedure was used; however, the selection process included only the grid points selected for benthic and water quality sampling. Finally, the stations to be sampled for sediment toxicity and tissue analysis were selected from the grid points chosen for trawling.

SAMPLING LOGISTICS

Five organizations were responsible for collecting samples: City of Los Angeles, Environmental Monitoring Division; City of San Diego, Metropolitan Wastewater Department, County Sanitation Districts of Los Angeles County, County Sanitation Districts of Orange County; and the Southern California Coastal Water Research Project (SCCWRP). The number of samples was based on the number of samples each agency collects in the summer quarter. Due to institutional restraints, such as insurance and travel restrictions, it was necessary to divide the sampling effort geographically. South of Point Dume, lines were drawn to divide the area into sample areas. Each agency sampled the geographic area that included their monitoring grid. SCCWRP, through contracts to MEC Analytical Systems, Inc., and MBC Applied Environmental Sciences, sampled the area north of Point Dume.

Between July 11 and August 22, 1994, water quality profiles were taken at 261 stations, benthic grab samples were taken at 252 stations, and trawls were taken at 114 stations. Since the participating organizations have separate field crews for each type of sampling, each station was sampled three times: once with a conductivity-temperature-depth profiler (CTD), once with a Van Veen grab sampler, and once with a otter trawl.

QUALITY ASSURANCE AND QUALITY CONTROL

Since five agencies were involved with sample collection and analysis, procedures for intercalibration and quality assurance/quality control (QA/QC) were of paramount importance. A field coordination team agreed on standard methods for collecting field samples and prepared a field operations manual for the survey (SCBPP, FCT 1994). The manual provided detailed descriptions of all procedures for sample collection and field analyses, including detailed QA/QC procedures and criteria.

Because methodologies (including instrumentation) differ widely among laboratories, the Committee opted to undertake a performance-based approach for sediment chemistry. The Committee envisioned a two-step process for implementing performance-based standards for laboratory analyses. In the first step, the laboratory would demonstrate the ability to perform the analyses by providing documentation about the procedure to be used, including documentation of the method detection limits and calibration curves, and by blind analysis of a known sample. Following successful performance in the first phase, the laboratory would continue to demonstrate performance by participation in interlaboratory intercalibration exercises, repeated analyses of Certified Reference Materials, calibration checks, and analyses of laboratory reagent blanks and fortified samples.

Intercalibration procedures for sorting and identification of specimens for benthic samples were developed by the specialty group for benthic sampling. Measurement Quality Objectives (MQOs), procedures for redressing problems, and standard reporting requirements were established for each stage of processing. Considerable effort was taken to ensure taxonomic consistency between the laboratories. Workshops under the auspices of the Southern California Association of Marine Invertebrate Taxonomists (SCAMIT) were held every two to four weeks to examine infaunal specimens and discuss taxonomic problems.

DATA ANALYSIS AND INTERPRETATION

The sampling design is structured so that the extent and magnitude of change can be compared across subpopulations; that is, the areal extent of some parameter (e.g., toxicity) can be compared in the north, central, and southern zones or in outfall and nonoutfall areas. It is also possible to compare parameters, e.g., the spatial extent of toxicity and sediment with DDT higher than 3 ppb.

Determining the areal extent is a two-step process. First, the Horvitz -Thompson estimation (Cochran 1977) is used to develop a cumulative distribution function (CDF) from the area-weighted data (Appendix 1). The CDF shows the range of indicator values of an indicator as well as information about central tendency and extreme values. Then a threshold value is selected. The threshold value divides natural and changed values. Based on the threshold value, the percent area exceeding the threshold can be estimated.

The process of selecting a threshold value will be simple for some indicators and more difficult for others.

For toxicity, the threshold can be set at the point where there is a statistically significant change in an experimental endpoint. For some sediment contaminants (e.g., silver), the thresholds can be chosen from estimates of the concentration of the compound expected to cause toxicity (Long and Morgan 1990). However, for a compound such as TOC, there is no definitive method to determine a threshold between natural and unnatural values. Regression analysis can be used to identify stations with higher than expected concentrations (Bergen *et al.* 1995, Daskalakis and O'Connor 1995). Then the sediment chemistry data along with data from other sources can be used to determine if increased concentrations are associated with anthropogenic activities. For demersal fish and benthic infaunal assemblages, the threshold will be based on an index (one for fish and one for infauna) that summarizes changes in community parameters, such as number of species and number of individuals. If the absolute value of the threshold is not clear, the Steering Committee will use all the available information to select a threshold.

SUMMARY

The SCBPP is a cooperative sampling effort intended to provide synoptic information about the ecological condition of the mainland shelf of Southern California.

The sampling design was based on a design developed by USEPA EMAP. Sampling points were chosen by random placement of a grid of points over the sampling area, followed by random selection of grid points and random placement of stations around the grid points. The grid ensured that the sampling effort was well distributed over the study area while the random placement of the grid and random selection of sampling stations provided randomness needed for statistical inference. Moreover, since the interpoint distance of the grid was known, each sampling point represents a known area so that the amount of area with a particular characteristic, e.g., the area with total organic carbon greater than 2%, can be estimated.

The sampling was designed for assessing ecological conditions in three geographic zones, three depth zones, the areas around the four largest municipal wastewater outfalls (treated cumulatively), the areas within 3 km of 11 rivers and stormdrains (treated cumulatively), Santa Monica Bay, and the area around the HTP outfall. The assessment of ecological condition will be based on measures of water quality, demersal fish and benthic infaunal assemblages, sediment characteristics, sediment toxicity, fish pathology and bioaccumulation, and marine debris.

The extent and magnitude of change between subpopulations will be measured by (1) developing a cumulative distribution function for a parameter and (2) selecting a threshold value to divide natural from changed. Then the percent area that has been changed will be estimated.

Analysis of data is in progress. Survey results will be presented in a series of reports, including an assessment of ecological conditions on the Southern California mainland shelf and an evaluation of the SCBPP survey design.

Return to Data Analysis

The Cumulative Distribution Function A cumulative distribution function (CDF) is the progressive summation of a distribution function. A distribution function presents the amount (e.g., frequency, percent of population, percent of area) for each category of a variable. The CDF presents the cumulative total (e.g., total percent area) for each category of a variable. This allows the determination of the amount of the distribution equal to or less than the category. Sokal and Rohlf (1995) describe the distribution function and cumulative distribution function for a normal distribution. For the SCBPP, the distribution function is

R0011328

the percent of the area of the SCB or of one of the subpopulations for the category of the variable; for instance, it is the percent of area with DDE of 10 ppb, 20 ppb, ... up to the maximum measured. The CDF shows the percent of area with DDE equal to or less than 10 ppb, 20 ppb, etc. In the SCBPP survey, because some areas (e.g., around the HTP outfall) were more intensively sampled than others, the number of points per unit area and the amount of area that the points represent varies. Therefore, the area weight, (i.e., the amount of area represented by the point) must be used to calculate the CDF. The CDF for parameter value x (e.g., DDE = 30 ppb) is the sum of the area weights for observations with values equal to or less than x divided by the sum of all the area weights in the population or:

$$cdfx = \text{Total } x\ (\text{areawt}_i)/\text{Total } (n)\ \text{areawt}_i)$$

where: *cdfx* = estimate of CDF for parameter value x
(e.g., DDE = 40 ppb)
areawt_i = area weight for parameter value x
n = total number of observations
x = parameter value

Impacts of Stormwater Discharges on the Nearshore Environment of Santa Monica Bay

Steven Bay and Kenneth Schiff

ABSTRACT

This report describes the first-year results of a three-year study to investigate the receiving water effects of stormwater discharges from Ballona and Malibu Creeks. Surface water and sediment samples were collected for analysis following four storm events in January and February, 1996. Surface water toxicity was present offshore of Ballona Creek and was proportional to the concentration of runoff in the plume. Deposition of runoff particulates offshore of both Ballona and Malibu Creeks was indicated by spatial changes in sediment characteristics, such as grain size and total organic carbon (TOC). Similar spatial patterns were present in samples collected after storms and during dry weather, indicating that the changes were persistent. Sediment contaminants, such as lead, total polychlorinated biphenyl (PCB), and total polycyclic aromatic hydrocarbon (PAH), were elevated at stations located nearest the mouth of Ballona Creek. Sediment contamination was less offshore of Malibu Creek and did not show a pattern related to stormwater discharge. The first-year results have not detected stormwater-related changes in benthic infaunal community assemblages or sediment toxicity near the discharges.

INTRODUCTION

Urban runoff has been shown to discharge large quantities of contaminants (Schiff and Stevenson 1996; SCCWRP 1990, 1993a) and can be toxic to marine organisms (Bay *et al.* 1996). Unlike municipal wastewater, stormwater runoff enters the nearshore marine environment, often through estuaries or wetlands, wholly untreated. New regulations and increased monitoring efficiency are enhancing in-channel measurements, more accurately characterizing wet weather inputs and the effectiveness of best management practices (LACDPW 1996). However, virtually no information exists on contaminant fates and their biological effects once wet weather discharges enter the marine environment.

The fates and effects of contaminants on the receiving environment cannot be predicted from in-channel measurements alone. The mixing of the freshwater plume with seawater alters the chemical state and solubility of some contaminants; particle aggregation and settling are also affected in complex ways. The nearshore environment is very dynamic, with waves and currents having strong influences on the deposition and distribution of stormwater contaminants. Much of what is known about the benthic effects of contaminants has been learned from studies of offshore ocean wastewater outfalls. These systems differ markedly from stormwater discharges in terms of discharge composition, variability, and receiving environment characteristics. Directed studies of stormwater discharge are needed to identify the contaminants of concern and their biological effects.

The research described in this report represents the initial results of a three-year program to investigate the correlation between stormwater discharge and environmental effects. This study, conducted in collaboration with the University of Southern California (USC), USC/SeaGrant, and the University of California at Santa Barbara (UCSB), has three principal objectives. The first objective is to measure the dispersion and mixing of stormwater plumes in Santa Monica Bay (this work was conducted by our collaborators and is not presented herein). The second objective is to examine the magnitude and characteristics of water column and sediment toxicity near stormwater discharges. This work element examines potential contaminant effects and provides an important link with similar data obtained from upstream measurements. The final objective of this project is to measure the impacts to benthic communities in the immediate vicinity of the discharge. This report presents the results of toxicity and benthic impact testing during the first wet season of sampling. Upon completion of the three-year study, an integration of these results with data obtained from our joint investigators will appear in a future issue of the Southern California Coastal Water Research Project (SCCWRP) Annual Report.

MATERIALS AND METHODS

The Ballona Creek and Malibu Creek watersheds were selected for evaluation in this study. Both watersheds are approximately the same size. Together, (Figure 1) they encompass over half of the entire Santa Monica Bay drainage area (Stenstrom and Strecker 1993). The Ballona Creek drainage basin is highly urbanized; 83% of the watershed is developed and comprised of predominantly residential land use. Almost the entire channel is concrete-lined. Conversely, Malibu Creek is predominantly undeveloped; 88% of the watershed is open land and the creek is in a natural state. These differences in watershed characteristics, combined with localized diversity in rainfall, lead to large variations in flow and pollutant loading to the ocean, even for the same storm event (LACDPW 1996). By comparing impacts associated with each watershed, we hope to distinguish between effects arising from urban and nonurban stormwater runoff.

Sampling and Sample Handling

The sampling program consisted of two phases. In the first phase, sediment samples were collected in November 1995 and January 1996 (Table 1) to examine the spatial extent of runoff-affected sediment offshore of each creek. These data were used to select sediment sampling stations for the second phase, consisting of sediment and water sampling during or soon after storms (wet season sampling). Wet season sampling was also coordinated with plume dispersion studies conducted by USC and UCSB. Sample dates (Table 1) and methods varied throughout the study because of the unpredictable nature of storm events, the limitations of ship availability, and the objectives of different study components. Water samples for toxicity were collected as soon as possible following a storm (8 to 48 h), while sediment samples were collected 7 to 12 d following target storms in order to allow suspended particles to settle.

The spatial survey consisted of two grids (13 to 15 stations each) surrounding the mouths of Ballona and Malibu Creeks (Figure 1). Stations were separated by approximately 2 km and extended 2 to 4 km upcoast or downcoast from each creek mouth. Sampling depths were approximately 10, 25, and 40 m. The spatial survey was completed prior to significant flow from either creek during the 1995 to 1996 wet season.

Wet season sampling was accomplished after four storm events during the 1995 to 1996 wet season (Table 1). Based upon the results of the spatial survey, four stations offshore of each creek mouth were targeted for post-storm sediment chemistry and infaunal sampling (Figure 1). Samples were taken at approximately 25 m at all eight stations to reduce any depth-related bias. One additional sediment sample was collected at each site on February 28 for sediment toxicity and chemistry testing. Continuous profiles of water column temperature, salinity, dissolved oxygen, and transmissivity were also taken at each sediment collection station (these data are not presented in this report).

Sediments were collected using a 0.1 m2 modified Van Veen grab from either the R/V LaMer or R/V Sea World. For contaminant analysis, only surficial sediments (the top 2 cm) from undisturbed grabs were collected. Sediment samples were placed in separate containers for grain size, TOC/total nitrogen(TN), trace organics, and trace metals analysis These samples were taken from the same grab but were not homogenized prior to splitting. Samples were either stored under refrigeration (grain size) or frozen until analyzed. Samples for sediment toxicity tests were taken from replicate grabs and stored under refrigeration.

For benthic invertebrate community (infaunal) analysis, entire sediment grab samples were gently washed through a 1 mm mesh stainless steel screen on the boat. The organisms retained on the screen were "relaxed" using MgSO4 (Epsom salts) in seawater. After 30 min, the sample was fixed with 10% borax-buffered formalin and returned to the laboratory. After 24 h, samples were rinsed with freshwater to remove formalin and preserved in 70% ethanol.

- Surface water samples (upper meter) were collected during each of the four storm events (Table 1). Five water samples were obtained from the Ballona Creek area during each event. Fewer samples were collected off Malibu Creek, due to difficulties in accessing the study area and the relatively small volume of runoff found in the surface water. Water sampling methods varied because of the necessity to use different boats for sampling operations. Surface water samples for January 31 and February 1 were collected by dipping into the water a glass jar attached to the end of an aluminum pole. Water samples for other storms were obtained with a submersible pump deployed off the side of the boat. Both sampling techniques may have captured portions of the sea [illegible] Both sampling techniques may have captured portions of the sea surface [illegible] no special effort was made to sample this portion of the water column. Samples were stored under refrigeration at SCCWRP and tested within 48 h.

- Locations of the water sampling stations were determined during each cruise and varied between events. Salinity measurements were used to select locations that represented a gradient of runoff concentration, usually aligned along a transect running between the creek mouth and a reference station (no apparent runoff) located up to 6 km offshore. Deviations from the general sampling plan occurred in response to available ship time, weather conditions, and the extent of the runoff plume.

Analytical Chemistry

Grain Size Analysis

Sediment grain size was measured using a Horiba Model LA-900 laser-scattering particle size distribution analyzer. The sediment sample was first homogenized, then a representative aliquot was passed through the instrument and the particle sizes were determined by detection of scattered (refracted and reflected) laser light.

Total Organic Carbon, Total Nitrogen and Total Volatile Solids Analysis

The TOC/TN measurements were conducted using a Carlo Erba 1108 CHN elemental analyzer, according to methods developed by SCCWRP (1993b). Sediment samples were homogenized, dried, and then digested with acid to remove inorganic carbon. Samples were then oxidized by combustion in the analyzer, and the evolved carbon and nitrogen were quantified using a thermal conductivity detector.

Total volatile solids (TVS) was measured using a Thermolyne Model 62700 muffle furnace. Sediments were dried at 60 C overnight, combusted at 500C, and then weighed after cooling. The TVS was determined from the net loss in weight after combustion. While not as specific a measure as TOC, TVS has been shown to be significantly correlated with TOC measurements in reference areas of the Southern California Bight (SCB) (Thompson *et al.* 1993).

Metals Analysis

Samples were prepared for metals analysis in accordance with Environmental Protection Agency (EPA) Method 3051 (EPA 1996). Dried sediment samples were digested using a nitric acid:hydrochloric acid mixture. Concentrations of aluminum, arsenic, beryllium, cadmium, chromium, copper, iron, lead, mercury, nickel, selenium, silver, and zinc were determined using a Hewlett Packard Model 4500 inductively coupled plasma-mass spectrometer (ICP-MS) according to EPA Method 200.8 (EPA 1991).

Pesticides and Polychlorinated Biphenyls

Analytical methods for chlorinated pesticides (DDTs) and PCBs followed EPA protocols (EPA 1986 or EPA 1983). Six DDT isomers and metabolites (o,p'-DDT, p,p'-DDT, o,p'-DDE, p,p'-DDE, o,p'-DDD, p,p'-DDD) and 27 individual PCB congeners (Congeners 8, 18, 28, 29, 44, 50, 52, 66, 77, 87, 101, 104, 105, 118, 126, 128, 138, 153, 154, 170, 180, 187, 188, 195, 201, 206, and 209) were quantified. Samples were also examined for 12 additional chlorinated pesticides (isomers of chlordane and lindane, hexachlorobenzene, and derivatives of endosulfan), but none of these compounds were detected for any sample in this study.

Specific methodological details for the sediment analyses can be found in SCCWRP (1994) or Zeng and Khan (1995), but a general description of the procedure follows. Samples for DDT and PCB analysis were homogenized and then centrifuged to remove pore water. Following extraction by methylene chloride, samples were cleaned of interfering compounds using activated copper addition and preparative columns of alumina and silica. Extracts were concentrated to 1 mL and injected into a Hewlett Packard Model 5890 II gas chromatograph equipped with a 60m by 0.25 mm in diameter (0.25 m film thickness) DB-5 fused silica capillary column and a 63Ni electron capture detector (GC-ECD) for analyte measurement.

Polycyclic Aromatic Hydrocarbons

The PAH analyses were conducted using EPA protocols (EPA 1986 or EPA 1983), which quantify 28 different PAHs. Specific methodological details can be found in Zeng and Khan (1995) or SCCWRP (1995a). Analysis was accomplished by injecting a portion of the same solvent extract used for the chlorinated hydrocarbon measurements into a Hewlett Packard Model 5890 II gas chromatograph equipped with a DB-5 column (60m by 0.25 mm in diameter by 0.25 m film thickness) and a Hewlett Packard Model 5870 mass selective detector in electron impact ionization mode.

Quality Assurance

Each batch of samples for metals or organics analysis included blanks, spiked samples, and standard reference materials to monitor method performance and recovery. Instrument calibration was verified prior to analyzing each batch of samples, and internal standards were added to each solvent extract to correct for variations in instrument performance.

Infaunal Community Analysis

Each infaunal sample was sorted into six different taxonomic groups: annelids, molluscs, arthropods, ophiuroids, miscellaneous echinoderms, and "other phyla." A minimum of 10% of each sample was re-sorted by another person to detect missed organisms. If sorting efficiency was less than 95%, then the entire sample was re-sorted. Biomass measurements were obtained by weighing each group of organisms to the nearest 0.01 g (wet weight).

Each organism was identified to the lowest taxon possible, using standardized nomenclature developed for the SCB (SCAMIT 1996). Species-level identifications were assigned by scientists who were experts in their respective taxonomic group and were active members of the Southern California Association of Marine Invertebrate Taxonomists (an interagency quality assurance group). Ten percent of all samples were re-identified and enumerated by a second taxonomist for quality assurance. All new species encountered were maintained in a voucher collection located at SCCWRP.

Toxicity Measurement

Three types of environmental samples were tested for toxicity: surface water, sediment interstitial water, and whole sediment. Surface water samples were not filtered or centrifuged before testing. Brine (prepared by the partial freezing of seawater) was added to samples with a salinity below 30 g/kg to adjust the salinity to 34 g/kg. Each water sample was tested at a single concentration; i.e., 100% sample or the maximum concentration after salinity adjustment. Four replicates of each sample were tested. The percentage of runoff present in each toxicity test sample was calculated from the initial salinity value and included dilution resulting from salinity adjustment. This calculation assumed that the percent of runoff present in the original sample was inversely proportional to the relative salinity, expressed as a percentage of the background value (outside of plume).

Interstitial water was extracted from the sediment samples by centrifugation twice at 3,000 x g for 30 min. Laboratory seawater was added to the samples to produce three test concentrations containing 100, 50, and 25% interstitial water. Three replicates of each concentration were tested.

Water quality measurements conducted during each toxicity test consisted of salinity, dissolved oxygen, pH, and total ammonia content. Measurements were made using electrodes that were calibrated daily. Measurements were made at the start of each test and at the end of the 10-d amphipod survival test. Electronic thermometers were used to measure water temperature continuously throughout the duration of each experiment.

- *Sea Urchin Fertilization*

All samples of surface water and interstitial water were tested for toxicity using a sea urchin fertilization test (Chapman [illegible] test consisted of a 20-min exposure of sperm to the samples at 15 C. Eggs were then added and given 20 min for fertilization to occur. The eggs were preserved and examined later with a microscope to assess the percent fertilized. Toxic effects are expressed as a reduction in fertilization percentage.

Purple sea urchins (*Strongylocentrotus purpuratus*) used in the tests were collected from intertidal areas in northern Santa Monica Bay. The tests were conducted in glass vials containing 10 mL of solution.

- A negative control (0.45 m and activated carbon filtered natural seawater from Redondo Beach) and a brine control (distilled water containing 50% brine) were included in each test series for quality assurance purposes. A reference toxicant test (copper in seawater) was conducted with each batch of samples to document sea urchin health.

- *Amphipod Survival*

The toxicity of sediment samples was assessed by measuring the survival of amphipods following a 10-d exposure period. Test methods followed standard guidelines (ASTM 1991). A one-liter sediment sample was removed from storage and manually homogenized with a large plastic spoon. A 2 cm layer of sediment was added to five replicate one-quart glass canning jars for each station. Approximately 750 mL of lab seawater, adjusted to a salinity of 30 g/kg, was added to each jar. The jars were fitted with aeration tubes and allowed to equilibrate overnight before the addition of the amphipods.

Twenty amphipods (*Rhepoxynius abronius*) were added to each jar. The test animals were collected from Puget Sound, Washington. A sample of collection site sediment was also included in the test, as a negative control. The test was conducted at 15C, under constant illumination. Surviving animals were removed from the sediment at the end of the exposure by sieving and were counted to determine the percent survival. Reburial success was not determined. A concurrent reference toxicant test consisting of a four-d exposure to cadmium in seawater was conducted to document amphipod health.

Data Analysis

The sea urchin fertilization test results were normalized to the control (lab seawater) response in order to compensate for variations in response between experiments. Normalization was accomplished by dividing the mean fertilization for each sample by the control fertilization percentage, then expressing the resulting fraction as a percentage.

Sediment characteristics and infaunal community parameters at the 25 m stations were summarized by calculating the mean and 95% confidence interval of all wet weather samples for each station (n = 3 or 4 for Malibu or Ballona, respectively).

RESULTS

Surface Water Effects

Toxicity

Toxicity was present in surface water samples collected near the mouth of Ballona Creek during three of the four sampling events . No Table 2toxicity was detected in water samples collected on January 22. Samples from this event contained little runoff (<4%), whereas water samples from later storm events contained up to 44% runoff (Table 2). Toxicity was always detected in water samples containing greater than 10% runoff, with samples containing the most runoff having the greatest toxicity (Table 2). The relatively small volume of runoff present in the January 22 samples was probably due to a delay in collection following the storm.

Toxicity was usually present in water samples collected nearest the mouth of Ballona Creek (Figure 2). Toxic water samples were restricted to a relatively small zone (<2 km offshore of Ballona Creek) on January 31 and March 5. A greater area of toxicity was present on February 21, with toxic water present up to 4 km from the mouth of Ballona Creek. Too few samples were collected to examine the longshore

...samples were collected to examine the longshore ...

No toxicity was detected in water samples collected near the mouth of Malibu Lagoon during three storm events. Toxicity was not expected to be found in the Malibu samples, since they contained less than 2% runoff (Table 2).

Sediment Effects

Spatial Patterns

Sediments from the spatial survey were analyzed for indicators of grain size (percent fines) and organic material (percent TVS). These parameters were examined to identify deviations in general sediment characteristics caused by stormwater particle deposition near each creek. Since most runoff contaminants associate with stormwater organic material or silt/clay particles, stations having elevated sediment fines or TVS (relative to nearby areas) were assumed to represent locations most likely to contain the highest concentrations of stormwater-derived contaminants.

At 25 m depth, sediments directly offshore of the mouth of Ballona Creek showed a distinct increase in percent of fine-grained material, relative to sediments collected at similar depths to the north or south (Figure 3). The proportion of sediment fines doubled offshore of Ballona Creek (40%) relative to the fines measured in sediments 4 km upcoast (22% fines, Table 3). Although less pronounced, this longshore spatial pattern also reached to 40 m depth, but was not evident at a depth of 10 m. Similarly, a spatial pattern in the sediment TVS content was associated with Ballona Creek discharges. At 25 m depth, TVS was approximately 75% greater in sediments sampled directly offshore of the creek (2.5%) compared to sediments 4 km upcoast (1.4%, Figure 3).

The spatial pattern in grain size or TVS at Malibu Creek was less distinct than at Ballona Creek. Background levels of TVS and fines in the Malibu study site were higher than off Ballona Creek, potentially obscuring patterns of sediment deposition from Malibu Creek. TVS provided the strongest indication of a spatial pattern produced by Malibu Creek discharges; TVS at 25 and 40 m depth directly offshore of the creek mouth was greater than in sediments collected at similar depths to the east or west (Table 3). The spatial pattern extended 2 to 4 km upcoast and downcoast. Similar to the Ballona Creek site, data for the 10 m samples showed little evidence of discharge-related changes.

Since the spatial patterns in sediment characteristics (TVS or fine-grained sediment) were greatest at a depth of 25 m offshore of Ballona Creek, benthic sampling stations were established at this depth for the wet season (Figure 1). All stations, including Malibu Creek sites, were established at the same depth to eliminate any depth-related bias among or between creek sites.

Sediment Concentrations

Ballona and Malibu Creeks

The analytical results for the four sets of post-storm sediment samples were used to determine the wet season average concentrations of sediment characteristics and contaminants directly offshore of the mouths of Ballona and Malibu Creeks. Sediments sampled at Malibu Creek contained twice the fines, 50% more TOC, and 25% more TN than Ballona Creek (Table 4). Of the 14 different inorganic/metal constituents, 7 were substantially greater in sediments offshore of Malibu Creek (Al, Be, Cd, Cr, Fe, Ni, Se); 3 constituents were substantially greater in sediments offshore of Ballona Creek (Pb, Hg, Ag); and the remaining 3 constituents were roughly similar in the sediments offshore of the two drainages (As, Cu, Zn). Ballona Creek had significantly higher sediment concentrations of total DDT, total PCB, and total PAH than Malibu Creek.

The differences in general sediment characteristics between the two drainage areas is of fundamental importance. The sediments offshore of Malibu Creek were significantly finer than sediments offshore of Ballona Creek. Concentrations of common marine inorganic constituents such as aluminum and iron were also highest offshore of Malibu Creek. Concentrations of these metals are typically high (in the were also highest [illegible] Concentrations of these metals are typically high (in the percentage range) and are related to the degree of geological mineralization (e.g., alumina-silicate silts and clays).

Inorganic contaminants offshore of Ballona Creek followed a pattern across the gradient of stormwater influence that was similar to the pattern observed in the spatial survey. Concentrations of stormwater-associated metals such as lead, copper, and zinc were significantly higher in sediments sampled directly offshore of the creek mouth, and decreased upcoast and downcoast (Figure 4). Wet season averages at distant stations 4 km upcoast were between 41% (for copper) and 70% (for zinc) of average concentrations directly offshore of the Ballona Creek mouth.

Organic contaminants offshore of Ballona Creek also followed a similar pattern across the gradient of stormwater influence (Figure 4). Total DDT, total PCB, and total PAH were highest in sediments sampled directly offshore of the creek mouth and concentrations decreased upcoast and downcoast. Wet season averages at distant stations 4 km upcoast were between 6% (for total PAH) and 41% (for total DDT) of average concentrations directly offshore of the Ballona Creek mouth.

Inorganic contaminants offshore of Malibu Creek followed a pattern across the gradient of stormwater influence similar to the pattern described for general sediment characteristics. Figure 4 shows the pattern for copper and lead. Wet season averages at distant stations 4 km upcoast were between 58% (for copper) and 80% (for zinc) of values measured directly offshore of the Malibu Creek mouth. Except for lead, metals were highest in sediments sampled 2 km downcoast from the Malibu Creek mouth. For lead, sediment concentrations were similar between stations within 2 km of the Malibu Creek mouth. The distribution of sediment contaminants offshore of Malibu Creek was less clear than at Ballona Creek.

Organic contaminants offshore of Malibu Creek generally did not follow a pattern across the gradient of stormwater influence (Figure 4). No consistent trend was established for the data, and organic contaminant concentrations were very low overall. The highest wet season concentrations of total PCB and total PAH were not found directly offshore of Malibu Creek, but 4 km downcoast. However, the lowest values for all three organic compound classes were regularly observed 4 km upcoast from the Malibu Creek mouth.

Identification of Enriched Contaminants

Unlike synthetic organic pollutants such as DDT or PCB, which are strictly anthropogenic in origin, trace metals are naturally occurring elements that are part of the earth's crustal matrix. Most metals, including prominent stormwater constituents like copper, lead, and zinc, have native concentrations within the detectable range of measurements for this project. Natural variations in sediment metal concentrations must be accounted for before anthropogenic enrichment can be identified. To compensate for these naturally occurring concentrations, iron was used as a reference element to establish baseline conditions and to evaluate anthropogenic enrichment of sediments (see *Iron as a Reference Element for Determining Trace Metal Enrichment in California Coastal Shelf Sediments,* this report). When the 1995to 1996 wet season lead data were normalized to iron, many Ballona Creek samples contained higher-than-expected concentrations (Figure 5), indicating enrichment. Interestingly, the most enriched concentrations (between 24 and 30 g/dry g) all occurred at the site directly offshore of the Ballona Creek mouth. All lead concentrations in Malibu Creek samples fell within the expected relationship with iron, indicating that these values were probably due to natural variations in sediment composition. Copper and zinc concentrations for Malibu Creek and Ballona Creek offshore sediments fell within the baseline relationship (data not shown), indicating that anthropogenic enrichment of these metals was not present.

Toxicity

Amphipod survival was high (89 to 98%). which indicated an absence of toxicity in all sediment samples (Table.5). The concentration of ammonia in the water overlying the sediment was slightly higher for stations within 2 km of either creek, possibly reflecting the organic enrichment identified by chemical analysis. These ammonia concentrations were not toxic and were within the range typically found in sediment toxicity tests.

Interstitial water from [illegible] sediment samples was nontoxic to sea urchin sperm (Table 5). Only interstitial water sampled from one station (6 km) upcoast of Ballona Creek was toxic, reducing fertilization by about 60% (relative to the control sample).

Infaunal Community Structure

A total of 30 samples were sieved, sorted, weighed, and identified for infaunal community structure analysis. A total of 8,531 individuals were identified, comprising 389 different taxa. About 90% of the total abundance at each creek represented species common to both sites. The dominant species recorded at each creek site included the polychaetes, *Spiophanes missionensis* and *Paraprionospio pinnata*; the mollusc, *Tellina modesta*; and the amphipods, *Amphideutopus oculatus* and *Ampelisca brevisimulata*. Interestingly, the Malibu Creek site also contained some organisms (e.g., *Amphiodia urtica*), which are typical of fine-grained habitats common in deeper water (Bergen 1995).

For the entire wet season, stations directly offshore of Ballona Creek and Malibu Creek at 25 m depth had similar diversity (Shannon-Wiener H'), evenness (Pielou's J), and species richness (Table 6). Abundance was slightly reduced offshore of Ballona Creek compared to Malibu Creek.

Examination of trends across the gradient of stormwater influence did not reveal any significant relationships to stormwater discharges (Table 6). Instead, mean abundance decreased moving upcoast of both creeks. Similarly, species richness was highest downcoast and lowest upcoast of the Ballona Creek mouth. Species richness was fairly constant across the gradient of stormwater influence at Malibu Creek; however, the station 2 km downcoast showed high variability. Diversity and evenness measures showed no strong trends between stations.

DISCUSSION

Results from the first year of this study, though preliminary, provide sufficient data to address several important questions regarding runoff effects in receiving waters.

Do stormwater discharge plumes contain toxic materials?

Study results indicate that surface water toxicity in the Ballona Creek area is present when runoff concentrations are greater than 10%. This finding correlates well with the level of toxicity measured in samples of Ballona Creek stormwater collected during the same storms (see *Toxicity of Stormwater from Ballona and Malibu Creeks*, this report). The average EC50 (concentration causing 50% reduction in fertilization) of Ballona Creek stormwater samples was 16%. Stormwater composition is highly variable, however, so future results may modify estimates of in-channel and receiving water toxicity.

The area offshore of Ballona Creek receives contaminant inputs from other sources (e.g., industrial and municipal effluents, marinas, and aerial fallout) that could contribute to water column toxicity in the area. However, the spatial pattern and magnitude of toxicity between the two sites, are consistent with Ballona Creek being the dominant source of toxicity. A further correlation between receiving water and Ballona Creek stormwater toxicity has been provided by studies conducted to characterize the toxicants. Preliminary toxicity identification studies indicate that the primary toxicants in both types of samples are similar (possibly divalent trace metals).

We were unable to obtain surface water samples from the Malibu area with runoff concentrations similar to those measured near Ballona Creek. Consequently, a direct comparison of the results between study areas cannot be accomplished at this time. It is not known whether the low runoff concentrations measured are representative of the area or reflect a deficiency in sampling methodology(e.g., delays in reaching the study site after a storm). It is anticipated that this issue will be clarified during the second year of sampling. Malibu Creek stormwater appears to be less toxic that Ballona Creek stormwater, with concentrations of 25% usually needed to produce toxic effects (see *Toxicity of Stormwater Runoff from Ballona and Malibu Creeks,* this report). Extending these results to surface waters, it is likely that less toxicity will be present offshore of Malibu Creek.

Does stormwater discharge produce long-lasting alterations in Santa Monica Bay sediment characteristics?

Discharges from Ballona Creek appeared to alter offshore sediment characteristics, as shown by spatial patterns in grain size and TVS. This pattern was persistent (present in dry weather) and could be observed at least 2 km upcoast and at 40 m depth. The spatial patterns at Malibu Creek were more complicated than at Ballona Creek, probably due to differences in oceanographic processes that modify particle fate, additional sources of fine-grained and organic-rich particles, and differences in background conditions.

Enhanced local deposition of silt/clay particles may be a common feature of stormwater discharges. Increases in sediment fines were observed at distances ≥ 2 km offshore of the Santa Clara River following large winter storms (Kolpack and Drake 1985). More research is underway at SCCWRP, USC, and UCSB to define the range of influence and deposition of storm discharged particles in Santa Monica Bay.

Are sediment contaminants elevated?

Sediments offshore of Ballona Creek were higher in concentrations of organic contaminants such as total DDT, total PCB, and total PAH as well as lead, a stormwater-associated metal. This contamination covaried with sediment characteristics across the gradient of Ballona Creek stormwater influence. Sediment concentrations of organic and inorganic pollutants were highest offshore of the Ballona Creek mouth and then decreased upcoast and downcoast.

Sediments offshore of the mouth of Malibu Creek were finer, contained more organic carbon and nitrogen, and had higher concentrations of some naturally occurring inorganic constituents. No evidence was found of enrichment of inorganic or organic contaminants from Malibu Creek stormwater.

Is sediment toxicity affected by stormwater runoff?

The results available to date show no evidence of sediment or interstitial water toxicity that can be attributed to discharges from Ballona or Malibu Creeks.

Amphipod survival was not reduced by exposure to sediments from any station. These results are similar to sediment toxicity data from the Southern California Bight Pilot Project (SCBPP), a regional study of coastal sediment quality conducted in 1994 (SCCWRP 1996). Sediment from 72 stations in southern California (in depths of 10 to 200 meters), including 13 sites in Santa Monica Bay, were collected and tested for toxicity using a similar amphipod survival test. No significant amphipod mortality was found at any of the SCBPP stations.

Amphipod survival tests do not provide a sensitive measure of sediment toxicity. Recent amphipod survival tests on highly contaminated sediments located near southern California wastewater outfalls failed to detect toxicity in samples that caused sublethal effects on other toxicity test species (SCCWRP 1995b) or contained altered benthic communities (SCCWRP 1993c). The 10-d amphipod survival test was used in this program because it is a reliable method commonly used in sediment quality studies, and toxic effects observed with this test are often associated with adverse benthic community changes.

Interstitial water toxicity measurements were included in this program to provide a more sensitive measure of sediment quality. Previous studies have detected interstitial water toxicity in sediments from southern California. Sea urchin fertilization was reduced in interstitial water samples from the Palos Verdes Shelf, with the magnitude of effects corresponding to sediment contamination level (SCCWRP 1995b). Toxic effects on sea urchin embryo development was produced by interstitial water from 15 of 72 samples tested during the SCBPP (SCCWRP 1996). The sea urchin embryo development test is usually more sensitive than the fertilization test when applied to interstitial water (Carr and Chapman 1995).

The sea urchin fertilization test of interstitial water did detect toxicity in one sample off Ballona Creek.

[illegible] Ballona Creek. This station was [illegible] of Ballona Creek (Figure 1), and the sediment chemistry data indicate this station is outside the area most influenced by the Creek (Figure 4). As increased interstitial water toxicity did not directly correspond to variations in sediment contamination, it is unlikely that the toxicity at this station is directly related to stormwater from Ballona Creek. All measured interstitial water quality parameters for this station (pH, dissolved oxygen, hydrogen sulfide, salinity, and ammonia) were within nontoxic ranges, although total ammonia concentration was higher than all other samples.

A cause for the interstitial water toxicity cannot yet be identified. This toxicity may indicate the presence of unidentified contaminants from an unknown source, or it may reflect temporary variations in sediment quality caused by natural factors or sediment storage. Additional research is needed to clarify the significance of the results. Additional toxicity tests of sediments from the Ballona Creek study area are in progress to assess the sublethal effects and bioavailability of the sediment-associated contaminants.

Are infaunal communities impaired?

No dramatic biological effects in the benthic community structure were evident from the first-wet season of sampling. No indications of a strongly degraded environment were found. Differences in community composition between sites offshore of the two creeks most likely resulted from variations in sediment characteristics (e.g., grain size) rather than differences in sediment-associated contaminants.

Due to relatively small sample sizes ($n \leq 4$), it is premature to reach conclusions regarding community disturbance at this time. However, these preliminary results are similar to previous reference surveys, which reported 273 to 358 individuals and 78 to 91 species per grab at depths of 30 m during the summer months (Thompson *et al.* 1987, 1993). Completion of the second year of infaunal analysis will provide a greater ability to detect subtle differences in communities across gradients of stormwater influence and determine whether the results are consistent over time.

ACKNOWLEDGMENTS

This project would not be possible without the dedication and effort of many outstanding SCCWRP employees, including: Dario Diehl, Darrin Greenstein, Andrew Jirik, Harold Stubbs, Liesl Tiefenthaler, Kim Tran, David Tsukada, Cherrie Vista, Charlie Yu, and Ann Zellers. Grain size analyses were performed by the City of San Diego Environmental Monitoring and Technical Services Department. Trace metal analyses were performed by CRG Environmental Laboratories (Los Angeles, California). MEC Analytical Systems, Inc. (Carlsbad, California) conducted the benthic biological analyses of the sediments. We also wish to acknowledge our co-investigators Patrick Hartney (USC Seagrant), Burton Jones (USC), and Libe Washburn (UCSB). This work was funded by the Los Angeles County Department of Public Works. We are grateful for the cooperation of their staff, including Jim Noyes, Gary Hildebrand, Bill DePoto, Tim Smith, and Mert Ramos.

INTRODUCTION

The Sacramento NPDES Stormwater Permittees include the County of Sacramento and the Cities of Folsom, Galt, and Sacramento. Under the terms of their NPDES permit, the Permittees operate a Comprehensive Stormwater Management Program, with the overall goal of reducing discharges of stormwater pollutants to the maximum extent practicable. The Comprehensive Program includes a New Development Management Program (NDMP) element, intended to improve the quality of stormwater runoff from areas of new development.

Under this program element, the Permittee agencies are responsible for approving the installation of stormwater controls in new developments within their respective jurisdictions. To help guide this approval process, the Permittees require additional information regarding specific structural control devices, especially with respect to the applicability and effectiveness of such devices for treatment of stormwater runoff in the Sacramento area. This report contains the results of research into the performance of selected on-site structural controls. Funding for this investigation was included within the 1998-99 Sacramento Stormwater Monitoring Program consultant contract.

Structural controls for improvement of stormwater quality can be considered to fall into two groups: proprietary devices that are manufactured off site and may be purchased for installation according to the manufacturer's specifications, and non-proprietary controls that can be designed and installed using information available in the public domain. The Permittees selected 14 proprietary devices and four public domain controls for this evaluation, each of which can be incorporated within a site development plan and installed on site. (Off-site or regional controls, such as detention basins, were not included in this investigation). Information was gathered for this report principally through available studies on the performance of public domain controls, and through a questionnaire requesting specific information about each product that was sent to manufacturers of proprietary devices. The information was then compiled and evaluated using a common format.

The Permittees plan to use the results of this investigation to identify stormwater controls considered acceptable for installation in new developments in Sacramento, and to identify areas where additional information is needed.

METHODS

The investigation was carried out under the direction of a working group involving representatives from the Permittee agencies and their consultants. The working group met initially in November 1998 to develop a working strategy and identify a preliminary list of controls for the investigation. In December a two-page questionnaire was prepared and mailed to manufacturers or distributors of the selected proprietary devices. The questionnaire requested specific information about applicability of the controls to the Sacramento area, existing installations, available sizes and capacities, and performance data and costs (see Appendix C for the questionnaire and cover letter). The questionnaire responses were compiled during January and February, 1999.

The investigation was originally intended to cover only proprietary structural controls thought to have potential for successful application in Sacramento. However, the working group determined that inclusion of several of the most commonly-used public domain controls would provide opportunities for appropriate comparisons of the leading available alternatives. The final list of controls established by the working group includes 16 proprietary devices and four public domain controls: grassy swales and three versions of media (sand) filtration technology.

Meanwhile, available information on the performance of the selected public domain controls was also compiled. Key sources of information (especially performance studies) on these controls included the *NDMP Stormwater Control Measure Study Literature Review Update* (LWA, 1998a), and other municipal and state agencies involved in stormwater management.

Working group members met briefly in February, 1999 to discuss the format to be used in evaluating the accumulated performance and cost data. The consultants then compiled the information in this format, and presented the preliminary results to a meeting of the full working group in March, 1999. Key issues addressed by the working group at this meeting included:

1. How to screen the results of the various available studies to determine whether there are sufficient data to demonstrate the effectiveness of the control, including whether the data should be considered to be technically valid?

2. How to "normalize" performance and cost data assembled from various disparate sources for direct comparisons of the various controls studied?

3. How to distill the normalized performance data into a "bottom line" judgement of the acceptability of each type of control for application in new developments in the Sacramento area?

The first issue, having to do with assessing data adequacy, proved to be somewhat complex. Several questions needed to be addressed in making this assessment:

- Do the study data represent hydrological conditions typical of the Sacramento area (in terms of typical storm depth, duration, etc.)?
- Does the influent quality used in the study represent typical new development runoff quality (and not, say, construction site runoff quality)?
- Were the data collected using appropriate techniques (e.g., using flow-weighted composite sampling instead of grabs, with proper attention to QA/QC issues) so as to accurately characterize influent and effluent quality?
- Are there enough data to permit conclusions to be drawn regarding performance and acceptability?
- Do the data indicate acceptable treatment performance in terms of pollutant removals?

To provide a protocol for screening data acceptability, criteria were developed to describe minimum acceptable data requirements, as follows:

- Studies to represent a minimum of two different sites, preferably a retail commercial site, a non-retail commercial site, and/or a residential site.

- Studies to represent typical new development runoff quality.

- Number of storms sampled at each site: 10
- Storm depth ranging from 0.15 to 1.5 inches
- Runoff duration ranging from 2 to 24 hours
- Average storm intensity ranging from 0.02 to 0.25 inches/hour
- Flow weight or time weight composite samples
- Analysis by a certified laboratory
- Removal efficiency with respect to TSS and zinc is reasonably equivalent to what is obtained with grass swales and sand filters. (TSS was chosen because of the preponderance of data. It is the most frequent constituent measured in all studies of stormwater treatment control measures, and serves as a surrogate for the pollutants that in stormwater tend to be primarily in the particulate form, like petroleum products, pesticides, lead, chromium, and phosphorus. Zinc was selected to represent the more soluble constituents, including itself as well as copper, cadmium, and the various nitrogen forms. Also, of the metals, zinc is typically present in runoff in concentrations sufficiently above the detection limit to allow meaningful evaluations of removal efficiency. However, the comparison of performance was limited to TSS at this time, because available data on zinc removal was limited.

The criteria for storm depth, duration, and intensity were selected by bracketing the values resulting from a first-flush design event established by the City and County for on-site control measures. The design event is a 2 year / 6 hour storm having an intensity of 0.18 inches/hour.

This protocol was then used to assess the adequacy of the available performance data for the selected controls. Most of the manufacturers of proprietary devices were able to provide some studies purporting to document the effectiveness of their products, but there were great discrepancies in the number and quality of these studies. Generally speaking, sufficient numbers of studies have been done for the public domain controls, typically by other local stormwater agencies, although the public record of studies for grassy swales is somewhat lacking.

The second issue, involving how to directly compare disparate performance and cost data for the various devices, was addressed by providing the means to "normalize" these data. Performance was assessed graphically, using a variable range of acceptable performance for TSS removal, with higher removal percentages expected at higher influent TSS concentrations. The acceptable range of TSS removal performance was derived principally from performance data produced by studies of properly functioning public domain controls. Cost was normalized to cost per unit flow treated (at approximately 0.1 cfs, 1 cfs, and 10 cfs) for each device where appropriate data were available. However, cost data were not used to assess acceptability of the products, only to provide a general comparison.

The bottom line issue of grading the products according to overall acceptability was addressed by determining the adequacy of the performance data, using the screening protocol described above, and then evaluating the valid data using the performance graph for TSS.

DESCRIPTIONS OF CONTROL MEASURES EVALUATED

Brief descriptions of the physical features, operation, application and limitations of the various proprietary and public domain control measures evaluated in this report are presented below. Summaries of product descriptions and target constituents for removal are presented in Table 1. Illustrations of each device, as available, are presented in Appendix B. For purposes of description, control measures are categorized based on principle of operation and design as follows:

- Wet Vaults
- Swirl Concentrators
- Deflection Screen
- Media Filters
- Drain Inlet Inserts
- Combined Systems
- Grass Swales
- Sand Filters (public domain)

WET VAULTS

Products in this category include the Jensen and Teichert Interceptors, Stormceptor, and Bay Saver.

Jensen and Teichert Interceptors

These two products are very similar in design, consisting of precast, rectangular concrete vaults. The units are typically multi-chambered with interior chambers separated by baffle walls. The number of vaults or vault units are increased to increase the flow capacity. The elevation of the outlet is such as to cause standing water in the vault, in the range of 4 to 4.5 feet. Total depth of the vaults, exclusive of risers, are in the range of 6 feet. Widths are on the order of 4 to 6 feet. These interceptors are essentially wet vaults or API (American Petroleum Institute) gravity separators. Hence, the units should be sized using criteria for either the settling of particles or flotation of petroleum products. Unless sized to treat the full design flow, these units require separate bypass piping to divert flows in excess of the unit flow capacity to avoid washout of material retained in the vault chambers. Oil adsorption pillows and coalescing plates can be added to the units to enhance capture of oils and grease. Both manufacturers produce several models with a range of flow capacities. Available flow capacities are listed in Table 7 in the Results section.

BaySaver and Stormceptor

Like the Jensen and Teichert Interceptors, these two products are essentially wet vaults designed to remove particulates and foatables, but they are round rather than rectangular. BaySaver and Stormceptor differ from each other in that the Stormceptor consists of one round manhole-like structure, and the BaySaver consists of two structures. The Stormceptor improves the removal of settleable solids over that of a conventional manhole by the use of a flow diverter. Up to a defined flow rate, the stormwater is diverted down and then laterally around the manhole. High flows are bypassed directly across the top of the diverter to the outlet. The diversion of high flows prevents the resuspension of previously settled material. There is some capacity at the top beneath the diverter for the accumulation of floatables.

In the BaySaver, gross settleable solids are removed in the first manhole. Like the Stormceptor, the Baysaver has a diverter, but it passes water into the second manhole where floatables are retained. Fine solids settle in both manholes. High flows are diverted through the second manhole. The purpose of the second manhole is to prevent the loss of previously accumulated floatables and fine sediments. Removal efficiency is highly affected by flow rate.

Both systems are sized for the peak of the specified design event with consideration for the total volume of the manhole or manholes. According to Stormceptor the volume also must be considered when determining efficiency. Both manufacturers produce several models with a range of flow capacities. Available flow capacities are listed in Table 7 in the Results section. The hydraulic capacity of each model offered by both manufacturers is greater than the treatment flow capacity.

Table 1. Summary of Product Descriptions

Product	Company	Product Description	Target Constituents[1]
Jensen Interceptor	Jensen Precast	A wet vault consisting of multiple chambers in series separated by baffles. Contains standing water, or dead storage, which enhances treatment.	Settleable and floatable solids, oil/grease and particulate pollutants
Teichert Interceptor	Teichert Precast	A wet vault consisting of multiple chambers in series separated by baffles. Contains standing water, or dead storage, which enhances treatment.	Settleable and floatable solids, oil/grease and particulate pollutants
BaySaver	BaySaver, Inc.	Consists of two standard manholes. The first is for removal of sediment and separation of floatables which are diverted by a special device into the second manhole for storage. Diversion device passes extreme flows through the unit.	Settleable and floatable solids, oil/grease and particulate pollutants
Stormceptor	CSR Hydro Conduit	A weir insert is placed in a round manhole vault to improve hydraulics thereby improving removal efficiency and retention of sediment. During low flows the insert directs the flow downward and then laterally towards the walls of the sump. Above the treatment flow rate, the excess flow above the design flow rate flows directly across the insert device towards the outlet.	Settleable and floatable solids, oil/grease and particulate pollutants
Downstream Defender	H.I.L. Technology, Inc.	Uses vortex separation with device installed in a round single manhole vault.	Settleable and floatable solids, oil/grease and particulate pollutants
Vortechs	Vortechnics	Vortex separation with the swirl device placed in a rectangular, shallow vault. Comes in nine standard sizes.	Settleable and floatable solids, oil/grease and particulate pollutants
V2B1	Kistner Concrete	Two manholes in series. Vortex separation removes particulates and floatables in first manhole. Floatables move to a chamber in second manhole for storage. Diverter in first manhole bypasses high flows from first to second manhole.	Settleable and floatable solids, oil/grease and particulate pollutants
CDS	CDS Technologies	Circular device; flow is directed to create circular flow like a vortex, but removal occurs as the water passes through a screen around the outer perimeter. Removal induced by countercurrent flows on opposite sides of the screen which also prevents clogging of the screen.	Settleable and floatable solids, oil/grease and particulate pollutants
StormFilter	Stormwater Management	Vertical cylinder with media of various types placed in the cylinder. Water enters laterally through the filter, enters a vertical center well which exits to an underdrain system. One standard size cylinder (15 gpm). Number of cylinders is a function of design peak flow. Pretreatment desirable under circumstances as defined by the manufacturer.	Varies with media. All reduce settleable solids. Some remove dissolved P. or dissolved metals.
Envirodrain	Envirodrain	Insert device: Rectangular unit consisting of one to three trays. Media include Absorbent W, activated carbon.	Petroleum hydrocarbons, sediment, litter
Fossil Filter	KriStar Enterprises	Insert device: Rectangular, square or circular body with an upper removable tray. Tray is trough extended around the circumference of the drain inlet. Open in the center for high flows. Activated alumina media placed in tray.	Petroleum hydrocarbons and other constituents that are not water soluble
HydroKleen	Weaver Manufacturing, LLC	Two types: box and tapering cylinder. Box: water directed to vertical chamber on one side for sediment. Water overflows to second chamber where it falls through media. Tapering unit collects sediment in perimeter trough; water overflows to center to pass downward through media.	Hydrocarbons, organically bound metals, PCBs, many pesticides, VOCs, sulfides
Ultra-Urban Filter	Abtech Industries	Insert device: Rectangular box for side curb inlet drain inlets. Media in bags attached to two sides and bottom through which water passes. Sorbent polymer for media.	Petroleum hydrocarbons, debris, suspended solids
StormTreat	Storm Treat Systems, Inc.	Circular device with two concentric chambers: closed inner chamber for settleables\floatables; open outer chamber with wetland plants in gravel. One size, about 9.5 diameter, off-line with live volume of 1400 gallons. Fills each storm, slowly drains in 5 to 10 days. Requires detention system to retain treatment volume plus several units placed together with flow manifold to match design volume. Pretreat to remove gross solids\debris.	Settleable and dissolved solids, oil/grease, particulate pollutants, and bacteria

1. As stated by each manufacturer.

SWIRL CONCENTRATORS

Products employing the swirl concentrator or vortex separation mechanism include Vortechs, V2B1, and Downstream Defender. All products are designed to remove settleable and floatable solids, oil and grease, and particulate pollutants.

Downstream Defender, Vortechs, and V2B1

The flow entry into these devices is designed so as to cause a swirling motion "around" the removal chamber. The three devices differ with regard to shape, number of units in the basic configuration, and inlet and outlet designs. Downstream Defender consists of one round manhole like structure. Water enters and passes around the outside of a circular chamber placed within the manhole. Settleable solids move to the bottom of the chamber. The Downstream Defender and the Vortechs have storage chambers below the vortex separation area. The Vortechs is rectangular, although the removal chamber that rests within the box is circular. The V2B1 consists of two manholes. The entry manhole is the vortex separator and the second, downstream manhole stores floatables within an inner chamber. Floatable pass from the first to the second chamber through a connecting pipe. High flows are bypassed through the entry manhole to the second manhole but past, rather than through, the storage chamber. Removal efficiency is highly effected by flow rate.

Each product is available in several flow capacities as reported in Table 7 in the Results section. The products are typically not sized based on flow capacity; rather they are sized to achieve an average of 80 percent removal of TSS over time. The resulting treatment flow capacity to achieve 80 percent TSS removal is approximately one quarter the maximum hydraulic flow capacity listed for the units, which the peak flow that can be safely passed through the unit. The estimated treatment flow capacities are used as the basis for comparison of these products.

DEFLECTION SCREEN

The deflection screen mechansim is employed in the CDS Continuous Deflective Separation device.

CDS

The CDS device is similar to the above swirl concentrators in two respects. The device has a circular removal chamber and flow moves in a circular motion. However, vortex separation is not induced. Rather, removal is accomplished with a screen located around the outer perimeter of the removal chamber. Water moves through the screen. The relatively high velocity of the water in the entry chamber is reduced to a very low level by the fact that the water in the outer chamber, around the screen, moves counter current to the outlet. The settleable solids "drop" down at the interface of the screen; the floatables pass upward. This hydraulic action also prevents clogging of the screen. The device, originally developed in Australia, was design to retain floatables, which has been of greater concern in Australia than the United States. The screen sizes currently offered (2400 and 4700 micron openings) are too large to effectively remove settleable solids less than 100 to 200 um, which are of concern in the United States. However, research has demonstrated that the screens are capable of removing solids much smaller than the screen opening. While the 2400 screen is still too large to effectively remove the smaller particles of interest, it is not necessary to have, for example, a screen with openings equal to the size of the particle of interest. CDS is currently experimenting with a 1200 micron screen which may prove sufficiently small to remove the particle sizes of interest.

The peak flow of the prescribed design event is used to size the unit. The manufacturer offers models having a wide range of flow capacities as indicated in Table 7 in the Results section. According to the manufacturer, performance is not affected by flow rate.

MEDIA FILTERS

Filtration through proprietary media is employed in the StormFilter device.

StormFilter

StormFilter is a vertical filter cylinder or cartridge with a unit capacity of 15 gpm. The desired total system capacity, based on the peak of the prescribed design event, is achieved by using a multiple cartridges. The cartridges are placed in a precast or cast-in-place vault. The cartridges are placed in a line. The number of lines depend on the vault capacity. Water enters radially (horizontally) through the filter media into an inner cylinder. The filtered water passes downward to an underdrain system that is contained in the bottom slab. A uniqueness of the system is the hydraulic control. To maximize the flow-through rate, each cartridge contains a simple, non-mechanical vacuum device that prevents water from flowing through the cylinder until the water has risen to the top of the cartridge. When this occurs the vacuum within the inner chamber is broken and water passes through until the water level reaches the bottom of the cartridge at which time the vacuum is reestablished. This action also apparently causes solids that have accumulated on the outer surface of the media to be released from the media to settle to the bottom of the vault, thereby extending the maintenance cycle. Several different media are offered, singly or in combination, depending on the treatment objective. Primary constituents targeted for removal include dissolved metals and nutrients. Pretreatment, which is typically provided to remove gross solids, extends the maintenance cycle period. Some pretreatment occurs in the cartridge vault, but pretreatment may also be provided in a separate smaller vault or manhole located upstream of the cartridge vault. If included, a detention facility located upstream of the StormFilter may be sufficient to provide the desired pretreatment depending on the sizing criteria for the detention facility.

DRAIN INLET INSERTS

Products installed as inserts into drain inlets or catch basins include Fossil Filter, Ultra-Urban Filter, Hydro-Kleen, and Envirodrain. The other products reviewed are considered end-of-pipe devices because they are applied after stormwater has been collected in a piped stormwater conveyance system.

Envirodrain, HydroKleen, Fossil Filter, and Ultra-Urban Filter

These four systems actually function as media filtration devices, but are grouped together because they are installed by insertion into standard drain inlet configurations. Each product is described in Table 1. They differ as to their basic configuration, boxes or trays, and the types of media. Different constituents may be targeted for removal by selecting different types of proprietary media. Each offers several different models, differing by shape, capacity, and therefore size. The issue is whether inserts can provide treatment levels equivalent to either the manufactured products presented above or the public-domain systems that are currently allowed by the Sacramento jurisdictions.

COMBINED SYSTEMS

A treatment-train approach, in which treatment processes are combined in series, is employed in the StormTreat system.

StormTreat

The StormTreat system is an off-line system consisting of two prefabricated concentric cylinders. The outer chamber has a diameter of about 9.5 feet and a height of 4 feet. Water flows directly into and around the inner chamber from either a detention facility or a pretreatment vault or manhole. Further settling of finer material occurs in this chamber. The water passes to the outer chamber, which is filled with gravel to support the growth of wetland plants. This outer chamber removes fine solids and dissolved pollutants. The capacity of the inner chamber is 1,400 gallons. This chamber fills during the storm. The release rate from the outer chamber is controlled at about 1 to 2 gpm. This slow withdrawal is necessary to obtain high levels of removal. The unit takes on the order of five to ten days to drain. Hence, to achieve treatment of the desired volume of water, detention storage must be located upstream of the StormTreat unit. This stored volume gradually flows though the unit over a period of five to ten days. Hence, it is important to recognize the inter-event time between storms when sizing the system . If the inter-event time for the Sacramento area is less than ten days, the potential exists for the unit to have residual volume of water when the next storm arrives. To avoid this problem, the volume of the detention/StormTreat system must be greater than the specified treatment volume. This can only be accomplished by incorporating the statistical nature of storms into the design process.

PUBLIC DOMAIN SYSTEMS

Grass swales and sand filters are the two public-domain treatment systems that are most commonly used at this time in the Sacramento region. The term "public-domain" is used to distinguish them from the manufactured or proprietary control measures that are evaluated in this report. Theses public domain systems are used as the basis of comparing the performances of the proprietary devices.

Grass Swales

Grass swales are gently-sloped grass-lined channels to which runoff is directed and which is used to convey runoff to a storm-drain piping system. Treatment takes place through a variety of physical, chemical and biological mechanisms as the runoff flows to and along the grass swale. Treatment efficiency is largely a function of depth of flow relative to grass height and velocity of flow.

Sand Filters

Sand filters are media filtration devices, but use sand as the filter media as opposed to a proprietary media product. With sand filters there are three configurations of interest: lineal boxes, open surface basins, and closed vaults. The three configurations are illustrated in Figure 1.

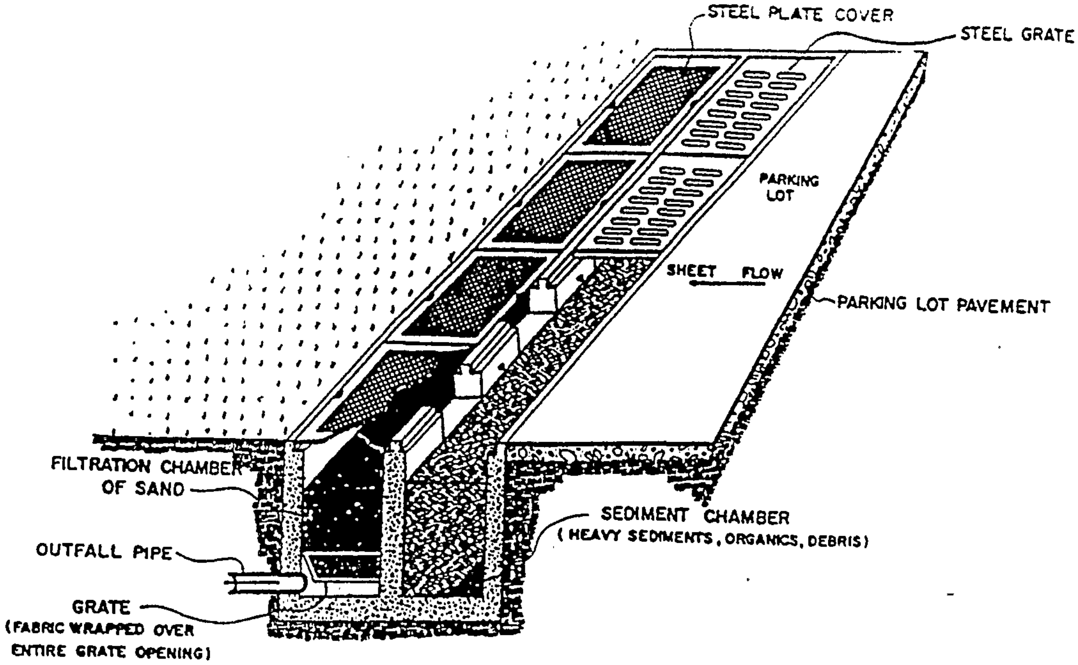

Figure 1a . Lineal Box Sand Filter

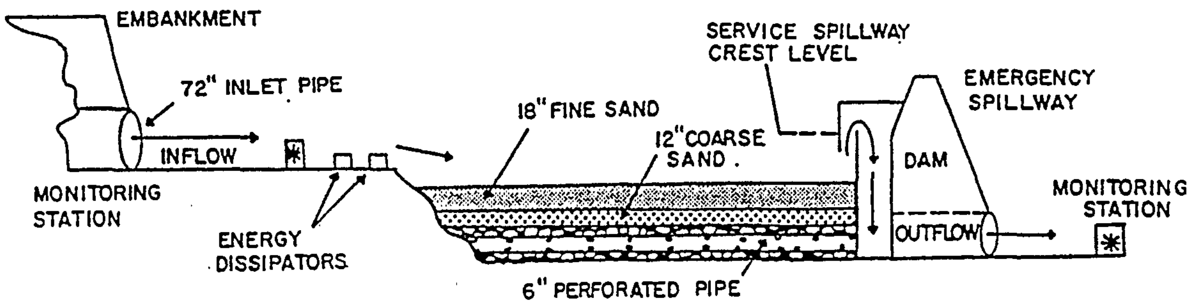

Figure 1b . Open Basin Sand Filter

R0011367

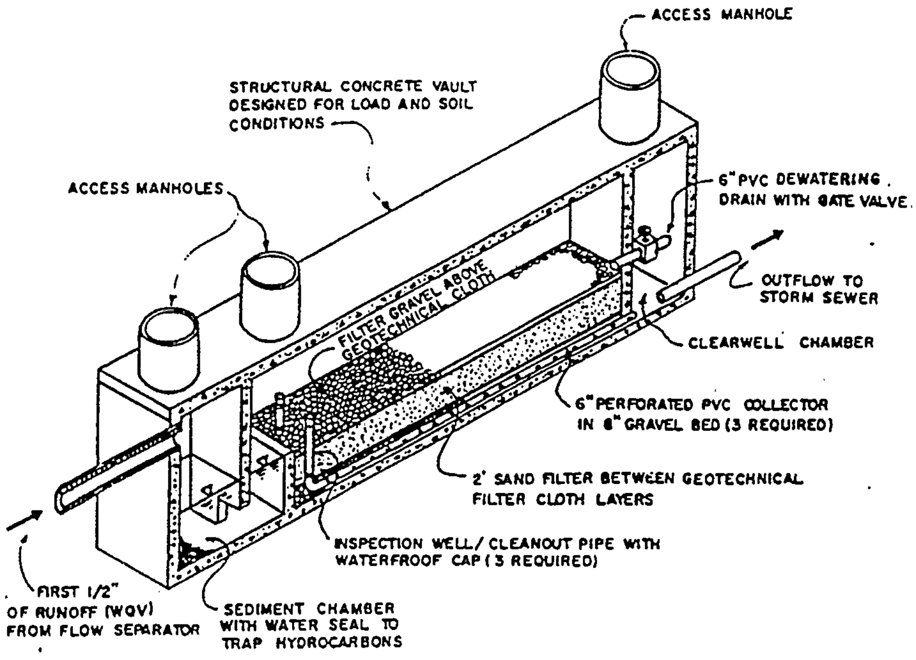

Figure 1c . Closed Vault Sand Filter

RESULTS

The results of this investigation include the following information and data:

- Summary of questionnaire responses
- Summary of performance data for proprietary control measures
- Summary of performance data for public domain control measures
- Summary of cost data for proprietary control measures
- Evaluation of proprietary control measures

QUESTIONNAIRE RESPONSES AND OTHER SOURCES OF INFORMATION

Questionnaire responses were received from manufactures or representatives of all the proprietary control measures of interest. The types of response data and information received about each product are summarized in Table 2. The information materials provided by product companies included a completed questionnaire, product brochures and technical literature, copies of available study reports, separate performance data, cost data, and design criteria. The number of product installations in California were extracted from the completed questionnaire and are listed in Table 2. Products that are no longer manufactured (Ecostar Oil/Water Separator) or are not appropriate as a stormwater control measures (Romag Stormwater Screen) were not further evaluated in this study.

In addition to the information provided by the product manufacturers, information and data from the recent literature review prepared for the Permittees (Larry Walker, 1998a) and the professional literature were used in compiling information about the various controls, particularly the public domain stormwater controls discussed latter in this section.

PERFORMANCE DATA SUMMARY — PROPRIETARY CONTROL MEASURES

Performance data supplied by the manufacturers and extracted from study reports and the professional literature are summarized in Table 3 for proprietary control measures. Performances are reported in terms of percent removal of total suspended solids (TSS), copper

(Cu), lead (Pb), zinc (Zn), and oil and grease (O&G). These constituents are typically of concern in stormwater runoff and are most often monitored. Other notable removal data are also

R0011373

summarized in the respective tables along with notes of interest regarding the studies from which the data were obtained. For sand filters there are no performance data for closed vaults. Nonetheless, as closed vaults are essentially underground basins, the data from open basins should represent the expected performance of closed vaults.

PERFORMANCE DATA SUMMARY — PUBLIC DOMAIN CONTROL MEASURES

Performance of public domain control measures, sand filters and grass swales, is of interest, as their performance is used as a basis for comparing the performances of the proprietary devices. Performance data for public domain control measures extracted from the professional literature are summarized in Table 4. The performances of grass swales and sand filters were evaluated with respect to TSS and zinc. TSS was chosen because of the preponderance of data. It is the most frequent constituent measured in all studies of stormwater treatment control measures, and serves as a surrogate for the pollutants that in stormwater tend to be primarily in the particulate form, like petroleum products, pesticides, lead, chromium, and phosphorus. Zinc was selected to represent the more soluble constituents, including itself as well as copper, cadmium, and the various nitrogen forms. Also, of the metals, zinc is typically present in runoff in concentrations sufficiently above the detection limit to allow meaningful evaluations of removal efficiency.

Plotted in Figures 2 and 3 are the TSS and zinc removal data for grass swales, respectively. Plotted in Figures 4 and 5 are the TSS and zinc removal data for sand filters, respectively. Efficiency is plotted as a function of influent concentration. This general relationship has recently been recognized (Bell, 1995) for sand filters but appears to exist for other treatment BMPs as well, like grass swales and wet ponds. Figures 2 through 5 clearly establish this fact. Presented in each of Figures 2 through 5 are two types of data points: individual storms and the overall calculated average efficiency in each study.

Shown in Figures 2 and 4 is a line called the "Line of Comparative Performance©", developed by Dr. Gary Minton of Resource Planning Associates. The line is a reasonable first approximation of the expected performance of public domain control measures with respect to the removal of TSS. The expectation is that data points must fall above and to the left of the line: this is loosely defined as acceptable performance. The line was developed from an evaluation of the performance data of several treatment systems studied in western Washington:

grass swales, wet ponds\wetlands, and sand filters. These lines are useful in evaluating the performance of proprietary control measures.

The results of the analysis of data from western Washington are considered applicable to the Sacramento area because of similarities in rainfall characteristics between the two regions, in particular average rainfall intensity (0.04"/hour in Seattle; 0.05"/hour in Sacramento), which appears to be a significant determinant of the TSS concentration in untreated stormwater (Roundtree, 1995). This general observation can be seen in the comparison of data from three regions: Seattle, Los Angeles and Austin. In a recent analysis of data collected for Caltrans District 7, the mean TSS concentration was determined to be 97 mg/L (Brown and Caldwell, 1997). A similar study in the Seattle area (Merrill, et al., 1989) determined a mean concentration of 71 mg/L from highways. In contrast, stormwater from a freeway in the Austin area had a median concentration of 202 mg/L (Barrett, et. al., 1998 and pers. comm.) where the average rainfall intensity is 0.12"/hour. Median values are usually lower than mean values. Unfortunately, there are no data in California on control measure performance to compare to the data that have been generated in western Washington.

Grass swales

Data were obtained for eight swales from six studies as listed in Table 5. However, only the swales studied by Khan (1992) were specifically designed for the treatment of stormwater. Four swales treated stormwater from retail commercial or residential areas; two treated stormwater from an urban freeway, and the drainage areas of two swales was not identified. TSS data are plotted in Figure 2 and zinc data in Figure 3.

Table 5. Performance Studies of Grass Swales

STUDY	LOCATION	TYPE OF SWALE	LAND USE	STUDY PERIOD
Barrett (1995)	Austin, Texas	Wide grassed area (two) between freeway lanes	Urban freeway	1994
Goldberg (1993)	Seattle, Washington	Designed grass swale, 570 ft. length	Residential	1992
Khan (1992)	Mountlake Terrace, Washington	Designed grass swale, 200 ft length.	Residential	1991
King County (1995)	Issaquah, Washington	Designed wetland swale, 350 ft. length.	Residential	1994
Oakland (1983)	Durham, New Hampshire	Designed grass swale, 200 ft length.	Supermarket	1982
Schueler (1994)	Central Florida	Two swales of 210 ft. length, one with wet pool, one with high infiltrative bottom.	Not provided	1987

Figures 2 and 3 suggest that the performance of grass swales is less consistent than sand filters (see Figures 4 and 5). A greater percentage of the data points fall to the right of the line in Figure 2, in comparison to Figure 4. There is considerably more scatter in zinc removals in Figure 3 in comparison to Figure 5. It is likely that the greater scatter is due to the variation in the designs of the swales that were evaluated, and the condition of the vegetation. Frequently, the design procedure does not take into consideration the need to have a wide swale with a flat bottom (rather than curved). A Manning's "n" on the order of 0.20 to 0.25 should be used rather than 0.05 to 0.07, the value typically used to size grass channels (Khan, et al., 1992). Swales that are too narrow result in channelized flow with water depths that exceed the height of the grass. To be effective at pollutant removal, the depth of the stormwater must not exceed the height of the grass. These conditions were likely present with the swale that was studied by Welborn et al. (1987). The authors evaluated a large swale, in terms of both length and width, treating stormwater from a medium density residential development. Essentially no pollutant removal occurred in 19 storms. The authors provided no insights as to the reason(s) for the poor performance. However, pictures were provided in the report, which show a swale with a pronounced curved or sloped, rather than flat, bottom and grass that is closely cropped although apparently thick and in good health.

Sand Filters

Data have been obtained of 11 filters from six studies as listed in Table 6. Eight filters were of the open basin type and three were lineal filters. Nine filters treated stormwater from retail commercial or residential areas; two treated stormwater from an industrial site. TSS data are plotted in Figure 4 and zinc data in Figure 5.

The data in Figure 4 indicate that sand filters are effective in the removal of TSS and are generally consistent in their performance from storm to storm, as the vast majority of data points tend to fall on or to the left of the Line of Comparative Performance. There does not appear to be differences in performance between the three regions represented by the data (western Washington, Austin, and Washington, D.C.). However, negative efficiencies have been observed in individual storms as noted in Figure 4 (from Horner et al., 1995 and Welborn, et al., 1987). In Washington. D.C., anecdotal observations of vault filters suggests that sediments previously deposited on the filter surface are scoured during large storms (Karikari, pers. comm.). Vaults, however, do not have bypasses, nor do lineal sand filters, except to the extent that inflow is limited by the capacity of the grate. However, the sand basins in Austin are off-line, suggesting that scour should not be an issue. However, negative removals were observed by Welborn, et al. (1987) in large storms.

The pattern of removal efficiency of zinc shown in Figure 5 is similar to TSS. More scatter in the data points might be expected given that a significant fraction of zinc is in the soluble form, which presumably would not be removed by sand. However, in two studies it was found that sand does remove dissolved zinc (Shapiro, 1998; Welborn, et al, 1987). The one significant outlier in Figure 4 (study average of 31% at influent concentration of 267 μg/L) was from the study by Horner et al. (1995) of lineal filters at an industrial site. The rather low efficiency is the result of the mathematical effect of one high-flow incident with a negative efficiency. Were this one incident excluded, the zinc removal would have been 87% over the test period.

Table 6. Performance Studies of Sand Filters

STUDY	LOCATION	TYPE OF FILTER	LAND USE	STUDY PERIOD
Austin (1990)	Austin, Texas	Open filter basin preceded by dry pond.	Residential - 2 filters Shopping mall- 1 filter Roadway - 1 filter	1984-1989
Austin (1996)	Austin, Texas	Open filter basin preceded by dry pond.	Shopping mall	1993-1995
Welborn (1987)	Austin, Texas	Open filter basin preceded by dry pond.	Shopping mall	1982-1984
Bell (1995)	Alexandria, Virginia	Lineal filter which contains a lineal wet vault.	Rental car parking lot	1994
Shapiro (1998)	Seattle, Washington	Open filter basin preceded by wet vault	Residential	1995-1997
Horner (1995)	Seattle, Washington	Lineal filter which contains a lineal wet vault.	Waterfront bulk cargo yard.	1994
King County (undated)	Seattle, Washington	Open sand filter basin preceded by grass swale.	Shopping mall	1993

COST DATA SUMMARY FOR PROPRIETARY CONTROLS

Cost data provided by manufacturers of proprietary control measures, including purchase, installation and annual operation and maintenance costs are summarized in Table 7. The products are listed alphabetically by type. Many of the control measures are available in several sizes and unit flow capacities. The costs of the various sized units and their associated flow capacities are listed in Table 7. To provide a means of comparing costs, a normalized, or unit cost, in terms of dollars (purchase plus installation) per cfs of rated capacity was computed for each control measure in three flow capacity ranges (approximately 0.1, 1.0, and 10 cfs). The normalized costs are reported in Table 7 . A review of these unit costs reveals that, in general, drain inlet inserts cost in the range of $3,000 to $5,000 per cfs flow capacity, while the other end-of-pipe devices, with the exception of media filters, cost in the range of $10,000 to $20,000 per cfs flow capacity. Media filters cost in the range of $40,000 to $75,000 per cfs flow capacity, but these devices target removal of dissolved constituents and provide a higher level of treatment. The unit cost were developed only for the purpose of general comparison and were not used as a basis for determining acceptance of the products. It is recognized that product performance is not a linear function of flow. A more comprehensive cost comparison may consider cost per annual flow volume treated. Such an analysis is beyond the scope of this report.

Costs of public domain control measures were not evaluated as part of this report. In most cases the cost of grass swales will be incorporated into the cost of landscaping a particular site. Some additional engineering costs may be incurred to properly size the swales for the design flow conditions. Sand filters are installed treatment devices, similar in this respect to the proprietary devices. The cost of sand filters will vary with size and complexity of construction.

Table 7. Cost Comparison Summary for Proprietary Stormwater Structural Control Products

PRODUCT	*COMPANY NAME*	*TYPE OF DEVICE*	*APPLICATION/ LIMITATIONS*	*UNIT FLOW CAPACITIES*	*COSTS, $*			*UNIT COST*
					Purchase	Install	O&M/yr	$/cfs

EVALUATION OF PROPRIETARY CONTROL MEASURES

The relevant questions are whether the available performance data for each of the proprietary control measures are acceptable in terms of collection and analytical protocols and whether the products perform as well as sand filters and grass swales, the two public domain control measures that are most commonly used at this time in the Sacramento region. Each of the proprietary control measures considered in the report was evaluated using the screening process described below. Those products that pass the screening process (i.e. provide acceptable data and are reasonably equivalent in performance to the public domain control measures) are considered acceptable for implementation as a stormwater control measure without condition and are recommended as devices to be accepted by the Permittees. Those products that do not pass the screening process are recommended as either "conditionally acceptable" or "not acceptable", depending on the deficiencies in the performance data.

Screening Criteria

Screening criteria, including sample collection and analysis protocols and data reporting protocols, were developed to determine the acceptability of each of the proprietary control measures. This comprehensive set of protocols is presented in Appendix A. These protocols are recommended as requirements to be adopted by the Permittees for acceptance of any future performance evaluation reports submitted by manufacturers of proprietary control measures seeking approval of their products for use in the Sacramento jurisdiction. Review of the studies currently available for the proprietary control measures considered in this report revealed that none of the products provided all of the requisite information listed in these comprehensive protocols. Because of the lack of this information, none of the technologies is considered acceptable at this time for placement on an "Acceptable" list. Consequently, a less-stringent set of criteria, as described in the Methods section and in Appendix A of this report, was developed to determine whether a product should be recommended as "conditionally acceptable" or "not acceptable" at this time.

The selection of the screening criteria was judgmental, based on what is reasonable given the number of studies and information about sand filters and grass swales. A review of Tables 5 and 6 suggest that the specification of two sites with 10 storms at each site is reasonable. The storm specifications outlined above are to ensure that the storms that were monitored are comparable to typical storms of the Sacramento region and that the range of storms brackets the City and County design storm for on-site control measures (2-year/6 hour storm).

Screening Results and Discussion

The available performance evaluation studies for each of the proprietary control measures were evaluated using the screening criteria described in preceding subsection. Results of this screening process are summarized in Table 8. Discussions of each of the control measures are presented below including recommendations regarding the products' current acceptability as stormwater control measures for Sacramento Stormwater Permittees. A summary of recommendations for product acceptance and follow-up is presented in Table 9.

Table 8. Summary Evaluation of Products

Product	Data Source/ Reference	TSS Removal %	Land Use	No. of Storms	Sample Type	Storm Depth Range (inches)	Storm Duration Range (hours)	Storm Intensity Range (in/hour)	Comments
Screening Criteria		See Figure 2 and 4		10	Flow wt. composites	0.15 to 1.50	2 to 24	0.05 to 0.25	See Appendix A

Jensen Interceptor

This system is essentially a wet vault, where sedimentation is the dominant pollutant removal mechanism. This type of device, therefore, should be able to provide the desired level of performance, if it is sized and configured properly. Using the manufacturer's sizing guidelines, this devise is generally designed to achieve only course pollutant removal.

Of the two studies of this product reported by the manufacturer, the Piner (1994) study did not provide sufficient data to draw any conclusions. The study by Kinnetic Laboratories (1996) provided data from six storm events, but the influent TSS concentrations may have been influenced by upstream construction activities during one or more storm events. Further, the study authors reported that "bypasses of the interceptor were common during most storm events". To account for the untreated bypass flow, the overall TSS removal efficiency was adjusted from 63 to 50 percent. The relatively low observed removal efficiency (compared to the public domain control measures) and the high frequency of bypassing suggests that this device may be undersized.

An issue with the use of wet vaults is their inability to remove dissolved pollutants; further, Kinnetic (1996) found that dissolved cadmium increased significantly between the influent and the effluent. Dissolved zinc increased in five of the six storms sampled, although the differences between the influent and effluent were not found to be statistically significant. The increase in concentrations of dissolved metals may be due to release of soluble metal species under anaerobic conditions in the pooled water. This hypothesis should be studied further.

The reported studies do not meet the established criteria (see Appendix A) in terms of sampling and documentation protocols.

Recommendation: Not acceptable.

Deficiencies:

1. Insufficient number of storms studied with proper protocol.
2. Insufficient number of sites studied with proper protocol.
3. Sizing criteria questionable.

Teichert Interceptor

The above observations for the Jensen Interceptor are applicable to the Teichert Interceptor.

Recommendation: Not acceptable.
Deficiencies:

1. Insufficient number of storms studied with proper protocol
2. Insufficient number of sites studied with proper protocol.
3. Sizing criteria questionable

BaySaver

Only one field study has been conducted and only three storms were sampled. Further, two of the storms were extremely small.

Recommendation: Not acceptable.
Deficiencies:

1. Insufficient number of storms studied with proper protocol
2. Insufficient number of sites studied with proper protocol.

Stormceptor

The manufacturer has conducted several other field studies not listed in Table 3. However, the sampling was limited to a few grab samples during each event, and therefore are not reported in Table 3. The minimum criteria are nearly met (four studies, but meeting the 10 storm criterion at only one site). However, performance is highly variable as indicated in Table 3. Two observations of significant note: in the study by Greb et al. (1998) in which 45 storms were sampled, the aggregate removal efficiency for TSS over the 45 storms was only 26%, as reported in Table 3. However, the study has been criticized by Stormceptor because it was found that salt from a salted sand pile (used for road deicing) was entering the Stormceptor, causing a dense layer of water in the lower half of the device. It therefore could be argued that this caused the low efficiency. However, at least 14 storm events occurred prior to the outset of the dense lower layer and for these 14 events the overall TSS removal efficiency was still only about 35%.

Recommendation: Not acceptable.

Deficiencies:

1. Insufficient number of storms studied with proper protocol
2. Inadequate performance

Downstream Defender

No field studies have been conducted. Performance evaluation is limited to a laboratory study in which sediment was added to potable water.

Recommendation: Not acceptable.

Deficiencies:

1. Insufficient number of storms studied with proper protocol
2. Insufficient number of sites studied with proper protocol.

Vortechs

Only one study has been conducted. Although the observed performance is promising. the study does not meet the 10 storm requirement.

Recommendation: Not acceptable.

Deficiencies:

1. Insufficient number of storms studied with proper protocol
2. Insufficient number of sites studied with proper protocol.

V2B1

No field studies have been conducted. Performance evaluation is limited to a laboratory study in which sediment was added to potable water.

Recommendation: Not acceptable.

Deficiencies:

1. Insufficient number of storms studied with proper protocol
2. Insufficient number of sites studied with proper protocol.

CDS

As previously indicated, CDS needs to offer a screen with much smaller openings. CDS is currently experimenting with a 1200 micron screen. CDS has conducted many studies but these have focused on the removal of gross solids. Only the study cited in Table 8 focused on the removal of pollutants, specifically TSS, phosphorus and nitrogen. Evaluation of 15 storms found that about 70% of the TSS was removed over all storms monitored. However, the CDS model, which employed a 4700 micron screen, was relatively ineffective at reducing the TSS when the influent concentration was less than 75 mg/L. Given the relatively mild storms occurring in Sacramento, and the relationship between TSS concentration and runoff rate, it is possible that for Sacramento, the TSS concentration of untreated stormwater will be frequently less than 75 mg/L.

Recommendation: Not acceptable.
Deficiencies:

1. Inadequate performance

StormFilter

Two studies are reported in Table 8, both of which meet the criteria, although not all of the rainfall information is available. Figure 6 presents a plot of the data from the two studies. The data from Stormwater Management (1994) shows satisfactory performance. The data points from Leif (1998) fall to the right side of the Line of Comparative Performance©. However, Leif (1998) evaluated the performance of only the filter unit, that is, the influent sample was taken at the entrance of the filter rather than the vault in which the filter was placed. Hence, the pretreatment efficiency of the forebay was not included. Taking this aspect into consideration, it is likely the data points would have fallen to the left of the comparative performance line.

A more significant consideration is that the two cited studies are of the flat bed system, rather than the cartridge system, which is now used. It therefore may not be appropriate to apply the findings from flat bed systems to the cartridge system as the unit flow rates (gpm/ft^2 of filter surface) may differ. The flat bed systems have 18" of media where as the thickness of media in the cartridge systems is only 7 to 9".

Stormwater Management, Inc has conducted several studies of the cartridge system, with several types of media: leaf compost, perlite, and either of these two media with a fabric. However, only grab samples, typically only one of the influent and one of the effluent, have been taken during these studies. While the two comprehensive studies have been of the flat-bed type system rather than the current cartridge system, the performance and studies are satisfactory.

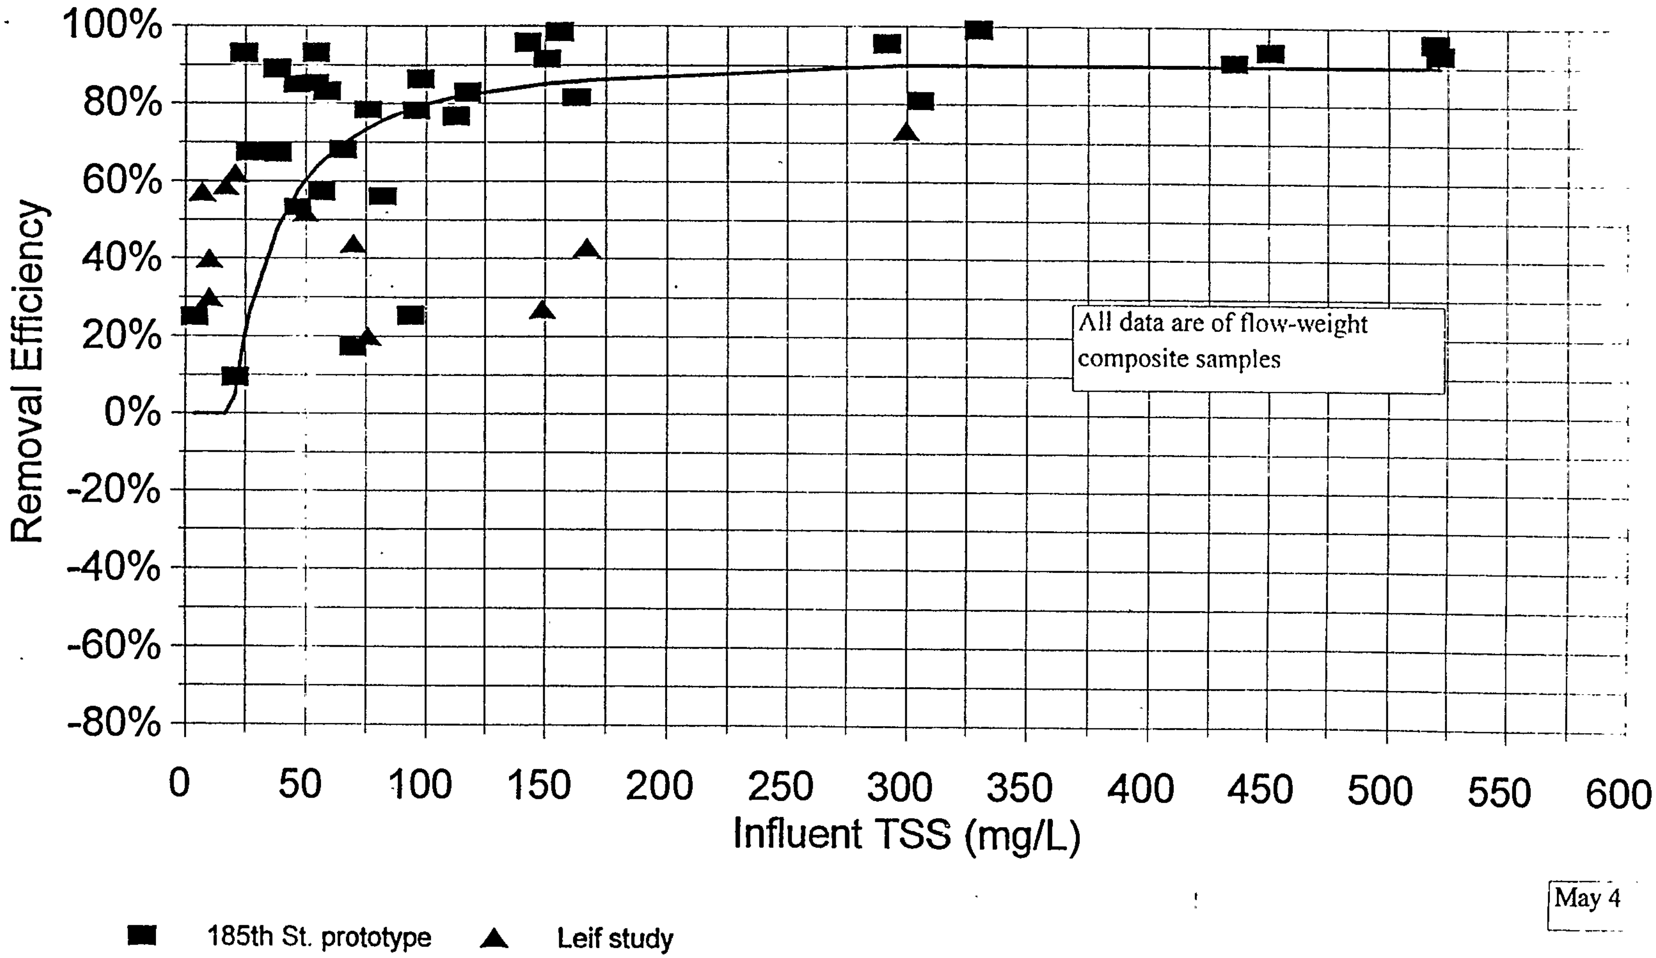
Recommendation: Conditionally acceptable.

Deficiencies:

1. Insufficient number of sites studied with proper protocol using cartridge system

FIGURE 6 STORMFILTER

TSS Removal - Flatbed System



May 4

R0011399

Envirodrain

No field studies of performance have been conducted.

Recommendation: Not acceptable.

Deficiencies:

1. Insufficient number of storms studied with proper protocol
2. Insufficient number of sites studied with proper protocol.

Fossil Filter

Two studies have been conducted that included consideration of the removal of TSS. With one study the removal efficiency was 0%. However, the influent TSS was only 9 mg/L and therefore further reduction would not be expected. Regardless, only one storm was sampled.

Recommendation: Not acceptable.

Deficiencies:

1. Insufficient number of storms studied with proper protocol
2. Insufficient number of sites studied with proper protocol.

Hydro-Kleen

No field studies of performance have been conducted.

Recommendation: Not acceptable.

Deficiencies:

1. Insufficient number of storms studied with proper protocol
2. Insufficient number of sites studied with proper protocol.

UltraUrban Filter

An extensive field study carried out in Santa Monica demonstrated that the filter removes litter and sediment from stormwater. However, as the influent and effluent were not sampled it is not possible to calculate efficiency. The manufacturer has conducted laboratory tests to evaluate the performance with respect to the removal of petroleum. However, the artificial stormwater that was created for the tests was not representative because sediment was not included in the stormwater. This is important because motor and diesel oil sorbs to sediment. The removal efficiency with regard to sediments is therefore important to evaluate, whether in a laboratory or field test, even if the pollutant of interest is petroleum products.

Recommendation: Not acceptable.

Deficiencies:

1. Insufficient number of storms studied with proper protocol
2. Insufficient number of sites studied with proper protocol.

StormTreat

Only one field study has been conducted. Further, in this field study only one grab sample was taken of the influent during each storm. Thus, efficiency cannot be properly determined. However, effluent concentrations of TSS and other pollutants were very low, indicating high efficiencies are achievable with this system. The TSS concentration in the effluent was typically less than 3 mg/L, with a high of 11.9 mg/L. It is important to note that StormTreat gradually treats the water for several days after the storm has passed. Hence, to use StormTreat, a detention system must also be included to retain the specified volume of water that is to be treated. This need suggests that before approving or conditionally approving this product, the manufacturer should be required to provide a sizing proceedure specific to the climatic conditions of California.

Recommendation: Not acceptable.

Deficiencies:

1. Insufficient number of storms studied with proper protocol
2. Insufficient number of sites studied with proper protocol.
3. Inadequate sizing procedure

Table 9. Summary of Product Recommendations

Product	Company	Date of Most Recent Study	Approval Recommendation	Follow-up Recommendation
Jensen Interceptor	Jensen Precast	1996	Not Acceptable	Studies at 2 sites w/ 10 storms each. Follow recommended protocol. Review sizing guidelines

CONCLUSIONS

This study has compiled the available performance data for 18 stormwater treatment control technologies (14 proprietary devices and four treatment technologies available within the public domain) and evaluated the potential of these controls to improve the quality of stormwater runoff from new developments in Sacramento, California. Cost data for the 14 proprietary devices were also compiled.

To be acceptable or conditionally acceptable by local stormwater agencies, a treatment technology should have demonstrated performance under conditions similar to those typically observed in the intended area of application. This means that adequate study data should be available to clearly demonstrate effective pollutant removals with the technology under typical Sacramento-area storm conditions, using influent quality representative of that typically found in runoff from Sacramento-area commercial and residential developments. Effective pollutant removal is considered equivalent to that provided by public domain controls – grassy swales and sand filters. The studies should be scientifically defensible and well-documented. A screening protocol was developed to evaluate whether adequate data had been produced for each of the devices studied.

The four public domain controls studied – grassy swales and three types of sand filters – have been documented to produce treatment effectiveness adequate to warrant continued recommendation for application in the Sacramento area. Furthermore, the demonstrated treatment performance of these technologies can be used as a relative measure against which to assess the acceptability of performance data from other (proprietary) treatment technologies.

Of the fourteen proprietary devices evaluated, none have adequate data at this time to recommend outright acceptance, using the screening protocol developed for this investigation. Only one device (StormFilter) is recommended as conditionally acceptable.

The inability to remove dissolved pollutants is a common problem with all of the products reviewed in this report with the possible exceptions of StormTreat and StormFilter.

RECOMMENDATIONS FOR FOLLOW-UP

1. Manufacturers of proprietary controls that are recommended as "not acceptable" at this time should be encouraged to conduct studies that can be used to demonstrate the effectiveness of their products for application in Sacramento-area new developments. A recommended data collection and documentation protocol is provided in Appendix A to this report. In general, studies that follow the recommended guidelines would be applicable to most of the western United States.

2. Product manufacturers capable of producing a report that meets the criteria for conditional acceptance should submit such reports. Conditional acceptance of a product should be determined on a case-by-case basis by the various Permittee agencies. It is further suggested that manufacturers must be required to produce a subsequent report that meets all the protocols listed in Appendix A. Failure to submit such a report in a timely manner would results in the product being removed from the "Conditionally Acceptable" list.

3. The manufacturers of the Jensen and Teichert Precast units should be encouraged to review their sizing guidelines and make corrections as needed to resolve any unnecessary treatment deficiencies.

APPENDIX A

COMPREHENSIVE PROTOCOL FOR PERFORMANCE EVALUATION OF PROPRIETARY STORMWATER CONTROL PRODUCTS

A manufacturer who wishes to have its technology considered for placement on the "Acceptable" list must submit a report that contains performance data from studies following the requirements outlined in this protocol. A technology may be "Conditionally Acceptable" if it is demonstrated to provide effective performance but does not meet all of the Comprehensive Protocol requirements, as described below.

While it is preferred that the field studies be conducted in the Sacramento region, this is not a requirement.

NUMBER AND TYPES OF SITES EVALUATED

- Studies are to be conducted at a minimum of two sites
- Land uses: more than one of the following - retail commercial, non-retail commercial, medium density residential, high density or multi-density residential.

SAMPLING REQUIREMENTS

- Number of storms per site: 10 (may occur in two consecutive years)
- Storm depth: from 0.15 to 1.50 inches
- Runoff duration: from 2 to 24 hours
- Average storm intensity: 0.05 to 0.25 inches/hour
- Type of samples: flow-weight composite samples, except where grab sampling is required by protocol. With data collected prior to July 1, 1999, time-paced samples are satisfactory for consideration for placement of the product on the "Conditionally Acceptable" list,
- Sampling procedure: To the extent possible, sampling is to occur through the entire period of runoff. Sampling is to occur for a period that represents at least 60% of the volume of each storm with an overall average of all storms of at least 75%. A minimum of ten aliquots must be taken during each sampled storm.
- Analytes: Influent and effluent TSS, pH, total recoverable zinc, copper, cadmium, oil/grease, TPH and, TP and TKN. If the device is also intended to remove dissolved constituents, the analytes shall include the dissolved species of the targeted constituents. Chemical samples are to be preserved following analytical procedures specified by *USEPA*. protocols and are to be analyzed using USEPA protocols. Analytical analysis is to be done by a certified laboratory. To be considered for placement on the "Conditionally Acceptable" list, only TSS data need to submitted.
- At the end of the test period, the sediment shall be removed, quantified, and analyzed. The sediment will be evaluated for the following: moisture content, particle size distribution, organic content, oil/grease, and zinc. To analyze particle size distribution, both the wet and

dry sieve test procedures will be used, following ASTM. These data are not necessary for placement on the "Conditionally Acceptable" list.

DOCUMENTATION PROTOCOL

1. A description of the test site including total acreage, total impervious acreage, a description of landscaping if relevant, the acreage draining to the device if it differs from total acreage. Include a description of the drainage system. (Not required for "Conditionally Acceptable" list).
2. A description of the treatment device including the design peak capacity. (Not required for "Conditionally Acceptable" list).
3. Complete drainage calculations showing the calculations to size the treatment device for the test site.
4. All raw data including laboratory reports. All data is to be reported including rejected data with an explanation for the rejection.
5. Statement from the analytical laboratory certifying the specified analytical procedures were followed in the analysis of the samples and that the appropriate preservation methods were followed.
6. Calculation of efficiency of each storm by comparing the influent and effluent concentrations of each storm. (Not required for "Conditionally Acceptable" list).
7. Calculation of the efficiency for all storms by comparing the total aggregate inflow loading of all storms to the total aggregate outflow loading for all storms.
8. Present a plot of influent concentration versus efficiency for TSS for each storm sampled. All data is to be plotted including rejected data with an explanation for the rejection. (Not required for "Conditionally Acceptable" list).
9. Start and end times of the precipitation period. (Not required for "Conditionally Acceptable" list).
10. Start and end times of the runoff period of each sampled storm. (Not required for "Conditionally Acceptable" list).
11. Start and end times of the sampling period of each sampled storm. (Not required for "Conditionally Acceptable" list).
12. Total rainfall depth. (Not required for "Conditionally Acceptable" list).
13. Rainfall depth during the sampling period. (Not required for "Conditionally Acceptable" list).
14. Total runoff volume
15. Runoff volume that occurred during the sampling period

16. Statement of certification signed by an officer of the manufacturer of the product that the protocol was followed.

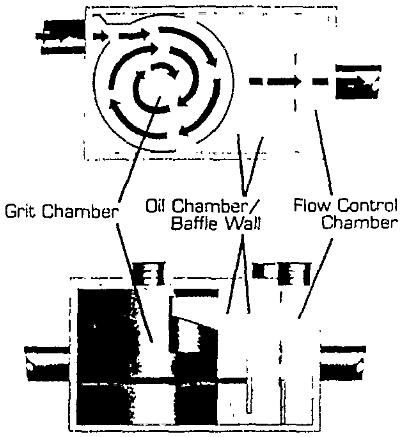
Operation

Plan View



Elevation View: Dry-Weather

Grit Chamber

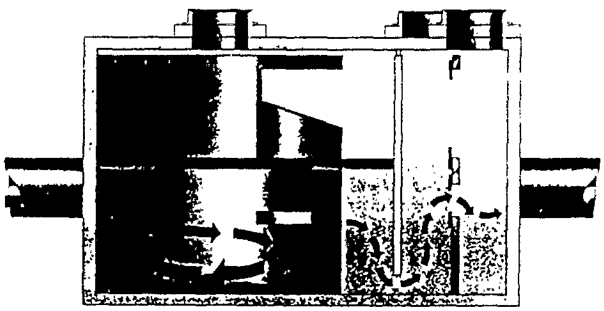
The swirling motion created by the tangential inlet directs settleable solids toward the center of this chamber. Sediment is caught in the swirling flow path and settles back onto the pile after the storm event is over.

Oil Chamber & Baffle Wall

The center baffle traps floatables in the oil chamber, even during clean-out. Highly resistant to flow surges.

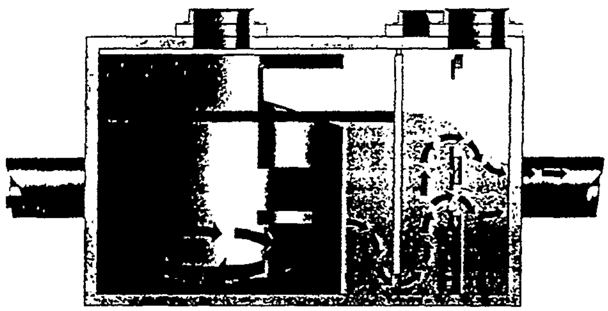
Flow Control Chamber

The weir and orifice flow controls:
1) Raise level and volume in the system as flow rate increases; and
2) gradually drain the system as flow rate subsides.



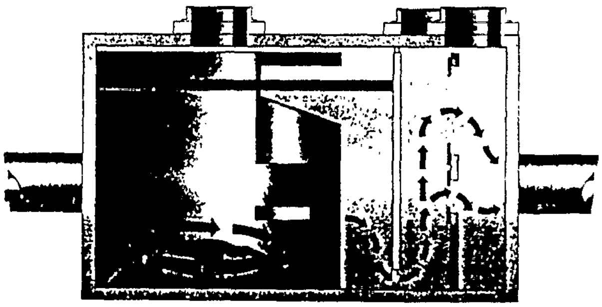
1) Initial Wet Weather Phase

During a two-month storm event the water level begins to rise above the top of the inlet pipe. This influent control feature reduces turbulence and avoids resuspension of pollutants.



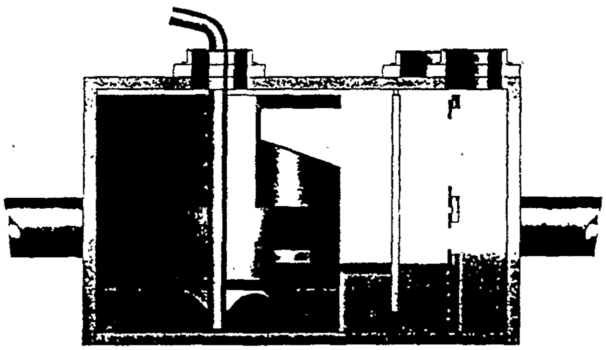
2) Transition Phase

As the inflow rate increases above the controlled outflow rate, the tank fills and the floating contaminant layer accumulated from past storms rises. Swirling action increases at this stage, while sediment pile remains stable.



3) Full Capacity Phase

When the high-flow outlet approaches full discharge, storm drains are flowing at peak capacity. The Vortechs System is designed to match your design storm flow and provide treatment throughout the range of storm events without bypassing. To accommodate very high flow rates, Vortechnics can assist designers with configuring a peak-flow bypass.



4) Storm Subsidence Phase/Cleaning

Treated runoff is decanted at a controlled rate, restoring the water level to a low dry-weather volume and revealing a conical pile of sediment. The low water level facilitates inspection and cleaning, and significantly reduces maintenance costs. The system's central baffle prevents transfer of floatables to the outlet during cleaning or during the next storm.

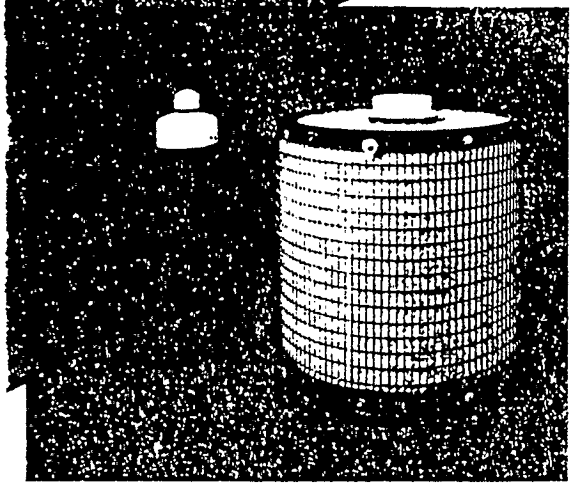
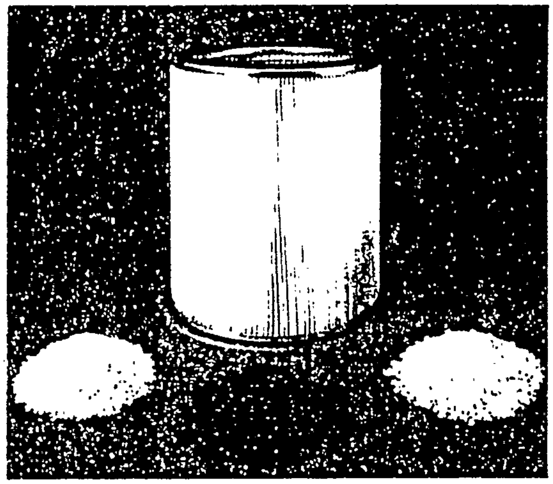
R0011416



The cartridge, shown with the hood removed, employs a siphon mechanism to efficiently draw polluted runoff through the media.



From left: Zeolite, CSF leaf media, perlite, and fabric inserts can be used individually or in combination to add to the system's versatility.

The StormFilter protects our environment by removing pollutants from stormwater runoff before they enter receiving waterways.

The StormFilter incorporates rechargeable cartridges housed inside vaults that are typically ordered as precast units. The cartridges contain various types of filtration media, including perlite, zeolite, fabric inserts and the patented CSF leaf media. With the StormFilter, you have the ability to select media based on site characteristics, as well as alter the media as a site matures or land use changes.

Nominal Flow	3-8 gpm	Mechanism	Gravity Feed Capable of All Types of Filter Medium
Electrical	None	Construction	100% Stainless Steel
Dimensions[2]	Standard/Custom Sizes		
Dry Weight	50 lbs.		

[1]Based on Filter Fabric used determines gallons per minute
[2]These measurements are based on the standard catch basin designs. Custom sizes also available

When Enviro-Drain stormwater filter is installed in catch basins, contaminated water enters through the grate and the water is diverted to enter Enviro-Drain, filtering out sediments, cigarette butts, rocks, leaves, and grass clippings in the top tray. The second tray is filled with Absorbent W™, a natural cellulose fiber that retains up to 7 times its weight in oil. The third filter is filled with activated carbon to neutralize fertilizers and pesticides. Each tray has its own characteristics and are properly spaced to eliminate clogging while providing aeration to the water which is needed to break down organic compounds and provide fish with adequate oxygen. By allowing you to use any variety or combination of filter medium Enviro-Drain stormwater filter is much more versatile and cost effective than other types of filters. Test results of Enviro-Drain stormwater filter proved to be very successful with up to 96% removal of efficiencies.* *Test results can be provided upon request.

ULTRA-URBAN™ FILTER with OARS® OnBoard

Narrative Description

The **Ultra-Urban™ Filter with OARS® OnBoard**, developed and manufactured by AbTech Industries, is an innovative low-cost BMP to help meet NPDES requirements. The Ultra-Urban™ Filter removes oil, grease, trash and sediment from stormwater runoff before it enters the storm drain system. The Ultra-Urban™ Filter is ideal for municipal, industrial and construction applications.

The Ultra-Urban™ Filter is designed for use in storm drains that experience oil and grease pollution accompanied by low concentrations of sediment and debris. The modular design of the filters will accommodate most storm drains. Trash and sediment accumulates in the internal basket while water is filtered through the unit to remove oil and grease. The proprietary **OARS® Smart Sponge™** polymer filtration media will remove up to 80% of the oil and grease in stormwater runoff -- from low concentrations typical of residential areas to high levels associated with illegal dumping of used motor oil. Oil is permanently bonded within the polymer eliminating the possibilities of leaching.

SUBJECT: PROPRIETARY STORMWATER CONTROL DEVICES, INFORMATION REQUEST

Dear Mr. ·

The Sacramento NPDES Stormwater Permittees include the City and County of Sacramento and the Cities of Folsom and Galt. The Permittees are responsibie for approving the use of stormwater controls in new developments within their respective jurisdictions, with the overriding goal of reducing discharges of stormwater pollutants to the maximum extent practicable. To help meet this goal, the Permittees are in need of additional information regarding specific proprietary structural control devices, especially with respect to the applicability and effectiveness of such devices for treatment of stormwater runoff in the Sacramento area. Your company was among those identified as a manufacturer or supplier of a proprietary device with potential application in Sacramento. The specific device identified is the Precast Interceptor.

Enclosed please find a brief questionnaire requesting specific information about your product. Please fill out the questionnaire to the best of your ability, using additional information and materials as appropriate. The information will be used to evaluate the potential usefulness of the specific device for achieving stormwater pollutant reductions in the Sacramento area.

The Permittees would greatly appreciate your timely response to this request. Please send your responses by January 11th to our consultant: Larry Walker Associates, 509 Fourth St., Davis, CA 95616, Attention: Armand Ruby. You may also contact Sherill Huun, City of Sacramento, Department of Utilities at (916) 264-1455 or Tom Garcia, County of Sacramento, Water Resources Division, (916) 874-6457 with any questions or comments you may have. Thank you for your cooperation.

Sincerely,

Larry F. Nash,
City of Sacramento

Tom W. Garcia,
County of Sacramento

EFFECTIVENESS OF STREET SWEEPING FOR STORMWATER POLLUTION CONTROL

TECHNICAL REPORT
Report 99/8
December 1999

T.A. Walker and T.H.F. Wong

COOPERATIVE RESEARCH CENTRE FOR
CATCHMENT HYDROLOGY

Effectiveness of Street Sweeping for Stormwater Pollution Control

T.A. Walker and T.H.F. Wong

Cooperative Research Centre for Catchment Hydrology

December, 1999

Preface

This report investigates the effectiveness of street sweeping as a stormwater pollution source control measure. The Cooperative Research Centre for Catchment Hydrology (CRCCH) Project U1 (Gross pollutant management and urban pollution control ponds) focuses on ways to improve the quality of stormwater runoff. The project covered means to reduce gross pollutants both before and after they entered the piped stormwater drainage system. This report describes a scoping study to assess the efficiency of Australian street sweeping practices in the removal of pollutants from street surfaces. This study has provided information on the effectiveness of street sweeping, currently practiced, in the collection of pollutants across the range of particle sizes representative of a street surface load.

It is a pleasure to acknowledge the contribution of Tracey Walker and Tony Wong to the Urban Hydrology Program. This work has provided important insights into the limited role street sweeping plays in improving stormwater quality.

Tom McMahon
Program Leader, Urban Hydrology
Cooperative Research Centre for Catchment Hydrology

Executive Summary

Street cleansing is a common (and expensive) practice undertaken by most urban municipalities with annual expenditure by a municipality often exceeding one million dollars. Street sweeping, essentially the operation of large trucks for cleaning street surfaces, is primarily performed for aesthetic purposes. It is, often perceived to lead to improvements in the environmental conditions of urban waterways by preventing pollutants deposited on street surfaces from reaching the stormwater system. There is, however, little available evidence to quantify the extent to which street sweeping can improve stormwater quality. This report investigates the effectiveness of street sweeping for stormwater quality improvement.

The effectiveness of street sweeping for stormwater pollution control is examined for two types of pollutants, gross pollutants (> 5 mm) and sediment (including associated pollutants). The research literature on street cleaning indicates a general dearth of studies that address the issues of gross pollutant management. Most studies predominantly examine the effectiveness of street sweeping for sediment and associated contaminant removal. This study looks at the effectiveness of street sweeping for gross pollutants using the results of Australian field studies, while sediment and other suspended solid removal is investigated with interpretation of results from overseas studies.

Experimental studies overseas found street sweeping to be highly effective in the removal of large solids greater than 2 millimetres under test conditions. However, field conditions are expected to significantly reduce the efficiency of solid removal because of limitations with sweeper access to source areas (mainly due to street design and car parking), sweeping mechanisms used and operator skills. Field studies undertaken by the Cooperative Research Centre for Catchment Hydrology (CRCCH) in Australia found significant stormwater gross pollutant loads generated from source areas in spite of a daily street sweeping regime.

An earlier CRCCH study, involving analysis of gross pollutant loads from a 50 hectare urban catchment of mixed residential, commercial and industrial land-use, found a clear relationship between the gross pollutant load in the stormwater system and the magnitude of the storm event. The shapes of the curves relating gross pollutant load to event rainfall and runoff were found to be monotonically increasing and representable by a logarithmic function. The shape of these curves suggests that the limiting mechanism affecting the amount of gross pollutants entering the stormwater system is rainfall dependent (ie. the available energy to re-mobilise and transport deposited gross pollutants on street surfaces) rather than being source limiting (ie. the amount of available gross pollutants deposited on street surfaces).

Overseas studies indicate that street sweeping is relatively ineffective at reducing the street surface load of fine particles (below 125 µm). The particle size distribution of suspended solids conveyed in stormwater in Australian conditions typically range from 1 µm to 400 µm with approximately 70% of the particles smaller than 125 µm. Therefore, street sweeping as it is currently practiced cannot be expected to be effective in the reduction of suspended solids and associated trace metals and nutrient concentrations in stormwater.

The study concludes that the performance of street sweeping for stormwater pollutant control is limited and must be accompanied by structural pollutant treatment measures to effectively reduce the discharge of gross and sediment associated pollutants in stormwater. The incremental benefits in increasing the frequency of street sweeping beyond what is required to meet street aesthetic criterion is expected to be small in relation to water quality improvements. As a result, there seems little benefit in conducting an in-depth field-based study into the effectiveness of street sweeping for stormwater pollution control.

Acknowledgements

The authors of this report would like to acknowledge the continued assistance and support provided by the Moreland City Council, particularly the cleansing manager, Les Horvath for sharing his knowledge of street cleaning operations. Many thanks to all those who were interviewed for Council information, especially Peter Barton from the City of Greater Dandenong who also arranged participation in an early morning street sweeping program.

In addition, Ranger Kidwell-Ross from American Street Sweeper magazine is thanked for his help and direction, and Roger Sutherland for forwarding current literature from America. The authors also wish to acknowledge in particular Dr Robin Allison for his advice and discerning suggestions, and Dr Francis Chiew for his comments and input.

1 Introduction

This report presents the findings of an investigation on the effectiveness of current Australian street sweeping practices in the collection of pollutants across the typical range of particle sizes found on street surfaces. The study was initiated to define and scope a further more-detailed field-based study to quantify the effectiveness of current street sweeping practices as an at-source stormwater pollution management measure. The term street sweeping is used here to describe essentially the operation of large trucks to remove deposited litter and debris from the kerb and channel of major roadways, streets, and carparks. The study examines the effectiveness of street sweeping practices to remove pollutants of two types:- (i) gross pollutant and litter removal and (ii) sediment and associated contaminant removal.

Over the past decade there has been an increase in the management of urban stormwater to protect urban waterways and receiving waters. These initiatives have, in part, resulted from community awareness of environmental impacts of urban stormwater pollution and their expectation that urban aquatic ecosystems should be protected from further environmental degradation.

Pollutants generated from urban land-use activities are transported by stormwater to urban receiving waters. Pollutants washed off street surfaces include gross pollutants, sediment and associated metals, nutrients, hydrocarbons and dissolved pollutants. Increased volumes of stormwater runoff and discharge rates resulting from increased impervious surface areas and hydraulically efficient drainage infrastructure throughout urban catchments have meant that the transport of urban pollutants to receiving waters is particularly efficient.

Most urban metropolitan councils perform cleansing of streets and similar impervious surfaces. This is commonly for the purpose of controlling gross pollutants, particularly litter, to maintain a level of street cleanliness and aesthetic quality. The focus on environmental issues is growing and local authorities are now considering street sweeping as a beneficial at-source method for reducing the amount of street borne pollutants entering the stormwater system. The actual contribution of street sweeping to the abatement of stormwater pollution is however not well understood. The objectives of street sweeping for street aesthetics and stormwater pollution control are very different, with the former placing particular emphasis on the visual impact of environmental pollution while the latter encompasses a much wider range of pollutant types and sizes. Despite street sweeping being widely considered an at-source stormwater pollution control method its effectiveness is unknown.

This report undertakes an interpretation of relevant street sweeping literature, research and survey results. The background to street sweeping operations, focusing on the effectiveness of sweeping for removal of street surface pollutants, is established in Section 2. The methodology undertaken for this investigation is discussed in Section 3. Results from a survey of 21 Melbourne Metropolitan councils on street sweeping practices are assessed in Section 4, to establish an understanding of current operations, target pollutants and sweeping frequencies. The different types of street sweeping mechanisms and their measured effectiveness are examined in Section 5. Pollutant types found on street surfaces are reviewed in Section 6, including an analysis of Australian sediment characteristics to assess the influence of street sweeping practices on fine particulates and associated contaminants.

Inter-event dry periods can influence street sweeping effectiveness and these are determined using Australian rainfall statistics in Section 7, and compared with current sweeping frequency and timing information. Section 8 examines field data to determine gross pollutant load generation and the influence of catchment land-use and associated sweeping frequency on pollutant load. The impact street sweeping has on gross pollutant loads entering the stormwater drainage system is discussed in Section 9, highlighting important issues affecting current sweeping efficiencies. Section 10 concludes with a summary of specific observations from each of the sections of the report from which the effectiveness of street sweeping as a stormwater pollution control method is assessed.

2 Background

2.1 Street Sweeping Pollutant Removal Monitoring

The role and usefulness of street sweepers to control street surface pollutants was first investigated in the late 1950's and early 1960's by the United States Environmental Protection Agency (US-EPA) and its associated researchers. Many of the US-EPA's National Urban Runoff Program (NURP) studies measured the efficiency of street sweeping as a stormwater pollution control method with particular emphasis placed on sediment and sediment-bound contaminants.

Since the late 70's studies have measured street sweeping effectiveness in terms of the reduction in end-of-pipe runoff pollution concentrations and loads rather than assessing the effectiveness of specific equipment. Sartor and Boyd (1972) found sweeping schedules based on a seven day cycle to be almost totally ineffective while daily sweeping was shown to potentially have a high level of pollutant removal for larger sized pollutants typical of street surface material (Sartor and Gaboury, 1984). Pitt and Shawley (1982) and Bannerrnan et al. (1983) concluded that only minor benefits to stormwater quality are provided by street sweeping practices. However, Terstrierp et al. (1982) and Pitt and Bissonette, (1984) demonstrated that street sweeping collects significant amounts of particles, for select particle size ranges, from street surfaces. The overall conclusion reached by the US-EPA, was that, as a water quality best management practice, street sweeping did not appear to be effective at reducing end-of-pipe urban runoff pollutant loads.

Subsequent investigations into the effectiveness of street sweeper mechanisms for water quality improvement report findings that vary to those presented in the conclusions of the earlier NURP studies. Alter (1995) and Sutherland and Jelen (1996b) assert that the NURP studies concluded that street sweeping is largely ineffective, because the sweepers used at the time of these studies were not able to effectively remove very fine accumulated sediments which are often highly contaminated. Sutherland and Jelen (1996a) suggest that street sweeping can significantly reduce pollutant washoff from urban streets due to the improved efficiencies of newer technologies now employed to conduct street sweeping in some American states. Their investigations showed that when street sweeping mechanisms and programs are designed to remove finer particles (ie. small-micron surface cleaners or tandem sweeping) it can benefit stormwater runoff quality.

2.2 Modelling Sweeper Pollutant Removal Efficiencies

Sweeping technologies with the ability to effectively remove accumulated sediments, including fine particles, may significantly increase the efficiency of sweeping for the removal of a variety of stormwater pollutants. Sutherland and Jelen (1993) described the use of a calibrated version of the Simplified Particle Transport Model (SIMPTM) as being able to accurately simulate the complicated interaction of accumulation, washoff, and street sweeper removal that occurs over a time period. For varying street sweeping operations Sutherland and Jelen (1997) employed the SIMPTM to predict the average annual expected reduction in total suspended solids (TSS) at two sites in Portland, Oregon. Sweepers used in their simulations included the NURP era broom sweeper, a mechanical broom sweeper, a tandem operation involving a mechanical broom followed by a vacuum sweeper and a newer technology, the small-micron sweeper. The predicted reductions in TSS showed that all of the newer street sweeping technologies are significantly more effective than the NURP era broom sweeper. It was further concluded that new street sweeping technologies designed for effective removal of fine particles, are capable of removing significant sediment loads and associated pollutants from urban street surfaces.

In a further study Sutherland and Jelen (1998) compared the new small-micron street sweeping technology to wet vaults, a widely used stormwater quality treatment method. The ability of the small-micron street sweeper to achieve significant reductions in urban pollutant washoff led Sutherland and Jelen to consider it an effective Best Management Practice (BMP) for stormwater pollution control.

2.3. *Factors Influencing Street Sweeping* Effectiveness

The pollutant reduction effectiveness of any street sweeping operation is dependent on the equipment used and the environmental and geographic conditions (eg. wind and presence of parked vehicles). Unless other influential factors (such as street parking) are addressed, the efficiency of individual sweeping mechanisms can be a relatively insignificant factor in the overall effectiveness of street sweeping operations. It is anticipated that the effectiveness of street sweeping programs depend more on factors such as land-use activities, the inter-event dry period, street sweeping frequency and timing, access to source areas and sweeper operation than the actual street sweeping mechanism. These factors all influence the deposition, accumulation and removal rates of pollutants on street surfaces. Physical features such as the degree of catchment imperviousness and the hydraulic characteristics of street surfaces can also influence the effectiveness of street sweeping. These factors require consideration before a thorough assessment of street sweeping efficiency for stormwater pollution control can be achieved.

3 Methodology

This study assesses the effectiveness of street sweeping for stormwater pollution control by:

- reviewing previous studies on sweeper performances and street pollutant characteristics,
- reviewing objectives for street sweeping operations (eg. aesthetic),
- considering rainfall distributions with street sweeping frequency and timing to investigate likely sweeper performance,
- examining field data from an earlier CRC study and others on gross pollutants,
- investigating the potential effects of changing street sweeping regimes on the gross pollutant loads in stormwater.

This study interprets available Australian and overseas field data on the measured efficiencies of street sweeping and street surface sediments. Various studies describing the particle size distribution of sediment loads were also collated to provide an insight into the particle size distribution pattern of suspended solids typical of street surface runoff. Some significant overseas studies on the partitioning of sediment sizes and the contaminant associations (eg. metals and nutrients) with each particle size partition were used to assess the pollutants likely to be discharged into the stormwater system from street surfaces. Information regarding street sweeping efficiencies and sediment contaminant associations from these studies are combined with data on Australian stormwater suspended solids characteristics to enable an assessment of street sweeping practices on removal of fine particulate associated pollutants.

A survey of street sweeping practices amongst municipalities in Melbourne was carried out to examine current sweeping objectives, procedures and mechanisms in these municipalities. This survey was also used to determine the perceived effectiveness of street sweeping in maintaining a certain standard of street aesthetics. Australian rainfall distributions were then examined and used to assess typical statistics of inter-event dry periods for Melbourne and other major capital cities in Australia. Melbourne inter-event periods were compared to the surveyed results of typical sweeping frequency and timing to investigate likely sweeper performance. This information facilitates a "hydrological basis" for selecting a street sweeping frequency that would optimise gross pollutant removal.

The study also examines data obtained from field studies previously undertaken by the CRC for Catchment Hydrology and others to investigate the effectiveness of street sweeping on litter and gross pollutant removal. Gross pollutant load data gathered at 192 side entry pit traps (SEPTs - baskets fitted into roadside stormwater entry pits) in the suburb of Coburg in Melbourne by Allison et al. (1998) were grouped according to the street sweeping frequencies in their respective streets. Similar data are available at two further study catchments in the suburbs of Carnegie and McKinnon in Melbourne (Hall and Phillips, 1997). The load data captured by the SEPTs during a typical street sweeping program are used to evaluate the amount of gross pollutants typically entering the stormwater system under normal Melbourne street sweeping frequencies and conditions. While it was not possible to compute a measure of pollutant removal efficiency owing to an inability to account for pollutants by-passing the SEPTs, the data nevertheless provided an insight on what might be the expected gross pollutant export load from streets that are swept at regular intervals.

4 Melbourne Street Sweeping Practices

4.1 Street Sweeping Operations

The responsibility of keeping urban streets clean, commonly by sweeping road surfaces with large vacuum trucks is an operation carried out by local government. A survey of 21 Melbourne metropolitan councils was performed to determine the motivation for the large expenditure on street cleaning. The results indicated that street sweeping is primarily undertaken for aesthetic purposes in response to community expectations. Table 4.1 summarises the street sweeping practices of 21 municipalities in Melbourne.

4.2 Target Pollutants

Street cleansing programs are generally designed to concentrate on collecting human derived litter to address the obvious visual impacts. However, during autumn, organic matter becomes a focus and the sweeping frequency is altered to reduce the safety hazard associated with decomposing leaf litter on street surfaces and to reduce drain blockages. Street surface sediment collection was not identified as a major issue when designing street sweeping programs.

Street cleansing programs involve what is often termed 'building line to building line' cleansing, incorporating footpath cleaning, and the standard kerb and channel street sweeping where it is apparent a large proportion of litter accumulates. This requires a combination of cleansing methods and equipment for the successful removal of such pollutants. Australian streets are cleaned customarily with large truck mechanical broom and vacuum systems. However, it is becoming common practice to operate smaller broom and vacuum sweepers designed for cleansing areas inaccessible to the traditional larger plants. The most commonly used sweepers are the regenerative air model, for both large truck and small plant systems.

4.3 Contracts and Sweeping Frequency

Under new competitive tendering legislation, the bidding process for street cleansing contracts establishes a requirement for operators to become very competitive. Contractor performance is measured against output based specifications set by the council. This means the council stipulates a set of cleanliness requirements they wish to achieve with a street cleansing program but not the frequency or operation methods used. Street sweeping practices therefore differ considerably between Melbourne metropolitan councils. Street sweeping frequencies can range from every two weeks to every six weeks in residential areas and from daily to every two weeks in commercial areas. Shopping centres and commercial areas are swept more frequently, typically ranging from once or twice a day in busy areas and once or twice a week in less popular areas. Street sweeping frequencies for residential areas range from once a week for highly populated areas to every six weeks in less populated areas.

Table 4.1 Street Sweeping Practices for Melbourne Municipalities

COUNCIL	PURPOSE	TARGET POLLUTANT	CONTRACT	FREQUENCY		SWEEPING MECHANISM	COUNCIL PERSPECTIVE

Note: Councils not listed were conducting tender negotiations for street sweeping practices during the time of the survey.
H & S = Health and Safety
SW = Stormwater Quality
CD = Community Demand

4.4 Council Perspective of Effectiveness

All but two councils indicated that street sweeping as it is currently practiced was an effective way of collecting litter. Numerous councils stated that street sweeping aided in the prevention of litter entering the stormwater system and therefore reduced the occurrence of stormwater pollution and drain blockage but had no data to validate these observations. Several councils regarded street sweeping as effective only when practiced in conjunction with other source pollution control methods such as bins, side entry pit traps and other gross pollutant traps.

Overall the survey indicated a general satisfaction with the effectiveness of street sweeping in collecting human derived litter and organic matter (gross pollutants) for aesthetic objectives. However, there is little quantitative information for councils to assess the effectiveness of street sweeping practices on stormwater pollution reduction. Throughout the literature there are many suggestions that street sweeping can have an effect on stormwater quality although the degree to which this practice is effective is unknown.

The assessment of the effectiveness of street sweeping in stormwater pollution control rather than just aesthetic requirements will need a detailed analysis of the following major influencing factors.

- street sweeping mechanism
- pollutant types (from sediment and associated contaminants to gross pollutants)
- sweeping frequency & timing
- pollutant load wash-off characteristics

Each one of these factors is examined in detail in the following sections of this report.

5 Street Sweeping Mechanisms

5.1 Types of Sweeping Mechanisms

Types of street sweeping mechanisms commonly utilised in Australian practice include:

1. Mechanical broom sweepers involving a number of rotating brushes sweeping litter into a collection chamber;
2. Mechanical broom and vacuum systems involving the combination of rotating brushes and a vacuum to remove street litter;
3. Regenerative air sweepers which are like mechanical vacuum sweepers but use recirculated air to blast the pavement, dislodging litter before it is swept by rotating brushes towards a vacuum for pick-up. This sweeper also uses water sprays for dust suppression,
4. Small-micron surface sweepers which combine rotating brooms enclosed in a powerful vacuum head in a single unit, performing a dry sweeping/vacuuming operation. A powerful fan pulls debris and air into a containment chamber before the air is finally passed through a series of filters to capture small micron material.

5.2 Sweeper Effectiveness

Pitt and Bissonnette (1984) found following a period of street sweeping trials that street sweeping equipment was unable to remove particles from the street surface unless the loadings were greater than a certain threshold amount. This value was found to be three times higher for a mechanical broom cleaner, most referred to in the US-EPA's NURP studies, compared to the regenerative air street sweeper trialed for a comparison in a study by Pitt and Bissonnette (1984). The study found the regenerative air vacuum sweeper to exhibit a substantially better performance than the regular mechanical street sweeper, especially for the smaller particle sizes. Such findings have progressively led to the mechanical broom method being replaced by the vacuum system method for street sweeping practices. The removal effectiveness data for the smallest particle sizes (less than 125 µm) between the two methods of street sweeping was however found to be inconclusive.

The regenerative air vacuum sweeper (Figure 5.1) is a common mechanism used for street sweeping in Australia. The recirculating air cycle tends to improve the effectiveness of sweepers for the removal of heavy debris but is less effective for removing fine sediment. The air blast is able to dislodge heavier

Figure 5.1 Australian streets are cleaned with large truck vacuum sweepers

materials and propel them into the vacuum airflow however finer materials often remain uncollected (Pitt and Bisonnette,1984). Fine particles may become airborne as a result of the air blast and take some time to settle back onto the road surface or may be left behind on the street surface.

The most recent technology to be employed for street sweeping is a highly effective, vacuum-assisted dry sweeper (the small-micron surface sweeper) originally developed and manufactured by Enviro Whirl Technologies Inc in the United States of America. The sweeper was originally developed for the containment of spilled coal dust along railway tracks. This system is reported to be extremely effective in removing fine street surface sediments and preventing their escape into the air by filtering air emissions down to sizes as small as 4 µm. Sutherland and Jelen (1997) described this system as having an advanced ability, when compared to other sweeping mechanisms, to remove a broad range of particles from road surfaces down to sub micron particulates. The small-micron surface cleaning technology has been shown by Sutherland and Jelen (1997) to have total removal efficiencies ranging from 70% for particles less than 63 µm up to 96% for street surface pollutants larger than 6370 µm.

Despite there being new street sweeping technologies reported to be more efficient, most municipalities and private street sweeping companies in Australia continue to use the mechanical broom and regenerative air vacuum street sweepers. This is because of the high capital costs of newer technologies and their limited availability on the Australian market.

Street Sweeping Mechanism:

- Mechanical and regenerative air street sweeping equipment requires a minimum threshold load of sediment on the street surface before they become effective.
- The threshold load can be three times higher for the mechanical sweeper compared to the regenerative air system.
- Overall the regenerative air sweeper exhibits a substantially better performance than the regular mechanical sweeper.
- Street sweeping technology is developing and improving to remove finer street surface particles for a variety of street surface loads,

R0011443

6 Pollutant Types

The effectiveness of street sweeping to remove pollutants, across the typical range of particle sizes found on street surfaces, has not yet been successfully quantified for Australian conditions. The examination of street sweeping effectiveness in the present study focuses on two pollutant types:- (i) gross pollutants and litter and (ii) sediment and associated contaminants. Gross pollutants have been defined as any solids that are retained by a 5 mm mesh screen by Allison et al. (1998) and this definition is adopted here. Solids washed off street surfaces which are smaller than 5 mm and not considered to be gross pollutants include a proportion of litter and organic matter but are predominantly sediment particles, typically between the course sand to fine silt range, and sediment associated contaminants.

6.1 Gross Pollutants

Allison et al. (1997a) undertook an investigation into the types of gross pollutants derived from an urban catchment. The study found typical urban gross pollutants transported by stormwater to include litter (predominantly paper and plastics) and vegetation (leaves and twigs) as shown in Figure 6.1. Organic matter comprised the largest proportion by mass of the collected gross pollutants and therefore should be a major consideration in street cleaning programs. The data was based on field monitoring of gross pollutants retained in a Continuous Deflective Separation (CDS) unit treating a catchment area of 50 hectares in Coburg, an inner city suburb of Melbourne.

Only a small number of investigations have examined street sweeping effectiveness on gross pollutant removal. Nilson et al. (1997) conducted an investigation into source control of gross pollutants in Adelaide and attempted to assess the efficiency of street sweeping for gross pollutant removal in stormwater. This study sought to quantify the amount of gross pollutants entering the drainage network in three similar streets swept at different intervals. Catch baskets in side entry pits were used to collect gross pollutants which were not otherwise collected by the sweeper for a street swept every day, once a week, and not at all. Trapped pollutants in these

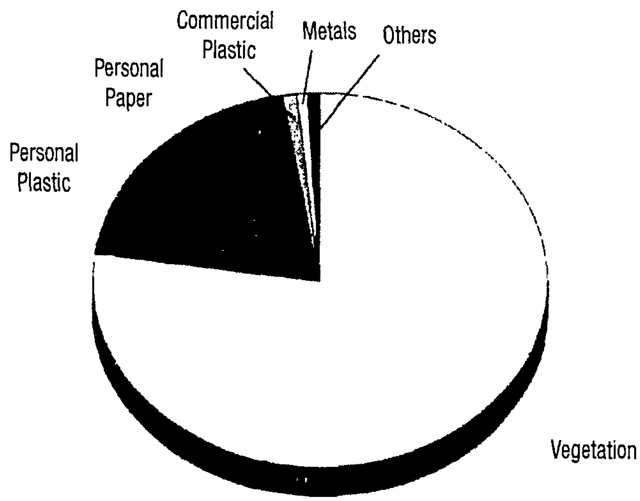

Figure 6.1 Composition of Gross Pollutants by Mass (Allison et al., 1998)

R0011444

baskets were removed and quantified weekly during the study.

The results of the study by Nilson et al. (1997) show little correlation between the frequency of sweeping, rainfall or wind-run in the catchment with the gross pollutant load collected in the catch baskets. The study provided little conclusive information on the effectiveness of street sweeping with respect to gross pollutants. The study found that typically, a significant amount of gross pollutants were mobilised into the stormwater system from the street during bursts of rain, wind or both, irrespective of the nature of the street sweeping program implemented. These results suggest the amount of gross pollutants or street surface load does not limit the amount transported into the stormwater system regardless of the street sweeping frequency.

The observed composition of the gross pollutant material collected by Nilson et al. (1997) was consistent with other studies conducted by Sartor and Boyd (1972), O'Brien (1994) and Allison and Chiew (1995), where gross pollutant loads measured in dry mass comprised approximately 70-90% organic matter, and 10-30% litter.

Broad-based investigations into street sweeping conducted by the US-EPA suggest that street sweeping efficiency increases with particle size. Sartor and Boyd (1972) found sweeper efficiency to be nearly 80% for the collection of particles greater than 2 millimetres under 'test' conditions (ie. sweeping more frequently than the occurrence of rainfall events and effective use of parking restrictions). Ideal street cleaning conditions are unlikely to occur during normal street sweeping operations, and sweeper efficiencies for collecting gross pollutants would be expected to be considerably lower than the recorded 80% despite any improvements gained through refinements of equipment since the study. In practice, the effectiveness of street sweeping for gross pollutant removal is influenced by a number of factors including: access to the street load, operator skills and sweeping speed, sweeping mechanism, time of day sweeping is conducted and weather conditions.

Gross Pollutants:

- Typical urban gross pollutants transported by stormwater include litter (predominantly paper and plastics) and vegetation (leaves and twigs).
- Significant amounts of gross pollutants are mobilised into the stormwater system during bursts of rain, wind or both.
- There is little correlation between the frequency of sweeping and the transport of gross pollutants into the stormwater system.
- Street sweeping efficiency increases with particle size.
- Sweeper efficiency can be up to nearly 80% for particles greater than 2 millimetres under 'test' conditions (ie. Sweeping more frequently than the occurrence of rainfall events and effective use of parking restrictions).

6.2 Sediment and Other Suspended Solids

Street sweeping performance for smaller street surface particles depends considerably on the type of street sweeper used and also conditions such as the character of the street surface (texture, condition and type), street dirt characteristics (loadings and particle sizes), and other environmental factors (Pitt and Bissonnette, 1984).

Sartor and Boyd (1972) found the removal efficiencies of sediment by conventional street sweepers to be dependent upon the particle size range of the street surface loads as shown in Figure 6.2. Mechanical sweeper efficiency was found to be generally low for fine material. This finding was supported by two further studies conducted by Bender and Terstriep (1984) and Pitt and Bissonnette (1984), who reported that the proportion of the total street load smaller than 300 μm was less affected by street sweeping. Pitt and Bissonnette (1984) also demonstrated that no effective removal was evident for street dirt particles smaller than about 125 μm for the regenerative air sweeper.

Mechanical broom sweepers are found to be effective at collecting larger particles but less effective than regenerative-air vacuum sweepers in removing the smaller particles (Pitt and Shawley, 1982). The regenerative air vacuum sweeper, although regarded as more effective at collecting smaller particle sizes does not successfully control or remove fine particles.

Problems are encountered with water-based dust suppression methods as they tend to resuspend the small micron particles and their associated attached pollutants, forming a slurry which either fills the cracks in the pavement or is discharged into the stormwater system. Similarly, fine particles can easily escape collection when they are re-mobilised into the air by the pavement blast used by the regenerative air sweeper to dislodge larger materials.

Studies by Pitt and Sutherland (1982) indicated that a significant proportion of the larger dirt particle sizes picked up by street sweepers are not easily transported by rain and that removal of these particles tends to expose the smaller sheltered particles. These smaller particles exposed by street sweeping are then more readily mobilised and transported into the stormwater drainage system during rainfall events. The small-micron surface sweeper sweeps dry, with no water being used, and thus overcomes problems associated with resuspension of fine particulates and associated pollutants by dust suppression sprays. These machines utilise strong vacuums in combination with uniquely-designed main and gutter brooms. The air filtration system, enables smaller particles to be removed from the street surface with the return of clean air to the atmosphere (ie. filters particles down to 2.9 microns). This relatively new technology is regarded to be a high-efficiency sweeper (Sutherland et al., 1998).

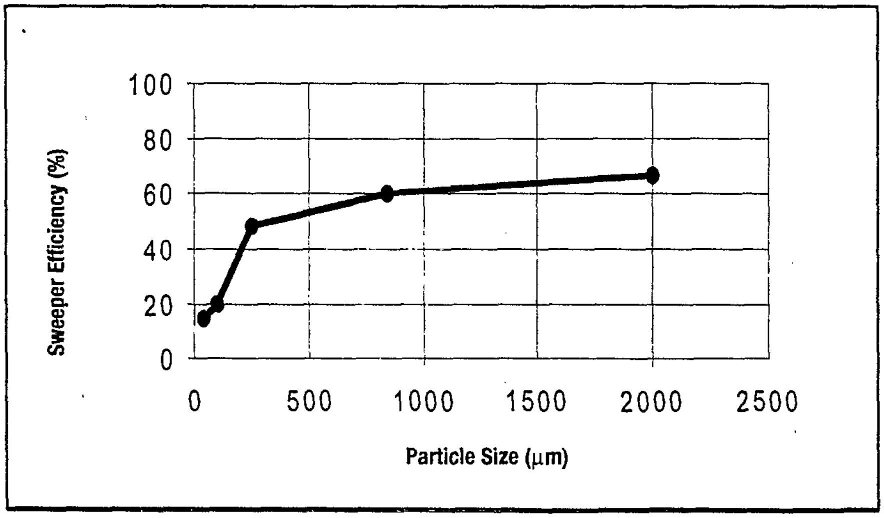

Figure 6.2 Street sweeping efficiency as a function of particle size (Sartor and Boyd, 1972)

R0011446

The removal performance of street sweepers for sediment has been often determined from sampling accumulated street dirt before and after sweeping has been conducted. Initial street surface conditions are established and the street swept at a specified speed of 7-8 kilometres per hour before it is sampled to establish the residual condition. The difference between initial and residual loadings by specific particle size defines the removal performance of street sweeping operations. It was concluded from this method that sweeping removes little, if any, material below a certain threshold. This threshold load was found to vary by particle size range. A series of mathematical equations developed by Pitt (1979) to describe this removal performance have been recently calibrated and employed by Sutherland and Jelen (1996a and 1997) to evaluate and compare the removal performance of numerous street sweeping technologies.

Sutherland and Jelen (1997), using their Simplified Particle Transport Model, tested the removal performance of the small-micron sweeper, along with a regenerative air vacuum sweeper, a mechanical broom sweeper, and a tandem operation that involved a single pass by a mechanical broom followed by a vacuum sweeper. The small-micron sweeper was shown to be the most efficient, with average total removal efficiencies of 70% for particles less than 63 μm and between 77% and 96% for particle sizes ranging from 125 μm to larger than 6370 μm. The small-micron sweeper demonstrated an ability to efficiently remove particles without any threshold level unlike the other sweepers tested. The regenerative air sweeper was shown to be the second most efficient with overall removal efficiencies calculated to range from 32% for less than 63 μm range to 100% for larger particles between 600 and 2000 μm. However, the removal efficiency of the regenerative air sweeper for particles between 250 and 2000 μm can drop to zero, due to the necessity of large threshold loads for particles within this size range. The tandem operation and mechanical broom sweeper were found to be the least efficient despite some recorded high efficiencies. This can be mainly attributed to the high threshold loads required by these operations before any significant sediment removal is recorded.

6.3 Contaminants Associated with Sediment

It is well recognised that a significant amount of metals and nutrients are transported as sediment-bound contaminants. Many investigations have found the concentration of sediment-bound contaminants to vary with particle size, with high concentrations of contaminants attached to the finer particles (Sartor & Gaboury 1984, Sartor & Boyd 1972). Hvitved-Jacobsen et al. (1991, 1994) investigated road runoff pollutant characteristics and found 60-80% of phosphorous, 30-40% of zinc, 70-80% of lead, 30-40% copper and about 55% of total nitrogen in road

Sediment and Other Suspended Solids:

- The removal efficiency of sediment and other fine organic particles by conventional street sweepers was found to be dependent upon a threshold level of load on the surface and the particle size range of the surface loads.
- Material smaller than 300 μm was less affected by street sweeping.
- No effective removal (>50% removal efficiency) was evident for particle sizes smaller than 125 um for conventional street sweepers (excluding the new small-micron surface cleaning technology).

runoff to be associated with particulates. While most particulate matter found on street surfaces is in the fractions of sand and gravel. Approximately 6% of particles are in the silt and clay soil size and they were found to contain over half the phosphorous and some 25 percent of other pollutants, as indicated in Table 6.1, adapted by Shaver (1996) from results of Sartor et al. (1974).

Many other investigations have found the concentrations of sediment-bound contaminants in street dirt to be associated with the fine particle size fraction. Pitt & Amy (1973), NCDNRCD (1993) and Woodward-Clyde (1994) have all shown that higher concentrations of pollutants such as heavy metals are associated with the smallest particle size fractions of urban dust and dirt. These data indicate that almost half of the heavy metals (represented by copper, lead and zinc) found on street sediments are associated with particles of 60 to 200 µm in size and 75% are associated with particles finer than 500 µm in size. Dempsey et al. (1993) undertook an analysis of particle size distributions for urban dust and dirt, and partitioning of contaminants into a number of size fractions to determine the concentrations of contaminants in each particle size range. Results show the highest recorded concentrations of Cu, Zn and TP to be associated with sand particles between 74 and 250 µm in size.

Colwill et al. (1984) found 70% of oil and approximately 85% of polycyclic aromatic hydrocarbon (PAH) to be associated with solids in the stormwater. That study demonstrated that over a period of dry weather conditions, increasing proportions of oil become solid associated where the highest oil content was found in sediments of 200 to 400 µm in size.

Sansalone et al. (1997), Fergusson and Ryan (1984), Baker (1980) and Wilber and Hunter (1979) all reported that heavy metal concentrations increase with decreasing particle size. Results presented by Sansalone et al. (1997) from particle size distribution and metal analysis indicate that zinc, copper and lead concentrations increase with decreasing particle size or, equivalently, increasing specific surface area. The absorption of contaminants to particles is often regarded as being directly related to the surface area per unit mass available for ion absorption. Measured specific surface area results presented by Sansalone et al. (1997) indicated that the assumption of smooth spherical particles to estimate available surface area

Table 6.1 Percentage of Street Pollutants in Various Particle Size Ranges

	Particle Size (µm)					
Pollutant	**<43**	**43 - 104**	**104 - 246**	**246 - 840**	**840 - 2000**	**>2000**
Total Solids	5.9	9.7	27.8	24.6	7.6	24.4
Volitile Solids	25.6	17.9	16.1	12.0	17.4	11.0
COD	22.7	45.0	12.4	13.0	4.5	2.4
BOD	24.3	17.3	15.2	15.7	20.1	7.4
TKN	18.7	19.6	20.2	20.0	11.6	9.9
Phosphates	56.2	29.6	6.4	6.9	0.9	0.0
All Toxic Metals	27.8	-	23.5	14.9	17.5	16.3

(Source: Shaver; 1990; adapted from Sartor, Boyd, and Agardy, 1974) grossly underestimated the actual available surface area of particulates transported in stormwater. Specific surface area values were found to deviate from the monotonic pattern expected for spherical particles. Particles in the mid-range to coarser end (100 to 1000 μm) of the distribution were shown to contribute a larger surface area than would normally be expected.

The sediment binding behaviour of other toxicants such as polychlorinated biphenyls (PCB's) and polycyclic aromatic hyrdrocarbons (PAH's) is different to that of heavy metals. Schorer (1997) reported PCB's and PAH's to have no correlation with particle size distribution or surface area but rather with the abundance of organic material. Results indicated that the organic material content in different particle size fractions was bimodally distributed with maximum measurements recorded for fine silt (2 - 6.3 μm) and fine sand fractions (63 - 200 μm). Concentrations of PAH's would therefore be expected to be attached to these particle size fractions.

A substantial database, identifying particle size distributions and other parameters that relate to reactivity and mobility of contaminants, has resulted from data collected by a number of US-EPA studies. However, to date only limited information regarding the physical and chemical characteristics of urban stormwater runoff are available for Australian conditions. Results from an investigation by Mann and Hammerschmid (1989) on urban runoff from two catchments in the Hawkesbury/Nepean basin indicated the existence of high correlations between total suspended solids (TSS) with total phosphorus (TP), total kjeldahl nitrogen (TKN) and chemical oxygen demand (COD). Ball et al. (1995) found that TSS and TP show similar characteristics and correlations to other overseas studies.

In relation to street sweeper effectiveness, the association of pollutants with sediment, particularly the finer fractions, would suggest street sweeping needs to remove these particles in order to provide effective stormwater pollution control. However, street sweeping has to date been found to be generally effective only for material larger than 300 μm (see section 6.2).

Contaminants Associated with Sediment:

- Significant amounts of metals and nutrients are transported as sediment-bound contaminants.
- Most of the total mass of contaminants is associated with the fine particles.
- Conventional street sweeping is generally ineffective at removing particles smaller than 300 μm and therefore will not effectively reduce the export of sediment-bound contaminants such as nutrients, metals and PAHs.

R0011449

6.4 Australian Conditions

Various studies undertaken by the US-EPA found the major constituents in street dirt to be consistently inorganic, mineral-like matter, similar to common sand and silt. This could be due to the fact that many of the US-EPA studies were conducted in cities where applications of screened sands are made to road surfaces. Street surface particulate matter has been described as having particle sizes ranging from about 3000 to 74 µm and less (Sartor and Gaboury, 1984).

A collation of reported particle size distribution curves for solids found on street surfaces and in street surface and highway runoff is shown in Figure 6.3. The collection of 20 particle size distribution curves presented in Figure 6.3 are derived from sampling solids from street surfaces and suspended sediment collected in road runoff from a number of overseas and Australian catchments.

It is evident from Figure 6.3 that despite the overseas data being collected from a variety of sources, locations and by various methods, they show a consistent distribution ranging from approximately 10 µm to approximately 10,000 µm. The particle size distributions derived from sampled road runoff from two Australian sites, one as part of an ongoing CRC project and the other by Ball and Abustan (1995), are also presented and appear to fall outside the range of the particle size distribution curves of the overseas catchments. The Australian data range from 2 µm to approximately 500 µm. There may be a number of possible explanations for this observed finer particle size distribution including differences in sampling and analysis techniques. However, it should be noted that the particle size distributions derived from overseas catchments were based on a variety of sampling and analysis techniques. The upper particle size limit can influence the position of the derived particle size distribution curve. Adjustments (Lloyd and Wong, 1999) to the overseas data to eliminate particles larger than 600 µm, to allow a common basis for comparison of these curves, still showed the Australian data sets to exhibit finer particle size characteristics. The significantly different particle size distribution of the Australian catchments may indicate fundamental differences in catchment characteristics.

The Australian sampled road runoff data displays a significantly finer particle size distribution, with a greater percentage of particles less than 125 µm (up to 70%). Although only based on sampling at two sites, the inefficiencies of street sweeping in removing particles less than 125 µm would result in little reduction of up to 70% of the particles found in runoff in these Australian catchments. The difficulty for Australian street sweeping is the fine nature of the sediment found on roads. Up to 70% of particles found on street surfaces are less than 125 µm compared to 20% for overseas road runoff data. The inefficiencies of street sweeping in the reduction of sediment-bound pollutants entering the stormwater system is therefore expected to have more severe implications under typical Australian conditions.

Removal of Sediment and Associated Contaminant:

- Limited sampling of sediment in street runoff in Australia indicates that 70% of particles are less than 125 µm compared to 20% for overseas data.
- The fine sediments found on Australian streets would suggest that conventional street sweeping will have a minimal effect on sediments and associated contaminants reaching stormwater systems.

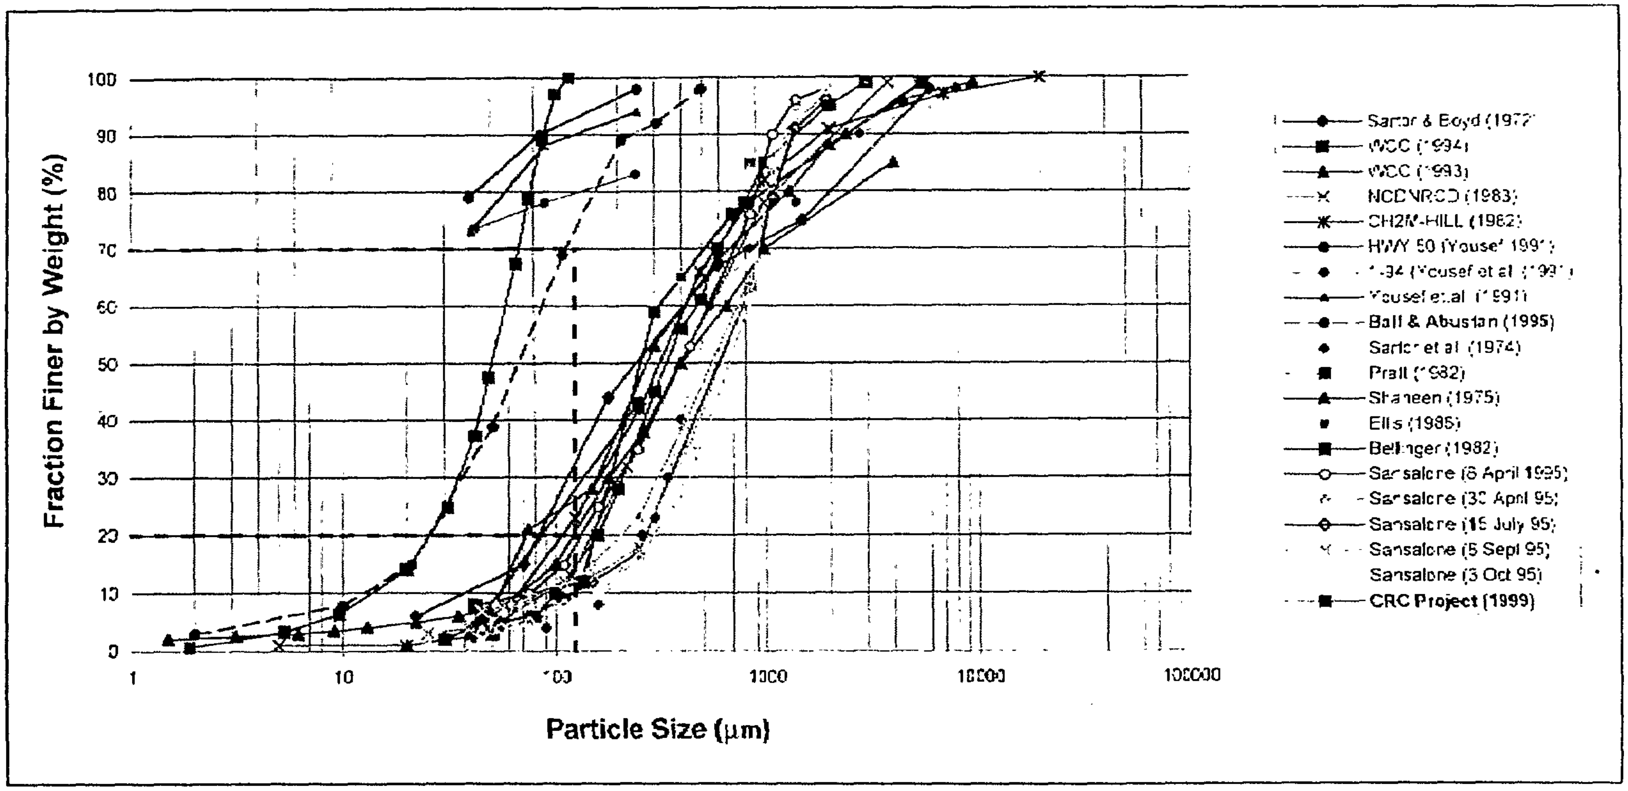

Figure 6.3 Particle Size Distribution of Suspended Solids in Road Runoff

7 Street Sweeping Frequency And Timing

7.1 Sweeping Frequency and Rainfall Patterns

Sartor and Gaboury (1984) concluded that the dominant influence on the effectiveness of street sweeping appears to be time intervals, ie. the relationship between the average interval between storm events (a function of local meteorological conditions) and the frequency at which streets are swept. Street sweeping operations are typically programmed for a fixed interval (eg. swept once per week). If the average time between rainfall events is much less than the sweeping interval, then much of the street surface load could be washed away by storm runoff, hence, making street sweeping relatively ineffective. In this context, analysis of rainfall statistics is important in the design of street sweeping programs to ensure street sweeping is compatible with the frequency of storm events and therefore optimise the effectiveness of street sweeping for removal of stormwater pollutants.

Generally street sweeping frequencies are determined according to land-use. Street sweeping frequencies, practiced by Melbourne metropolitan municipalities, generally range between daily sweeping for busy commercial areas and every six weeks for residential areas. The sweeping frequency in the CBD of Melbourne could however involve numerous sweeps throughout the day. Councils ordinarily stipulate sweeping specifications for the purpose of meeting community demands for aesthetic quality and amenity improvement. The inter-event dry period between storms is not often a factor considered when street sweeping programs are formulated. However, if municipalities are willing to incorporate stormwater management objectives into street sweeping programs, the occurrence of rainfall events should become a significant design factor.

The minimisation of pollutant washoff, particularly fine particulates and associated contaminants, from street surfaces requires compatibility of street sweeping frequency and timing with rainfall characteristics and the daily activities in the catchment. Fine particulates and associated contaminants are often mobilised with even the smallest amount of runoff while gross pollutants often require a minimum runoff rate to be reached before they are mobilised. In areas which are not swept daily, the selected street sweeping frequency should ideally reflect the relationship with the inter-event dry period (time between storm events) typical of the catchment. For those catchments currently on a daily street sweeping regime, the time of day when street sweeping is conducted should be selected to limit the period in which the pollutants deposited on street surfaces are exposed to the risk or likelihood of wash-off associated with a storm event.

7.2 Inter-Event Dry Period

It can be assumed that the majority of pollutants transported into the stormwater system occur during rainfall event periods. Therefore if the street cleaning frequency is longer than the average inter-event dry period it can be expected that the accumulated pollutants, on road surfaces, will have a higher likelihood of being washed into the stormwater system before being collected by the street sweeper.

Melbourne rainfall was characterised from analysis of rainfall over a 105 year period by Wong (1996). The analysis identified storm events as having a thirty minute minimum storm duration. A six hour minimum period of no rainfall to define the conclusion of a rainfall event. Using this definition for a storm event, the analysis found the mean period between storms in Melbourne to be 62.4 hours (2.6 days) with a standard deviation of 76.8 hours (3.2 days). There is an apparent trend in Melbourne of longer periods between storms in summer months, with a maximum mean period of 108 hours (4.5 days) in February and a minimum mean period of 45 hours (1.9 days) in August as shown in Figure 7.1. Wong (1996) also carried out an analysis of the rainfall data for a number of major cities in Australia, and the statistics according to their respective months are presented in Table 7.1. The influence of seasonality on the period between storms for the cities is shown in Figure 7.2.

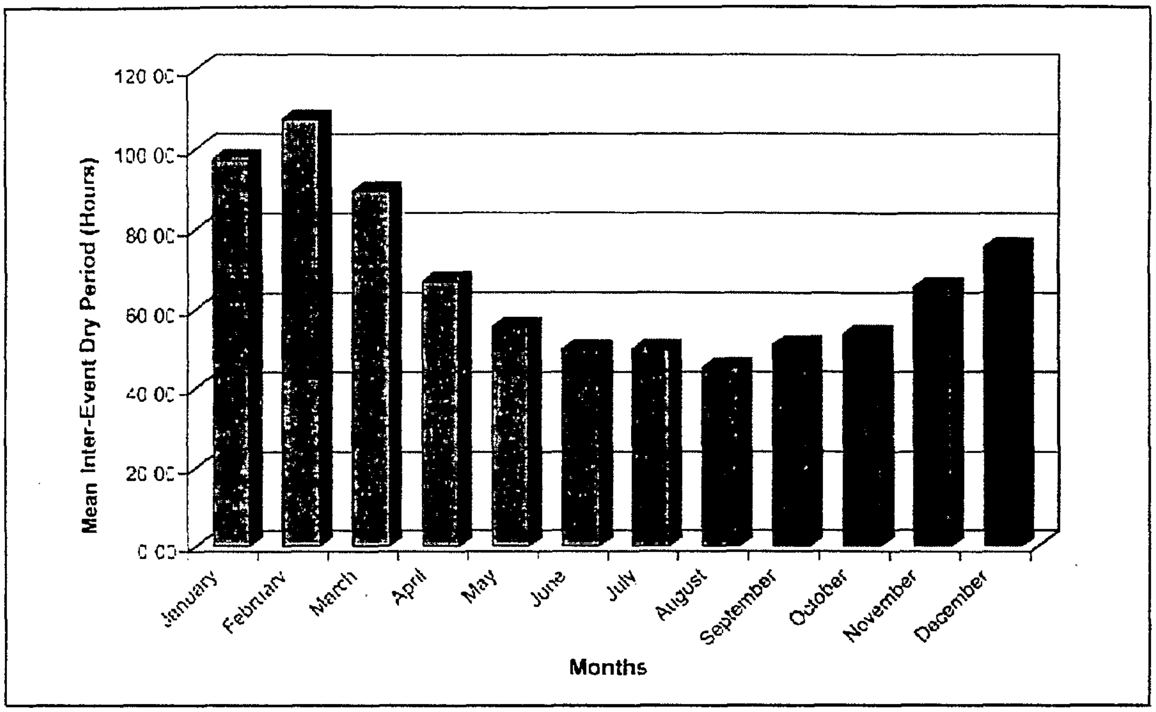

Figure 7.1 Melbourne Mean Monthly Inter-Event Dry Period

Table 7.1 Mean Inter-Event dry Periods (Hours).

CITIES	JANUARY	FEBRUARY	MARCH	APRIL	MAY	JUNE

Perth	39.96	53.79	62.20	88.16	141.96	193.17
Sydney	91.48	98.50	97.78	77.87	68.92	76.31

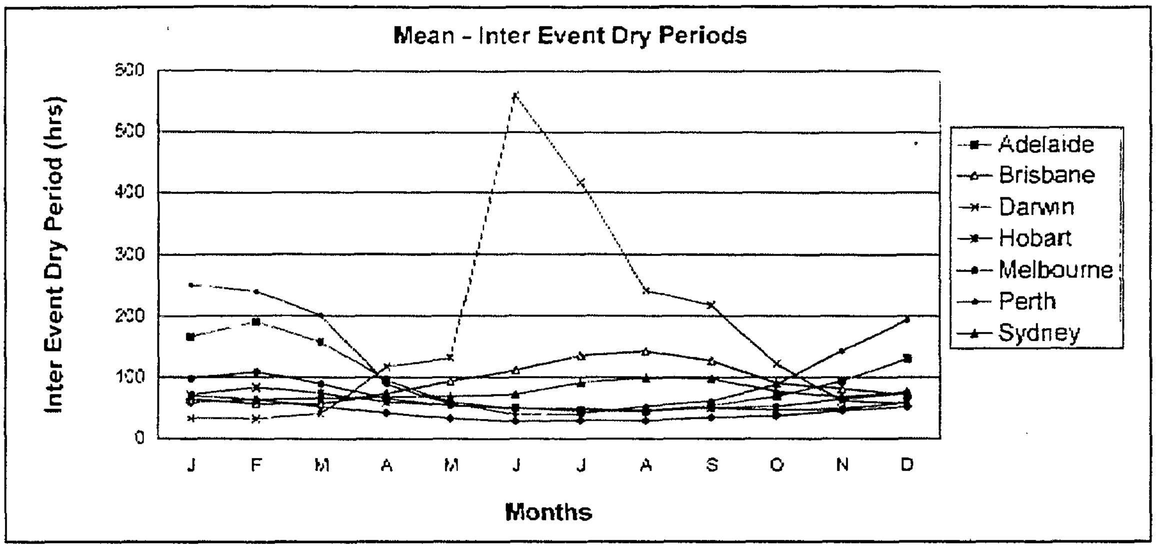

Figure 7.2 Mean Inter-Event Periods for Australian Cities

Of the cities analysed, Darwin shows the most inter-event dry period variability between seasons, ranging between 32 hours (1.3 days) and 561 hours (23.4 days), with the longer periods, unlike Melbourne, occurring during the winter months. The variable nature of inter-event dry periods, both between seasons and capital cities highlights the importance of street sweeping program design being specific to location and flexible to accommodate for season variability.

Based on consideration of typical inter-event dry periods, one would question the effectiveness of current Australian street sweeping practices in effectively preventing pollutants entering the stormwater system if the street sweeping frequency, designed for aesthetic objectives, is significantly lower than the frequency of storm events. If streets are only swept every six weeks then it is likely that storm events occurring within this period will flush a large proportion of the accumulated pollutants into stormwater drains before sweeping has the opportunity to collect it. In the case of gross pollutants, Allison et al. (1998) suggested a minimum rainfall amount before there is sufficient runoff to re-mobilise these larger size pollutants. As a gross pollutant export control, sweeping frequency equivalent to approximately three times the mean inter-event period appears to be appropriate (see Section 8.1).

Sweeping Frequency and Rainfall Patterns:

- The variable nature of inter-event dry periods, both in terms of seasonal variation and dependence on climatic locations, highlights the importance of street sweeping program designs which are specific to location and flexible to accommodate the local meteorological conditions and seasonal variability.
- It is anticipated that if street sweeping occurs at a longer interval than the inter-event dry period of the catchment, street surface pollutants will have a much higher likelihood of being flushed into the stormwater system before being collected by the street sweeper.

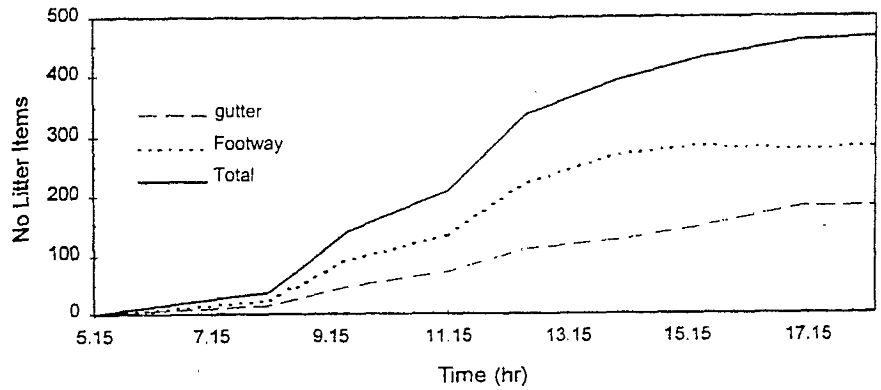

Figure 7.3 Daily Litter Generation (Hall and Phillips., 1997)

7.3 Street Sweeping Timing

Analysis of street and footpath litter accumulation along a 280 m section of strip shopping centre in the Melbourne suburb of Carnegie during a typical business day was conducted by Hall and Phillips (1997). This commercial land-use area is subject to typical street sweeping operations carried out daily by the Glen Eira municipality. Detailed recording of the gross pollutant load generated over a day from 5:15 to 18:30 commenced immediately after street sweeping and footpath cleaning and concluded when trade had effectively ended. The data indicates that the rate of accumulation of litter is highest between the times of 8:00 and 17:00 with litter accumulation effectively ending around 17:00 hours in the evening (see Figure 7.3).

The data plotted in Figure 7.3 suggest that the time of day a rainfall event occurs can alter the amount of litter available for re-mobilisation to the stormwater system. The time of day at which street sweeping is practiced is expected to have an effect on the amount of litter entering the stormwater system due to the exposure time of deposited pollutants to wash-off processes. Street sweeping is most commonly conducted in the early morning leaving the accumulated pollutants, especially litter from the day before, to a longer exposure period and the likelihood of over night rainfall events capable of flushing them into the stormwater system.

The study by Hall and Phillips (1997) also involved comparing accumulated litter items from street surfaces and side entry pit traps (SEPTs) in drains following rainfall events. The Carnegie urban catchment was monitored over a seven day period, and litter material was measured from bins, footpaths, street surfaces and SEPTs located in stormwater drain inlets. Footpath litter items were not considered when determining the effect of rainfall due to their surfaces being sheltered from rainfall and associated washoff mechanisms. When only street material is considered, up to 77% of the calculated street items entered the stormwater system during rainfall events. These data suggest that street washoff is the principal mechanism for transport of gross pollutants into the stormwater system.

Street Sweeping Timing:

- Recorded gross pollutant load generation over a typical day indicates that the accumulation of litter in a shopping strip begins at 8:00 and effectively ends around 17:00 hours.
- Early morning street sweeping allows the exposure of deposited street surface litter items to a higher likelihood of being transported into the stormwater drainage system.

8 Gross Pollutant Wash-Off Characteristics

8.1 Gross Pollutant Load Generation

The study by Allison et al. (1998) showed that stormwater runoff is the principal means by which gross pollutants are transported to the stormwater system. Ten storm events (larger than 3 mm of rainfall) and their transported gross pollutant loads in the Melbourne suburb of Coburg were monitored using the CDS unit from May to August 1996 (Allison et al., 1998). Monitoring was carried out in a 50 hectare catchment and the amount of gross pollutants transported during each of the 10 events was found to be correlated with the event rainfall depth as shown in Figure 8.1. A similarly high correlation between the gross pollutant load retained in the CDS unit and event runoff was also obtained as shown in Figure 8.2.

According to the fitted relationship between the wet gross pollutant load generated and the depth of rainfall (see Figure 8.1), events of less than 3.7 mm may be considered to be insufficient for re-mobilisation and transport of deposited street surface loads. The corresponding threshold for runoff (see Figure 8.2) is 0.70 mm. The fitted relationships between gross pollutant wet load and event rainfall depth or runoff show a trend of increasing gross pollutant load with increasing rainfall or runoff. Although the curves are monotonically increasing, the rate of increase in gross pollutant loads decreases with rainfall and runoff indicating a possible upper limit of gross pollutant load transported into the stormwater system during large rainfall or runoff events. The fitted curves in Figure 8.1 and 8.2 may be interpreted as indicating that the limiting mechanism for stormwater gross pollutant transport, in the majority of cases, is not the supply of gross pollutants but rather the processes (ie. the stormwater runoff rates and velocities) influencing the mobilisation and transport of these pollutants.

If the mobilisation and transportation of gross pollutants from the street surface depends on a rainfall depth greater than 3.7 mm, it is likely that the inter-event dry period for gross pollutant transporting storm events, in Melbourne will be longer than the calculated 2.6 days for all recorded storm events. Analysis of the cumulative frequency distribution of event rainfall depth for Melbourne over a 105 year record is presented in Figure 8.3. The analysis shows that approximately 35% of all recorded rainfall events are greater than 3.7 mm giving an average inter-event dry period of 178 hours (7.4 days) for gross pollutant transporting storm events.

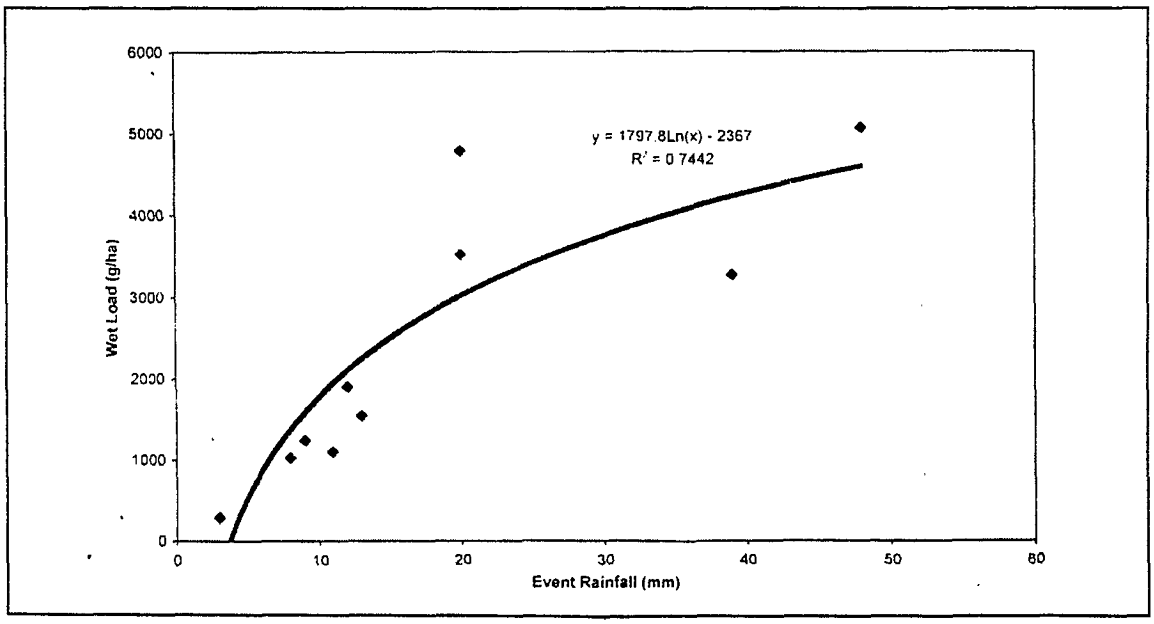

Figure 8.1 Gross Pollutant Wet Loads v's Rainfall (after Allison et al., 1998)

R0011456

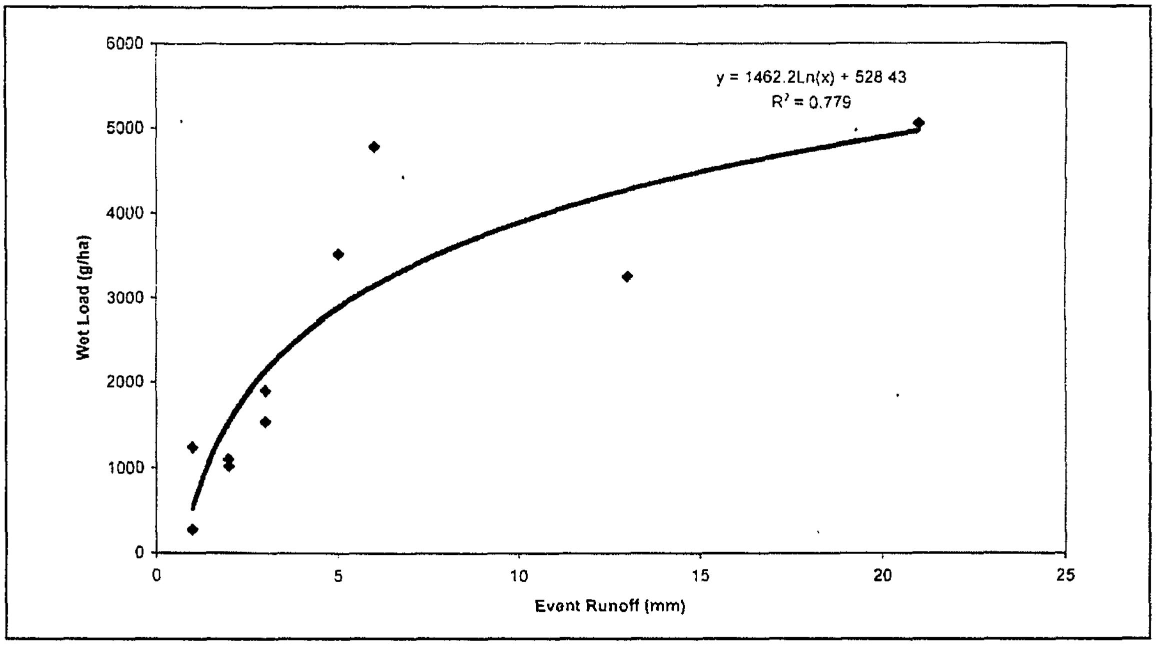

Figure 8.2 Gross Pollutant Wet Loads v's Runoff (after Allison et al., 1998)

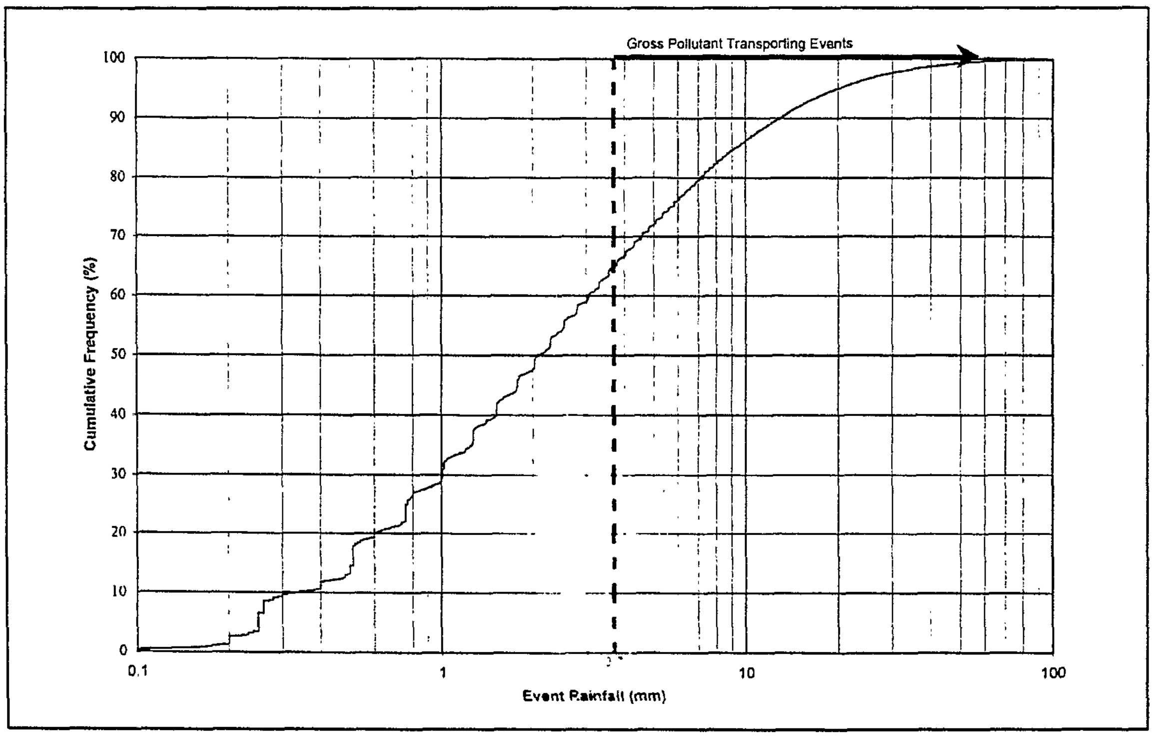

Figure 8.3 Cumulative Probability Distribution of Event Rainfall Depth for Melbourne

R0011457

The Coburg gross pollutant wet load data have incorporated the effect of Moreland City Council's street sweeping practices which range from daily to fortnightly, depending on land-use. How exactly any alterations made to the street sweeping frequency would affect the gross pollutant load in stormwater (see Figure 8.2) is not known and cannot be ascertained from the data collected. However, it is possible for some inference of the effectiveness of street sweeping in limiting the export of gross pollutants from street surfaces to the stormwater system to be made, and this will be discussed in Section 9.2.

Despite rainfall wash-off being the dominant factor transporting gross pollutants from street surfaces, litter can also reach the stormwater system during dry weather periods. The litter monitoring study, conducted by Hall and Phillips (1997), in the Carnegie commercial catchment indicated that during dry days numerous gross pollutant items are transported into the stormwater system by factors other than stormwater runoff (eg. wind or direct dumping). That study focused on measuring the number of litter items as well as material composition collected daily over seven days, from identified catchment pollutant sources. SEPTs were placed in drain entry pits located in the study area to determine the number of litter items reaching the stormwater system from the identified catchment pollutant sources (including bins, footpaths and street surfaces). The results showed that up to 78 items of litter in total (per day) were collected in SEPTs during periods without rainfall. A substantial amount of the material trapped during recorded dry days were lighter items (polystyrene) although numerous heavier items were also found, indicating possible direct littering rather than wind blown transportation of street surface pollutants.

Gross Pollutant Load Generation:

- Data collected in the Coburg catchment indicated washoff of gross pollutants becomes significant for storm events greater than 3.7 mm of rainfall depth or 0.70 mm of runoff.
- The limiting mechanism affecting the transport of gross pollutants in the majority of cases appears to be re-mobilisation and transport processes (ie. stormwater runoff rates and velocities) and not the supply of gross pollutants.
- Approximately 35% of all recorded rainfall events in Melbourne are greater than 3.7 mm giving an average inter-event dry period of 178 hours (7.4 days) for gross pollutant transporting storm events.

8.2 Influence of Catchment Land-use

As part of the same project, Allison et al. (1997b) investigated the effectiveness of side entry pit traps (SEPT's) by monitoring 192 SEPTs installed in all publicly owned side entry pits of the 50 hectare Coburg catchment as shown in Figure 8.4. The study aimed to assess the effectiveness of SEPTs by using a CDS unit located at the outlet of the catchment to collect any gross pollutants which may pass the SEPTs. The SEPTs were monitored from 2 August 96 to 15 November 96. During these four months, the traps were cleaned out on four separate occasions. For each of these clean-outs the total SEPT load (wet & dry) for each trap was calculated. Gross pollutant load data from that study are used for further analysis in this study.

SEPT gross pollutant wet load data were grouped according to the practiced street sweeping regime defined by catchment land-use. Figure 8.5 displays the three identified land-use sub-catchments in the Coburg catchment (50ha) as the daily swept South East (SE) commercial sub-catchment (13ha), the fortnightly swept North West (NW) & South West (SW) residential sub-catchments (24.5ha) and the daily / fortnightly swept North East (NE) mixed land-use sub-catchment (12.5ha).

The total SEPT gross pollutant wet loads were calculated and categorised according to street sweeping regime, defined by the three sub-catchment land-use types and are presented in Table 8.1. The days between clean outs, total rainfall between clean outs and the number of storm events, are also presented in Table 8.1. For the purpose of this analysis a storm event was identified as a storm that had the potential to re-mobilise deposited solids from the road surfaces and is described as a gross pollutant transporting event (ie. greater than 3.7 mm after Allison et al., 1997b). The SEPT wet loads have been normalised into a load (g) per unit catchment area (ha) to enable gross pollutant loads from the sub-catchments to be compared.

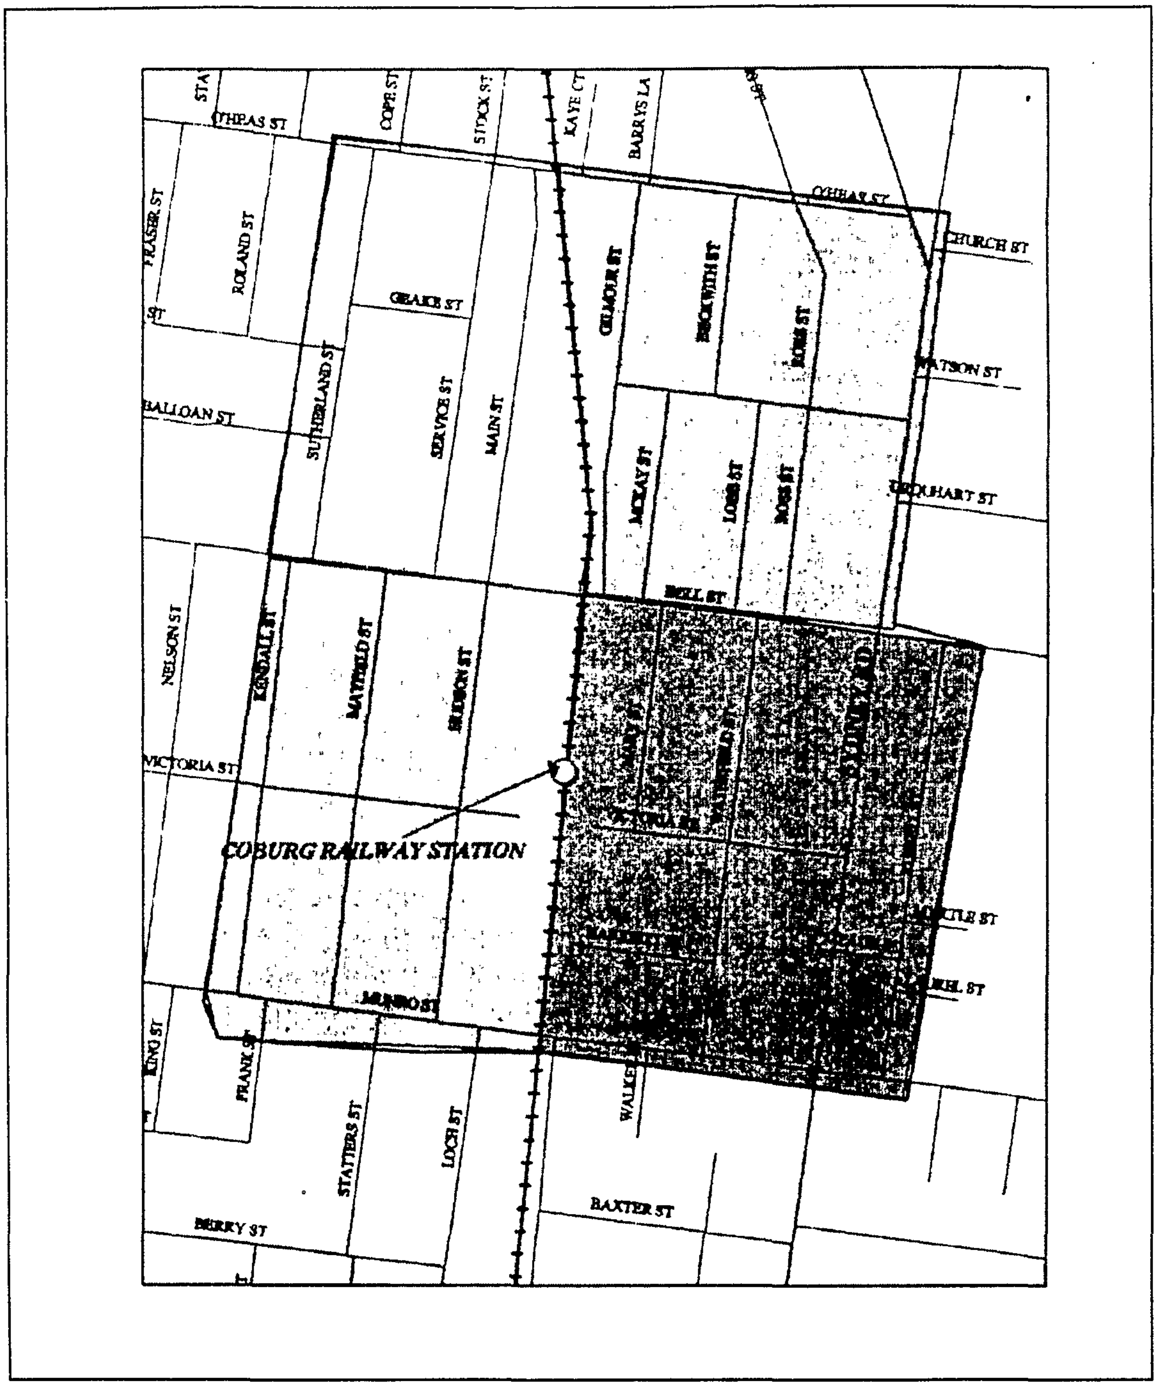

Figure 8.5 Land-use Sub-catchments in the 50ha Coburg Catchment
(source Moreland City Council and Merri Creek Management Committee, 1997)

Table 8.1 Event Rainfall and Related SEPT Total Gross Pollutant Wet Loads

Clean-out Date	Days between clean-outs	Total Rainfall (mm)	Storm Events (>3.7mm)	Single Event Rainfall (mm)	Event Rainfall (mm)	Commercial Wet Load (g/ha)	Residential Wet Load (g/ha)	Mixed Wet Load (g/ha)
29-Aug-96	27	55	5	(6.4) (10) (5) (15) (12)	48	5000	2408	1760
30-Sep-96	32	74	6	(11) (12.3) (16.4) (4.4) (9.4) (11.5)	65	20154	10041	6880
15-Oct-96	15	25	2	(8.2) (14)	22	6462	3143	1840
15-Nov-96	31	47	2	(7) (35.4)	42	6538	5878	1920

As indicated in Table 8.1, calculated total SEPT wet loads ranged from 1.8 kg/ha for the mixed land-use sub-catchment to as much as 20.2 kg/ha for the commercial sub-catchment. Figure 8.6 displays the comparison between land-use and total SEPT wet load, indicating commercial land-use contributes larger loads of gross pollutants per hectare compared to residential and mixed land-use catchments. This is in spite of daily street sweeping in the commercial sub-catchment compared to once every two weeks in residential and mixed land-use areas. Three of the four clean outs showed the ratio of gross pollutant load generation between the commercial and residential areas to be approximately 2.0. There was however, one clean out, that of the 15 November 96 which gave a significantly lower ratio of 1.1. It is interesting to note that the gross pollutant load generated from the mixed land-use was the lowest in all the four clean outs.

Many factors other than land-use contribute to the differences observed in the amount of gross pollutants exported from the different areas, including wind, traffic volume, topography, population density, community awareness and importantly the hydrologic conveyance system. Hydrologic conveyance factors which can influence gross pollutant export include the number of side entry pits in the stormwater system (ie. the average distance to entry pits from within the catchment), the degree of catchment area imperviousness and the extent of "supplementary areas" (defined as pervious areas over which runoff from impervious areas needs to traverse when discharging towards the stormwater drainage system) in these sub-catchments. Catchment topography, average distance along roadside kerbs and the extent of supplementary areas influence the required energy to re-mobilise and convey deposited gross pollutants to the stormwater system. The fraction imperviousness of the catchment influences the magnitude of the runoff from the catchment which in turn determines the energy available for re-mobilisation and transport of deposited gross pollutants in the catchment.

The results presented in Figure 8.6 are consistent with results from a separate study by Allison undertaken during 1995 to investigate the transport of gross pollutants from different land-uses within a 150 hectare catchment in Coburg. Gross pollutant loads from two storm events (27 January 95 and 31 May 95) were monitored at three locations representing mixed commercial/residential, residential and light industrial land-uses as shown in Figure 8.7 (Allison et al., 1998). On commencement of storm runoff, specifically designed gross pollutant samplers (Essery, 1994) were lowered, at varying time intervals, into the flow and used for gross pollutant sampling as illustrated in Figure 8.8.

Gross pollutant loads from the two storm events monitored for each land-use area are presented as dry mass per hectare of catchment area in Table 8.2. The computed unit area dry loads for the different land-uses were compared against the weighted average dry load for the three combined sub-catchments. These data indicate that commercial land-use catchments generate approximately twice the amount of gross pollutants compared to residential land-use and as much as three times the amount generated from light industrial land-use catchments.

(source Allison et al. 1998)

R0011462

Table 8.2 Gross Pollutant Dry Mass Loads and Weighted Averages (after Allison et al., 1998)

Land Use	**Area** (ha)	**Total dry load per unit area**		
		27-Jan-95 (g/ha)	31-May-95 (g/ha)	Value / Weighted Average
Commercial	9.5	423	747	1.6
Residential	26.5	292	308	0.8
Light Industrial	2.5	242	63	0.5
Total	38.5			
Weighted Average		321	400	

Allison (1997b) noted that material often blinded the SEPT basket pores, leading to overflows from the baskets and thus a reduction in trapping efficiencies. The field study into the efficiency of SEPTs, found the trapping efficiency of SEPTs to be between 60% and 70% (Allison et al. 1998). The SEPT total wet loads given in Table 8.1 can thus be assumed to be an under estimation of gross pollutant loads generated from the respective sub-catchments.

The gross pollutant loads for three of the four SEPT clean-outs (see Figure 8.6) show similar relative contributions from the different land-use catchments as that derived from the study by Allison (1998) and summarised in Table 8.2. The commercial catchment was found to have generated the most load of gross pollutants on each of the clean out dates in spite of daily street sweeping. As noted earlier, the ratio of commercial to residential land-use gross pollutant load from three of the four clean out dates is approximately 2.0 except for the data from the clean out of 15 November 96. The gross pollutant load transported from the commercial area preceding the clean out of the 15 November 96 was found to be significantly lower than expected when compared to corresponding data from the residential area.

The gross pollutant load from the clean-out of 15 November 1996 was transported by two gross pollutant transporting storm events (ie.<3.7 mm), one with an event rainfall of 6.8 mm and the other 35.4 mm.

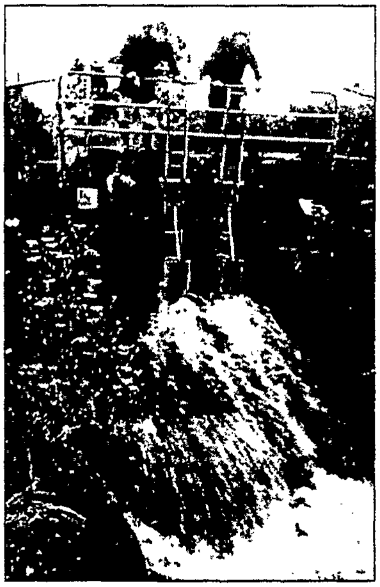

Figure 8.8 Sampling Gross Pollutants from Different Land-use Sub-catchments in Coburg (source Allison et al, 1998)

The lower than expected gross pollutant load from the commercial area in this clean-out may be related to a possible "supply limiting condition" during the large 35.4 mm storm event (a trend not apparent in the fortnightly swept, residential catchment). This notion is explored in Section 9.3.

Influence of Catchment Land-use:

- The fraction imperviousness of a catchment influences the runoff during storm events which influence the available energy for mobilisation of deposited gross pollutants.
- Commercial land-uses contribute larger loads of gross pollutants despite more intensive street sweeping frequencies.
- Relative gross pollutant loads generated from different land-uses show that commercial areas produce approximately twice the amount of gross pollutants than residential and three times as much as light industrial, despite a daily street sweeping regime in the commercial area compared to fortnightly in the residential and industrial areas.
- A number of transport factors are thought to also influence gross pollutant loads from different land-uses. Some of these factors include:-
  - Number of entrances to the stormwater system,
  - Fraction of catchment imperviousness,
  - Extent of pervious area over which runoff needs to traverse towards the stormwater drainage system.

9 Discussion

9.1 Gross Pollutant Load and Rainfall Depth Relationship

The relationships between the gross pollutant load and rainfall depth (Figure 8.1) and runoff (Figure 8.2) derived from the Coburg data incorporate the effect of a typical Melbourne municipal street sweeping program, ranging in frequency from daily to fortnightly sweeping depending on catchment land-use. The relationships clearly show a trend of increasing gross pollutant load to the stormwater system with increasing rainfall or runoff, indicating that the limiting mechanism for stormwater gross pollutant transport in the majority of cases is stormwater runoff rates and velocities. While the curves are monotonically increasing, the rate of increase in gross pollutant loads entering the stormwater system decreases with rainfall and runoff indicating a possible upper limit of gross pollutant load transported into the stormwater system at relatively high rainfall depths or runoff. This possible upper limit of gross pollutant load may reflect the gross pollutant load deposited on street surfaces which is available for re-mobilisation into the stormwater system. A modification of the street sweeping frequency could potentially adjust this upper limit value, thereby altering the shape of the gross pollutant export curve as conceptualised in Figure 9.1.

9.2 Impact of Street Sweeping on Gross Pollutant Loads

It is not known how exactly any further alterations made to the street sweeping frequency will affect the gross pollutant export curve. Nevertheless the illustration in Figure 9.1 postulates that if street sweeping effort were reduced it can be expected that the gross pollutant load will increase, initially for those events with large rainfall depths. Further reduction in street sweeping frequency will ultimately lead to the increase of gross pollutants in stormwater systems becoming evident for even smaller storm events. Similarly, by increasing street sweeping effort, the reduction in gross pollutant load would essentially be confined to events of large rainfall depths. Figure 9.1 postulates that in most gross pollutant export events, the export load is defined by the size of the storm event rather than the available pollutant surface load.

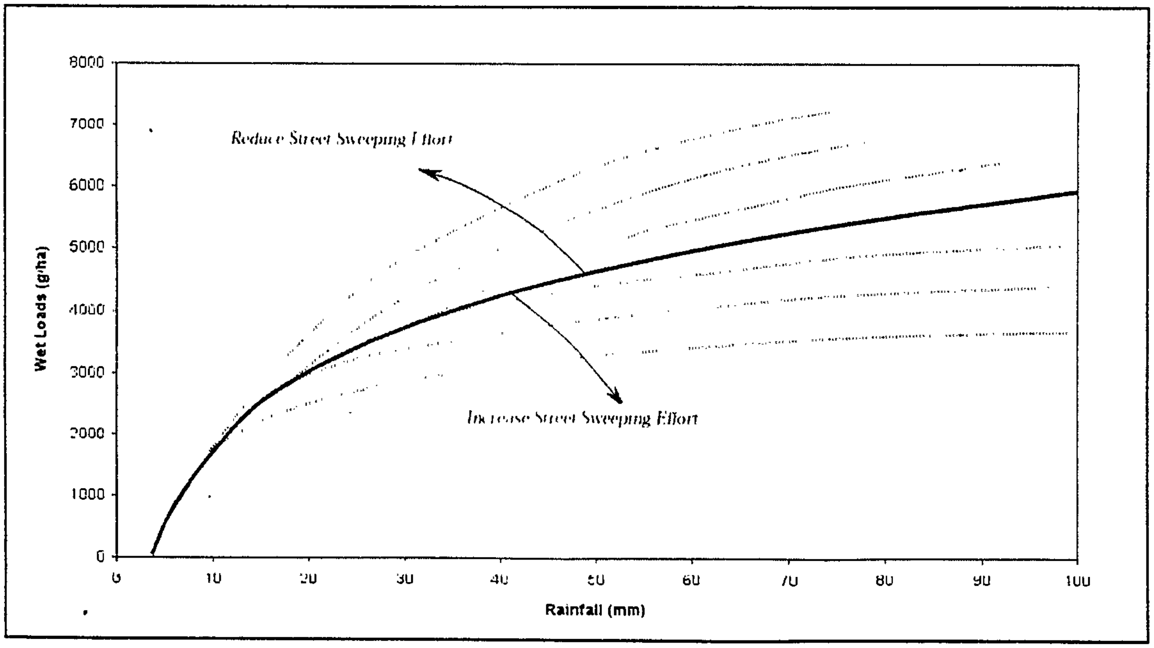

Figure 9.1 Hypothetical Gross Pollutant Load and Street Sweeping Effort

9.3 Supply Limiting Condition

The lower than expected gross pollutant load from the commercial area for the clean-out of the 15 November 96 noted in Table 8.1 of the previous section of this report may be explained by a possible "supply limiting condition" occurring during the large 35.4 mm storm event. It is possible that during this large event the available gross pollutants in the catchment have been substantially removed from the street surface and mobilised into the stormwater system, a trend not apparent in the fortnightly swept, residential catchment.

Based on the results of this investigation, it is postulated that a source limiting storm condition may have occurred during the 35 mm storm event. Storm events greater than 35 mm occur less than 3% of the time in Melbourne (see Figure 8.3) indicating that the occurrence of such a gross pollutant supply limiting condition would be very rare. This may have important implications for assessing the effectiveness of street sweeping. The incremental benefits of increasing the present street sweeping effort in the Coburg catchment (from the daily frequency of the commercial areas and fortnightly frequency in the residential areas) are expected to be low. The limiting factor affecting the transport of gross pollutants in the majority of cases appears not to be the supply of gross pollutants but instead the pollutant mobilisation and transport processes (ie. rainfall patterns and depths, runoff rates and velocities).

9.4 Street Sweeping Efficiency Issues

The use of new street sweeping technologies may contribute to reducing pollutant loads in the stormwater system as advocated by Sutherland and Jelen (1997). Taking into account influencing factors such as the inter-event dry period and catchment characteristics may enable the frequency and timing of street sweeping operations to be redesigned to meet specified stormwater improvement objectives for specific conditions. Street sweeping frequencies that are equivalent to three times the mean inter-event period (approximately 8 days for Melbourne) is considered to be appropriate as approximately 35% of storm events are considered to be gross pollutant transporting events. Also, conducting street sweeping at a time of day which enables the collection of pollutants when the rate of load acummulation of street surface has reached its highest would reduce the time pollutants are potentially exposed to the likelihood of rainfall events.

Factors contributing to inefficiencies in street sweeping are not confined to rainfall patterns (affecting the build-up and wash-off processes), frequency and timing of sweeping, size of pollutants and the sweeper mechanism. Street sweeping inefficiencies are further exacerbated by everyday practice limitations. Significant practice limitations associated with street sweeping include the inability of sweepers to access the street surface load due to parked vehicles (see Figure 9.2), inappropriate street design, poor road surface conditions and operator speed. Street sweeping program specifications must address these influencing factors as well as improving sweeper mechanisms before stormwater quality improvements may be realised from street sweeping practices.

The principle objective of street sweeping in meeting community demand for a standard of street cleanliness, and the perceived success of sweeping to fulfil this objective makes street sweeping an important municipal operation. However, there is little evidence to suggest significant incremental benefits in stormwater quality, particularly the removal of contaminants associated with the fine particulates, can be gained with increased street sweeping frequency.

The use of new street sweeping equipment may lead to increased effectiveness particularly for gross pollutants and coarse to medium sized sediment. There are however other operational limitations which will reduce the actual effectiveness of street sweeping from that determined under controlled test conditions. Furthermore, the use of new equipment will need to be associated with a street sweeping frequency that matches the catchment meteorological characteristics. Their cost effectiveness will need to be evaluated against the cost of installing and maintaining end-of-pipe or in-transit gross pollutant traps.

Figure 9.2 Street sweeping pollutant removal effectiveness is limited by parked cars

R0011468

10 Conclusions

This study has investigated the effectiveness of street sweeping for stormwater quality improvement. A number of factors are identified as influencing the effectiveness of street sweeping for the collection of street surface pollutants for stormwater pollution control rather than just aesthetic requirements. These factors include street sweeping mechanism, pollutant type, sweeping frequency and timing and also pollutant wash-off characteristics.

The most important conclusion from this study is that current Australian street sweeping practices are generally ineffective as an at source stormwater pollution control measure. Current street sweeping practices are found to be not only ineffective for the reduction of fine sediment and sediment-bound contaminants but also for larger gross pollutants capable of entering the stormwater system. Current Australian street sweeping mechanisms and practices are therefore regarded as providing very little benefit for stormwater quality improvements, due to inefficiencies at reducing a variety of pollutants from entering the stormwater system over a range of conditions. Street sweeping should be therefore accompanied by structural pollutant treatment measures to effectively reduce the discharge of gross and sediment associated pollutants in stormwater.

Increasing the frequency of current street sweeping practices beyond what is required to meet aesthetic objectives is not expected to yield substantial incremental benefits in relation to receiving water quality improvements. There seems little benefit in conducting detailed field monitoring investigations into quantifying the effectiveness of street sweeping as a stormwater pollution control measure for current Australian street sweeping mechanisms or operations. Other specific observations from this study are listed below.

Sweeping Mechanisms

- Mechanical and regenerative air street sweeping equipment requires a minium threshold load of sediment on the street surface before they become effective.
- The threshold load can be three times higher for the mechanical sweeper compared to the regenerative air system.
- Overall the regenerative air sweeper exhibits a substantially better performance than the regular mechanical sweeper.
- Street sweeping technology is developing and improving to remove finer street surface particles for a variety of street surface loads.

Gross Pollutants

- Significant amounts of gross pollutants are mobilised into the stormwater system during bursts of rain, wind or both.
- There is little correlation between the frequency of sweeping and the transport of gross pollutants into the stormwater system.
- Street sweeping efficiency increases with particle size.
- Sweeper efficiency can be up to nearly 80% for particles greater than 2 millimetres under 'test' conditions (ie. sweeping more frequently than the occurrence of rainfall events and effective use of parking restrictions).

Sediment and Other Suspended Solids

- The removal efficiency of sediment and other fine organic particles by conventional street sweepers was found to be dependent upon a threshold level of load on the surface and the particle size range of the surface loads.
- Material smaller than 300 μm was less affected by street sweeping.
- No effective removal (>50% removal efficiency) was evident for particle sizes smaller than 125 μm for conventional street sweepers (excluding the new small-micron surface cleaning technology).

Contaminants Associated with Sediment

- Significant amounts of metals and nutrients are transported as sediment-bound contaminants.
- Most of the total mass of contaminants is associated with the fine particles.
- Conventional street sweeping is generally ineffective at removing particles smaller that 300 μm and therefore will not effectively reduce the export of sediment-bound contaminants such as nutrients, metals and PAHs.

Removal of Sediment and Associated Contaminant

- Limited sampling of sediment in street runoff in Australia indicates that 70% of particles are less than 125μm compared to 20% for overseas data.
- The fine sediments found on Australian streets would suggest that conventional street sweeping will have a minimal effect on sediments and associated contaminants reaching stormwater systems.

Street Sweeping Frequency

- The variable nature of inter-event dry periods, both in terms of seasonal variation and dependence on climatic locations, highlights the importance of street sweeping program design which are specific to location and flexible to accommodate the local meteorological conditions and seasonal variability.
- It is anticipated that if street sweeping occurs at a longer interval than the inter-event dry period of the catchment, street surface pollutants will have a much higher likelihood of being flushed into the stormwater system before being collected by the street sweeper.

Street Sweeping Timing

- Recorded gross pollutant load generation over a typical day indicates that the accumulation of litter in a shopping strip begins at 8:00 am and effectively ends around 5:00 pm.
- Early morning street sweeping allows the exposure of deposited street surface litter items to a higher likelihood of being transported into the stormwater drainage system.

Gross Pollutant Load Generation

- Data collected in the Coburg catchment indicated washoff of gross pollutants becomes significant for storm events greater than 3.7 mm of rainfall depth and 0.70 mm of runoff.
- The limiting mechanism affecting the transport of gross pollutants in the majority of cases appears to be re-mobilisation and transport processes (ie. stormwater runoff rates and velocities) and not the supply of gross pollutants.
- Approximately 35% of all recorded rainfall events in Melbourne are greater than 3.7 mm giving an average inter-event dry period of 178 hours (7.4 days) for gross pollutant transporting storm events.

Influence of Catchment Land-use

- The fraction imperviousness of a catchment influences the runoff during storm events which influence the available energy for mobilisation of deposited gross pollutants.
- Commercial land-uses contribute larger loads of gross pollutants despite more intensive street sweeping frequencies.
- Relative gross pollutant loads generated from different land-uses show that commercial areas produce approximately twice the amount of gross pollutants than residential and three times as much as light industrial, despite a daily street sweeping regime in the commercial area compared to fortnightly in the residential and industrial areas.
- A number of transport factors are thought to also influence gross pollutant loads from different land-uses. Some of these factors include:-
  - number of entrances to the stormwater system,
  - fraction of catchment imperviousness,
  - extent of pervious area over which runoff needs to traverse towards the stormwater drainage system.

National Pollutant Removal Performance Database for STPs: 2nd Edition

The Center recently completed the second edition of the *Stormwater Treatment Practice (STP) Pollutant Removal Performance Database* (the "Database") which modifies, clarifies, and expands upon the original *National Database of BMP Pollutant Removal Performance* (the First Edition) by Brown and Schueler (1997).

The First Edition included 129 studies and spanned a 19-year period; the minimum storm sampling criteria was four sampling events, and little effluent concentration data was included. Major changes to the First Edition include the following:

- Addition of 24 studies
- Elimination of studies that did not meet the new minimum storm sample criteria of five
- Update of existing entries to include effluent concentration and other data where available
- Addition of new fields

Eight of the studies included in the First Edition were deleted because of insufficient storm sample size. In addition, concentration data were added to existing studies to make the database a more powerful analysis tool. More than half of the original studies included both influent and effluent concentration data, and these data were not consistently included in the First Edition. Finally, several fields were added since the First Edition, including *Age of the Facility*, *Drainage Class* (based on drainage area), *Land Use Quantification* (e.g., percent commercial, residential, etc.), and storage in *Watershed* and *Impervious Inches*. Unfortunately, many studies did not report these data explicitly. Consequently, the database does not currently have sufficient data to develop relationships between specific site or design characteristics and performance. One exception is the *Drainage Class* field, which classifies ponds and wetlands as Pocket, Regular, or Regional. Although the results are not conclusive, sufficient data are available to characterize each data class.

Table 1. Median Pollutant Removal (%) of Stormwater Treatment Practices

2. Excludes vertical sand filters and filter strips
3. Refers to open channel practices designed for water quality

NOTES:

- Data in parentheses represent values from the First Edition (Schueler, 1997; Appendix D).
- Shaded regions indicate a difference of at least ± 5% from the First Edition.
- N/A indicates that the data are not available.
- TSS = Total Suspended Solids; TP = Total Phosphorus; Sol P= Soluble Phosphorus; TN = Total Nitrogen; NOx = Nitrate and Nitrite Nitrogen; Cu = Copper; Zn = Zinc

The statistical reanalysis of the First Edition revealed some changes in the pollutant removal efficiencies of STPs (Table 1). These changes can be attributed to the addition of new studies and revisions to the older studies. Most of the shaded regions represent a pollutant removal increase of at least 5%. Three exceptions are nitrogen removal for filtering practices, which decreased by 16%; and zinc and soluble phosphorus removal of stormwater wetlands, which decreased by 18% and 10% respectively. The STP group with the greatest change over original data is filtering practices. This result is not surprising, since a significant number of changes were made to this group (five studies were added to the original 14). In particular, the negative soluble phosphorus in the original was caused by a few values from organic filters, and from one perimeter filter that had become submerged, releasing soluble phosphorus.

Table 2. Median Effluent Concentration (mg/L)[1] of Stormwater Treatment Practice Groups

2. Data based on fewer than five data points
3. Excludes vertical sand filters and filter strips
4. Refers to open channel practices designed for water quality

NOTES:
- N/A indicates that the data is not available.
- TSS = Total Suspended Solids; TP = Total Phosphorus; OP = Ortho-Phosphorus; TN = Total Nitrogen; NOx = Nitrate and Nitrite Nitrogen; Cu = Copper; Zn = Zinc

Median effluent concentrations by STP groups are summarized in Table 2. Effluent concentration data were added to the Database as a supplement to the pollutant removal capability of STPs. In some instances, pollutant removal percentage may not be a good indicator of the overall removal capability of a STP. Pollutant removal percentages can be strongly influenced by the variability of the pollutant concentrations in incoming stormwater. If the concentration is near the "irreducible level" (Schueler, T. 2000. "Irreducible Pollutant Concentrations Discharged from Urban BMPs," Article 65 in The Practice of Watershed Protection. Center for Watershed Protection. Ellicott City, MD.), a low or negative removal percentage can be recorded even though outflow concentrations discharged from the STP were relatively low. Although these data represent a median, unlike the group mean reported in Schueler (1996), the data suggest that the typical concentration data reported in this initial study and are high compared with the results from the Database.

The data presented in this study support the contention that most STP designs can remove significant amounts of sediment and total phosphorus in urban runoff. Most STP groups, on the other hand, showed a lower ability to remove nitrogen. This result suggests that non-structural nutrient reduction methods, in addition to stormwater STPs, may be needed to meet nutrient reduction targets.

Significant gaps do exist in our knowledge of the removal capability of certain STP designs and stormwater parameters. Filling these gaps should be the major focus of future STP monitoring research. The more well-studied STP groups (ponds, wetlands, and filters) should be re-directed to investigate internal factors (i.e., geometry and sediment/water column interactions) that may create the wide variability in pollutant removal that is characteristic of STP monitoring. Finally, more research is needed with respect to bacteria, dissolved metals, and hydrocarbons; all of these are pollutants associated with human health impacts. Such research could be of great value in developing better designs and reducing pollutant removal variability, allowing for more reliable pollutant reduction at the watershed scale.

The full report, "National Pollutant Removal Performance Database for Stormwater Treatment Practices: 2nd Edition," is available from the Center for $25. Please access our web site at www.cwp.org for ordering information.

STORMWATER MANAGEMENT

Metals Removal using StormFilter™ Technology (Field Studies)

September 11, 2000

Overview: Data collected from several StormFilters are presented below. The data pertain to both total and dissolved zinc (Zn), copper (Cu) and lead (Pb) removal using various field sites and the CSF® leaf media or surface modified zeolite (SMZ) mixed with perlite.

Site Descriptions: Several sites are presented within the Results section below. The following list helps describe each site, site use and sampling protocol used for evaluation.

Giles (Olympia, Washington) – 200-acre watershed comprised of mature commercial and residential developments, 12' x 37' StormFilter with 80 cartridges. Samples were taken using flow pacing and grab sampling.

Lake Stevens (Snohomish County, Washington) – roadway runoff prior to bridge, 30,000 ft^2 of impervious, 8' x 14' StormFilter with 9 cartridges. Sampling was flow weighted and composite.

Caltrans Maintenance (California Department of Transportation maintenance facility, San Diego, California) - storage and repair of equipment, 3) 8' x 18' StormFilters with 79 cartridges. Samples were composite and flow paced over the entire storm.

Straley's BP (Bremerton, Washington) – gas station, 8' x 16' StormFilter with 23 cartridges. Samples were taken using flow pacing. Samples were also composite to obtain a first flush sample (first 1 hour of runoff).

Results: Tables One, Two, Three, Four and Five present the acquired metals removal observed at the sites listed above. The tables are organized according to the filtration media and metal. Table One and Two pertain to the CSF leaf media and zinc and copper removal. Tables Three, Four and Five present the use of SMZ surrounded by perlite for the removal of zinc, copper and lead, respectively.

Calculations pertaining to percent removal were calculated using Equation 1 below:

$$\%\,Removed = \left(\frac{Influent\ Concentration - Effluent\ Cocentration}{Influent\ Concentration}\right)\times 100 \quad (Equation\ 1)$$

Discussion: As presented, metals removal varies with influent concentration and with respect to the dissolved fraction of the metal entering the StormFilter. Most observations show that high influent concentrations produce a higher percent removal. The dissolved fraction also influences percent removal in that the higher the dissolved fraction, the more difficult the metal is to remove.

Removal of the dissolved fraction of metal is primarily associated with cation exchange where a calcium or magnesium atom is displaced by a zinc, copper or lead atom. This occurs within the media's lattice and requires that the dissolved metal carry a positive charge. However, stormwater is a complex mixture of nutrients, organic compounds and suspended solids. Metals such as copper and zinc can also travel with small dissolved organic compounds (colloids) and do not have the positive charge needed for removal through cation exchange. In a sense, these metals are inert due to charge association with the organic molecules. However, analysis of the colloidal fraction is detected when analyzing for dissolved metals although the metal is not 'purely' dissolved and carrying a positive charge. (Note: Colloids can pass through a 0.45-micron filter when filtering for dissolved metal analysis.) Removal of the colloid bound metal is difficult due to the lack of a positive charge and the extremely small size of the associated organic molecule.

Removal of the solid bound metal (actually attached to the suspended solids) is promoted through the process of stormwater filtration. The process is a physical straining of the suspended solids that, in turn, removes the associated solid bound metal. (Note: The removal of this fraction of metal is associated with total metals analysis due to all particles being larger than 0.45 microns.)

Catch basin inserts to reduce pollution from stormwater

S-L. Lau*, E. Khan and M.K. Stenstrom***

*Civil and Environmental Engineering Department, University of California, Los Angeles, 4173 Engr. I, Los Angeles, 90095-1593 California, USA

Abstract Stormwater contamination represents the largest source of contaminants to many receiving waters in the United States, such as Santa Monica Bay in Los Angeles, California. Point sources to these same waters generally receive secondary or better treatment before they are released, and they are usually discharged through outfalls that diffuse the wastewater plume to prevent it from contacting the shoreline. Stormwaters receive no treatment and reach the receiving waters through a variety of ways, but most enter through catch basins or inserts to storm drains that terminate at the beach or in shallow coastal areas. Under these conditions, the stormwater discharge may have greater impact on the quality and utility of the receiving water than the treated wastewater discharges. One method of reducing pollution is to equip catch basins with an insert that can capture pollutants. A number of commercially available devices exist but few have been evaluated by independent parties in full-scale applications. A series of tests using bench and full-scale devices under both laboratory and field conditions were conducted to evaluate their ability to remove trash and debris, suspended solids and oil and grease in stormwaters. The results presented in the paper should provide a basis for future insert development and application.

Water Science and Technology Vol 44 No 7 pp 23–34 © 2001 IWA Publishing and the authors

Introduction

Most industries and municipalities in the United States have full secondary wastewater treatment, and some have nutrient removal and filtration. As a consequence of these reductions in water pollution, stormwater now represents the greatest threat to aquatic habitants in the United States. Stormwater quality has been largely ignored in many areas, although there is usually concern for flood control and flood damage prevention. As a result, we have stormwater management systems that prevent floods at the expense of environmental protection.

Los Angeles is a good example of an area that has emphasized flood control at the expense of environmental protection. In this highly urbanized area there is little opportunity to reduce stormwater pollution through traditional means. The average imperviousness is more than 60% in many cases. Land values are such that it is prohibitively expensive to retro-fit storage basins or infiltration zones. This paper addresses a potential best management practice for such urbanized areas. The stormwater system has been constructed with catch basins, which may be several cubic meters in volume. These catch basins can be retrofit with devices, called "inserts", to capture pollutants. A number of commercially available devices exist, but few have been evaluated by independent parties in full-scale applications. The authors conducted a series of tests using bench and full-scale devices to remove trash and debris, suspended solids (TSS) and oil and grease (O&G). Field tests were also performed with boards, screens and baskets to observe their ability to remove or prevent debris from entering storm drains. The results are sufficiently promising to suggest additional testing with a variety of devices.

Background

Santa Monica Bay is the receiving water for a major portion of the City of Los Angeles metropolitan area. The watershed is 1072 km^2, and is largely urbanized, serving a proportion of the three million people in Los Angeles and more than 11 million people in the metropolitan area. Only two wastewater treatment plants discharge directly into the bay; the largest is the Hyperion Treatment Plant (~1.3×10^6 m^3/day). This plant has recently achieved full secondary treatment, and discharges secondary treated wastewater via an 11 km outfall. The second source is a petroleum refinery that has advanced wastewater treatment. Another source is Los Angeles County's Joint Water Pollution Control Plant (~1.3×10^6 m^3/day, ~60% secondary), which discharges outside of the bay, and is upgrading to secondary treatment. Currents carry the partially treated wastewater into the bay.

The improved treatment has decreased pollutant discharge to the bay by more than an order of magnitude during the past 20 years. As a result, non-point sources now contribute an increased fraction of the total pollutant mass to the Bay (Wong *et al.*, 1997). The non-point contribution is already the major source for many pollutants, e.g. heavy metals, and will become the major source for many more pollutants as full secondary treatment is achieved. Reclamation and water conservation will further reduce point source contamination to the bay.

Various agencies, cities and environmental advocacy groups have proposed structural methods for reducing stormwater pollution. These methods are all difficult to employ because they are small-scale solutions that must be applied to a very broad area, across many jurisdictions with varying interests in controlling stormwater pollution. One proposed method for controlling discharges is to use catch basin inserts.

Catch basin inserts are devices that can be placed into a catch basin or stormwater insert, which will in some way reduce pollutant discharge to the receiving water. A variety of devices have been proposed and marketed, but very few have been evaluated by independent sources, or have been used long enough to create a record of performance. In order to establish creditable performance of insert devices, a consortium composed of the Santa Monica Bay Restoration Project and 14 other Santa Monica area jurisdictions funded a two-year study to determine if inserts are a viable method for controlling stormwater pollution. The results of this initial study (WCC, 1998) were sufficiently promising to warrant additional laboratory testing and a field study.

Objectives were established for testing and insert development. These were based in part upon environmental impact of the pollutants, but in greater part upon the ability of a hypothetical device to remove the pollutant in the constrained volume of a catch basin (generally only a few cubic meters). Litter (trash, debris, etc.), particulates and oil and grease were selected as pollutants of concern. Litter was selected because of its interest to regulators and its high visibility with the public. Total Daily Maximum Discharge Limits (TMDLs) will soon be applied to the Santa Monica Bay Watershed, and litter will be among the first. Particulates, as measured by total suspended solids (TSS) are especially important because a large fraction of the heavy metals in stormwater are adsorbed to their surfaces. Oil and grease, especially oil and grease from vehicular areas, is important because it may contain many anthropogenic compounds that may be toxic to aquatic life.

The approach was divided into two parts: dry and wet weather. This was required because of the seasonal rainfall and the desire to collect litter during the long dry period (generally April to November). It was envisioned that controls would be used in dry weather that would be removed in the wet season. Additionally, public agencies were adamant not to increase flood risks. The approximate cost of installation should be no more than US$ 500; cleaning should be infrequently required. A survey of the member cities suggested that, on average, catch basin cleaning occurred no more frequently than once every two months for beach communities, and approximately once per year for Los Angeles County, as a whole. A problem-solving, practical approach was required. The inserts should not

increase flood risk and should only marginally change the way stormwater is removed from streets, without increasing the accumulation on streets. Safety considerations such as avoiding confined space entries were important. The public agencies responsible for managing the inserts would soon tire of them if they could not be conveniently, economically and safely maintained.

A sampling program was conducted and differed from previous programs in that samples were collected directly from stormwater on street surfaces, just prior to entry into catch basins. Litter was not measured in the water quality program but was measured during the dry periods as accumulation in the catch basins.

Sampling program

Four locations were selected and sampled during the storm events of the 1997–1998 wet season. This was significant in that it is an El Nino year, and rainfall was at least 200% greater than normal. Table 1 shows the sites and information about them. They were all in the City of Santa Monica and within 4 km of each other.

Samples were taken by scooping 100 to 200 ml at a time until 8 l samples were collected. For short storms only one such sample was collected. For longer storms, three samples were collected and averaged. The oil and grease concentrations were measured by solid phase extraction (Lau and Stenstrom, 1995) and do not include the oil adsorbed to suspended solids. Table 2 shows the mean and standard deviation of conventional water quality parameters for 14 storm events between October 1997 and February 1998. Generally, water quality is worse for Site 1, although the variability tends to make statistical significance

Table 1 Site description

testing difficult. Trash and debris were not quantified, but trash and debris from the commercial sites was obviously greater. Table 3 shows the results for selected metals (only four storm events), as a total concentration and the distribution that was adsorbed onto the suspended solids. These results tended to confirm that metals were associated with the suspended solids.

Toward the end of the sampling period, various insert devices had been evaluated, and it became apparent that the devices could remove larger particles. Therefore additional sampling was performed to determine the size of the particles that compose the TSS. Site 1 was monitored for three storms and the TSS was determined by bailing several hundred litres of water through sieves. Particle sizes are shown in Table 4. These results suggest, for example, that a device that could remove particles larger than 75 µm could remove 39% of the TSS.

Insert evaluation

A survey of all commercially available inserts was performed. At the time of the survey (1997–1998), no devices were found that met all the criteria. A number of promising technologies were found that could treat stormwater, but not for the most common catch basin geometry used in greater Los Angeles. After some review, a concept was developed for a basket that could be inserted and removed through the opening of the catch basin, as shown in Figure 1. Several manufacturers offered prototypes featuring this general concept. This device has the advantage of being useful for both dry and wet weather applications. This design has the advantage of easy installation. An insert that is flexible, or is no greater in width than the opening in the curb, can be inserted and removed from the street. Two chains or cables to the curb support the insert. Workers do not need to enter the catch basin, which in some places is considered a confined space. Alternatively, if worker entry to the catch basin is permissible, the inserts can be installed by bolting to the interior wall. Additionally, high flows are directed around the insert, and flood risk is not increased. Additional material including photographs is available elsewhere (WCC, 1998).

The climate in Southern California presents a special opportunity for dry weather control. The litter that accumulates during the spring and summer, if not removed from catch

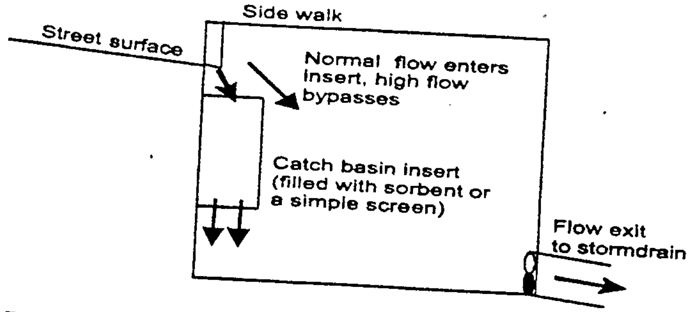

Figure 1 Elevation view of the model catch basin insert developed in this study. Typical minimum basin dimensions are 1 m tall by 0.75 m deep by 1 m wide. The minimum opening is typically 0.15 m

basins, is swept into the bay by the first large storm of the season. To mitigate this problem, the basins are cleaned in September or October. One community has routinely covered catch basins (curbside inlet only) in the dry season to prevent litter build up, insect and rodent problems. Street sweepers then remove the litter, and street sweeping is routinely practiced in these locations. The cover consisted of a plywood board, extending the entire length of catch basin with a gap of 1–2 cm between the bottom of the board and the pavement to allow for nuisance water to enter the basin. The covers or "boardovers" are used only for catch basins in sensitive or high litter-producing areas, and must be removed prior to the rainy season.

To better understand the utility of this practice, two catch basins were covered with plywood and two with wire screens with 2.5 cm square openings. Trash accumulation was monitored. The screens and boards provided roughly equal performance, preventing more than 95% of the build-up in the catch basin, as compared to controls with no covers. Tests were conducted with conventional street sweepers to show that they were capable of removing material that accumulated at the bottom of the covers, and that the sweeper did not destroy the covers. The covers are especially useful in areas with high pedestrian traffic.

Tests to evaluate the inserts' ability to remove contaminants from flowing stormwater were conducted in phases at different scales. Bench scale tests, full-scale laboratory tests and field tests were conducted. Field tests were conducted primarily during the second year of the study. The majority of the testing evaluated oil and grease removal. Many commercially available inserts or stormwater treatment devices claimed that sorbents could be used to remove the oil and grease from stormwater. Previous tests by the authors (Lau and Stenstrom, 1995) also suggested that this might be promising.

Tests were first conducted in columns with 5 cm diameter and height of 5 cm, with mixtures of used motor oil (to simulate the oil and grease in stormwater from commercial areas) and tap water using many different types of sorbents. The oil and grease concentration was generally set to approximately 25 mg/l, which is higher than found in this study, but closer to concentrations of oil and grease found in earlier studies by the author (Stenstrom *et al.*, 1984; Fam *et al.*,1987). Emulsified oil was produced by intensely blending used motor oil with 1 l of tap water to produce a "stock" mixture, which was then further diluted when pumped to the column. Free oil and grease was produced by pumping oil and grease using a syringe pump into a mixing "tee" which was then applied to the columns. The combined flow was allowed to "trickle" through the loosely packed column.

Table 5 shows some of the results. The reported efficiencies are for the period when the sorbent remains "fresh" or unexhausted. As the sorbent is saturated, its efficiency will decline. The mass of adsorbed material per unit mass of sorbent, analogous to "*Q*" or "*M*" for activated carbon isotherms, is an important parameter for overall operation. It

determines the sorbent replacement frequency and therefore the economics of operation. Further work in our laboratory is ongoing to determine these parameters. The sorbents shown in Table 5 are similar, or very similar, to commercially marketed products. The polypropylene materials are used in oil spill control pads and booms. The straw is also used for oil spill clean-up.

None of the sorbents was effective in removing the emulsified oil and grease in this type of experiment. The polypropylene sorbents were evaluated in other tests with 8 to 12 hour contact times and were able to remove 40% to 60% of the oil and grease. If tightly packed into columns, they will remove emulsified oil and grease from waters pumped through under high pressure, but this filtration procedure is not economically feasible for stormwater.

A new series of tests was performed in the full-scale catch basin simulator. This simulator is composed of a stilling chamber, a 0.6 m wide flume that simulates street surface, and a catch basin with a 0.9 m wide opening. Contaminants are released into the flume at controlled rates to produce the desired concentrations. Tap water is used for stormwater. This size is the same as the smallest catch basin routinely constructed by the Los Angeles County Department of Public Works. It was constructed of plywood and cement and built above grade to allow easy access. The 0.9 m opening could accommodate a variety of types of inserts. The inserts were temporarily clamped to the walls of the catchbasin and were easily changed and refitted, as needed.

Two prototype designs were extensively tested. The first used OARS sorbent, which was placed in metal boxes with open tops and screened bottoms. Stormwater flows from the top, through the OARS sorbent, which has a particle size from 5–30 mm with a density of 0.22 g/ml (our measurements, not the manufacturer's specifications). The internal arrangement of the box traps suspended solids and trash. This allows the box to perform as oil and grease, suspended solids, and trash removal device. It also means that in installations where high trash and suspended solids are present, the box may clog before the oil sorption capacity is reached. The second insert extensively tested used polypropylene cloth as a sorption/filtration media. The cloth is supported by a geotextile used for stabilizing soils. The cloth is available in different weights. The geotextile has openings of approximately 1 cm by 8 cm. The prototype inserts have a metal collar at the top, which forms the support for the geotextile. The insert is flexible and can be compressed for insertion though an opening smaller than its height. This design has all the previously cited advantages, and can also be easily constructed in custom sizes.

Tables 6 and 7 show the results for both sorbents. The oil and grease removal efficiency ranged from 40% to more than 90%, depending upon sorbent condition and influent concentration. Removal efficiency was generally higher with higher influent concentrations. The media used in tests 1 and 2 for OARS had been used in the field for four months and represented partially used sorbent. Several tests (Figures 2 and 3) were conducted using the same media, in an attempt to exhaust the media.

Also shown in Tables 6 and 7 are test results for TSS and PAH removal. For the case of TSS, sand particles were sieved and recombined to produce an evenly divided mixture, by mass of sand with US standard meshes of 40, 60, and 100 (approximately 400 to 120 μm). The box removed 99% of the large particles and 78% of the smallest particles. PAH removal was measured by spiking tap water with known masses of PAHs and then measuring effluent concentrations. The removal efficiency ranged from 16% to 61%. Again, the total capacity of the insert was not determined, so the mass of solids or PAHs that can be removed before maintenance is not known. This is the subject of further testing in our laboratory, and should be evaluated in the field as well.

Field tests

Field tests were conducted in the second year of the project at commercial and residential sites. Six sites were initially selected. Three used the polypropylene style insert (two in commercial areas) with double thickness liners, two used the OARS containing insert (one in a commercial area), and one used a simple wire mesh basket (~1 cm opening, in a residential area) with no sorbent or filter media. The inserts were observed to bypass flow at the greatest runoff condition and gradually bypassed more flow as they became clogged. After about two months of active rainfall, the bypassing became more frequent and the polypropylene sorbents were replaced with medium screens (see test 14 in Table 7).

Testing ended for the OARS type sorbents. When stormwater bypassed the insert, there was no change in street runoff rate or increased accumulation on the street surface; the clogged insert had no impact on stormwater removal rate from the street. Sampling was performed as before, except that effluent samples were also collected.

Each residential site was ~12,000 m^2 in area, and the three commercial sites had areas ~5000 m^2 each. Table 8 shows the average water quality for the second year of the study. The values are similar to those shown in Table 2. The standard deviations are high, which is typical for stormwater. Site 2 in Table 2 is similar to the commercial sites used in the second year. The residential sites in the two studies are similar in land use and housing density. The high standard deviations mask water quality comparisons; however, turbidity, COD, DOC, chloride, SPE oil and grease and are higher in the commercial sites (one-tailed test at $\alpha = 0.15$).

The water quality data shown in Table 8 serves as the influent for an efficiency test of the inserts. Effluent samples were collected from the insert using a cup on a stick. Samples were collected when the inserts were not bypassing. Removals for the polypropylene insert inal M* (g)

averaged 21, 36 and 34% for TSS, VSS and turbidity, respectively. The OARS device averaged 21, 9 and 12% for the same parameters. The variability in oil and grease removal rates precludes making any conclusion. Table 4 suggested that 26% of the sediment in stormwater might be removed by a filter that captures solids greater than 150 µm. The removals in actual field test are below this prediction, but are not too much different, especially considering the highly variable nature of stormwater. The TSS procedure captures 100% of all particles greater than 0.8 µm; the majority of the material that composes suspended solids is less than the size that can be removed by insert filters.

At the end of the study, the polypropylene bags and screens were removed and the contents were air dried. The material smaller than 12,700 µm (0.5 in) was weighted, screened and reweighed. Table 9 shows the results from the first part of the study. The inserts at the two commercial sites tended to recover smaller particles. Table 10 shows the results for the second part of the study. This study used a much coarser mesh screen, but still recovered many small particles. Again, there is much more finer material at the commercial sites.

The final data reduction was to calculate an equivalent concentration of captured material per unit of runoff volume. This is similar to an event mean concentration, in that the total runoff volume can be multiplied by the coefficients to produce an expected mass of

captured litter and particles. Table 11 shows these results. The coefficients are shown in units of kg/m^3. Note that the solids larger than 12,700 µm are included. These coefficients were calculated using the catchment area for each site, rainfall observed during the study, and runoff coefficients of 0.39 for residential and 0.6–0.7 for commercial sites. These totals include material swept or blown into the catch basin during non-rainy periods, which in Southern California is the majority of the time. The coefficients in Table 11 will have two systematic errors. The coefficients will be lower than the actual load, since the insert devices are imperfect and bypass at high flow. The coefficients are higher than the actual load carried by stormwater, due to the flux of material in dry weather. The coefficients can be used as a first-order approximation of the litter and debris to be expected from commercial and residential sites in urban areas in climates similar to Los Angeles.

Conclusions

This manuscript has briefly described the results of laboratory and field tests to determine the opportunities for using catch basin inserts to remove specific pollutants (oil and grease, litter and suspended solids). The inserts have the advantage of using the existing urban infrastructure to remove stormwater pollutants at low cost. The estimated cost of each insert is less than US$ 500. An insert design has been proposed that is easy to install and does not require workers to enter the catch basin. Observations during storms showed that they do not create flooding problems, even when they are clogged. Laboratory testing has showed that free oil and grease (simulated by used automobile crankcase oil) can be removed by a variety of sorbents in simple flow-through contacters. Emulsified oil can generally not be removed. Oil and grease removal in field tests was inconclusive. Laboratory testing showed that particles can be removed down to a size of 100 µm, and field results showed that much smaller particles can also be trapped. Laboratory testing showed that the sorbents can remove dissolved PAHs with efficiencies ranging from 16 to 88%. Additional testing is needed to further demonstrate the utility of these inserts. The removal capacities for oil and grease and suspended solids, which will dictate maintenance frequency and cost, need to be determined. The results presented in this paper are preliminary and should be applied with caution. The authors hope that they will stimulate others to develop catch basin insert technology.

Acknowledgements

This work was supported in part by a US-EPA funded Watershed project, the Santa Monica Bay Restoration Project and a consortium of local cities, led by the City of Santa Monica. Additional funding was provided by two manufacturers. The patents or potential patents that cover these products are not known to the authors. There is no financial or business relationship between the authors, UCLA and any insert or sorbent manufacturer. We are thankful to Lee-Hyung Kim, Ed Zaruba, Ruta Skirrus, and the Woodward-Clyde team for their assistance.

Performance of a Proprietary Stormwater Treatment Device: The Stormceptor®

The Stormceptor® is a popular proprietary storm water treatment device that has been widely applied across the U.S. and Canada in recent years. Its primary application is on small, highly impervious sites. A schematic of the device is shown in Figure 1. The device is popular because it is relatively easy to design, can be easily installed in a wide variety of applications, and can be installed in small sites without sacrificing land area. The typical device incorporates a circular holding tank that receives runoff from a flow diversion structure. Storms that exceed the capacity of the off-line device are diverted to the downstream drainage network. Unlike other stormwater practices, the Stormceptor® is designed and sized primarily on the *rate* of stormflow rather than its *volume*. Consequently, the Stormceptor® provides treatment within a much smaller area than is possible with most other stormwater practices.

A much anticipated monitoring study was recently completed by Steve Greb (Wisconsin DNR) and Robert Waschbusch (USGS) that provides the most comprehensive and independent performance evaluation of Stormceptor to date. They installed a Stormceptor® unit as a retrofit at the Badger Road public works maintenance yard in Madison, Wisconsin in mid-1996. The maintenance yard was about 4.3 acres in area and almost completely impervious. The yard was used for refueling, maintenance and parking of heavy vehicles, and also for storage of road salt, sand, yard wastes, and other materials.

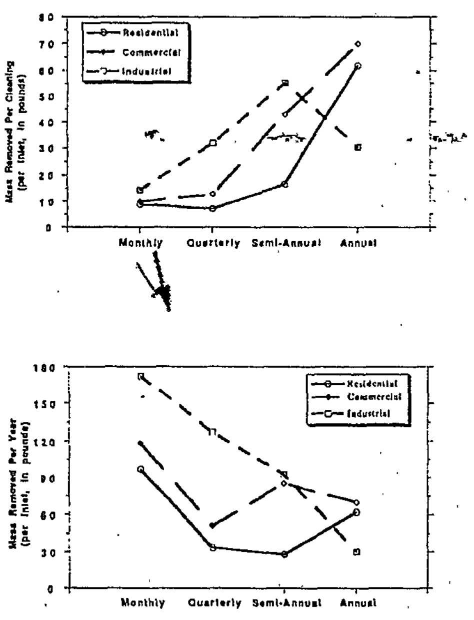

Figure 1: Schematic of Stormcepter® Unit with Sampling Locations

Maintenance yards often rank among the "dirtiest" pollutant source areas in the urban landscape, and the Badger Road yard was no exception. The median total suspended solid (TSS) concentration was reported to be 251 mg/l, which slightly higher than the Wisconsin commercial street median concentrations of 232 mg/l (Bannerman *et al.*, 1996). The median chloride and total dissolved solids (TDS) runoff concentrations were 560 and 3,860 mg/l respectively, suggesting that stockpiled salt and other organic materials at the yard were a key pollutant source area.

The Stormceptor® unit selected for the retrofit at the Madison yard was the STC 6000 model with a sediment storage capacity of 610 ft^3. According to Stormceptor®'s sizing guidance, this unit has a sediment storage capacity of 142 ft^3/ac and is projected to have a suspended solids removal rate of approximately 75% (Stormceptor®, 1997).

Greb and his colleagues had to develop sophisticated monitoring techniques to measure the performance of such a small treatment unit. They installed flow-integrated storm samplers at the inflow and outflow locations of the Stormceptor® treatment tank, as well as at the bypass weir (see Figure 1 for locations). This sampling arrangement was needed to determine how much runoff volume bypassed the unit and was therefore not treated. If the bypass volume is high, then the treatment efficiency for the device would need to be adjusted downward. Although 24% of monitored storm events experienced some flow bypass around the Stormceptor® treatment tank, the team computed that only 10% of the total runoff volume during the study actually bypassed the device during the sampling period.

Flow was measured directly using a flow meter which was connected to a data-logger to initiate sampling during storm events. One composite sample was

R0011495

collected at the inflow and outlet for each storm event containing between five and 40 subsamples that was used to compute event-mean concentrations for the various pollutant constituents.

The sampling team evaluated the performance of the Stormceptor® during 45 precipitation events over a nine-month period that ranged in size from .02 inches to 1.31 inches. The monitoring study extended from August, 1996 to May, 1997 and included snowmelt events. During 15 storm events, the team evaluated 37 different pollutants, including a variety of solids, nutrients, metals, and polycyclic aromatic hydrocarbons (PAHs). For the remaining 30 storms, the team measured only three parameters: total suspended solids, total dissolved solids, and total phosphorus.

So how well did the Madison Stormceptor® work? Generally, the observed removal rates were lower than the manufacturer's expectations. The computed removal rates for the Madison unit are provided in Table 1. The Stormceptor® performed about as well as conventional catch basin inlets (Pitt, 1998) and certainly better than the traditional oil/grit separator. Note that the removal rates in Table 1 indicate both the actual removal efficiency of the tank, and an overall efficiency that accounts for untreated bypass flow. For example, the TSS removal rates drops from 25 to 21% when stormflow bypass is considered. The team conducted a particle size analysis and found less than 5% of the trapped sediment in the tank was of the silt or clay sized particle size. Nearly all of the trapped sediment were larger sand sized particles.

Closer examination of Table 1 indicates that Stormceptor® had a low to moderate ability to remove particulate pollutants (e.g., solids, PAH and metals), but virtually no ability to remove soluble pollutants (with the exception of dissolved phosphorus). This is not surprising since the device relies on particulate settling for pollutant removal. Total PAHs had among the highest overall removal rate at 37%. Although oil and grease were not directly monitored, the team found that about 120 gallons of oily material had accumulated in the tank during the nine-month study. The sizeable volume of oily material was likely generated from diesel fuel from a nearby refueling station.

Another key finding of the Madison study was that Stormceptor®'s ability to remove suspended solids was dependent on the depth of rainfall in each storm event (see Figure 2). The Stormceptor® achieved fairly high rates of TSS removal (40 to 80%) when rainfall depths were less than 0.2 inches, but removal rates dropped sharply as rainfall depths increased. Winter storm events were excluded from Figure 2(a) because imported stockpiled snow at the yard contributed snowmelt that could not be related to specific measured rainfall depths.

Several factors could have affected the overall performance of the Madison Stormceptor®. First, the sampling effort included storm events during the late winter and spring of 1997. Cold temperatures and the high salinity of the water could have degraded particle settling conditions within the Stormceptor® tank during these events. Pitt (1998) found that winter settling velocities were about half of the settling velocity expected during the summer months for the same-sized

Table 1: Reported Pollutant Removal Efficiencies for the Stormceptor® From Madison, Wisconsin, Dept. of Public Works Maintenance Yard (Sreb *et al.*, 1998)

	Tank Efficiency			Overall Efficiency Including Bypass		
Pollutant	Total load in	Total load out	Removal efficiency (%)	Total upstream load	Total downstream load	Overall removal efficiency (%)
TSS (kg)	1,257	943	25	1,506	1,192	21
TDS (kg)	29,743	36,022	-21	30,051	36,330	-21

R0011496

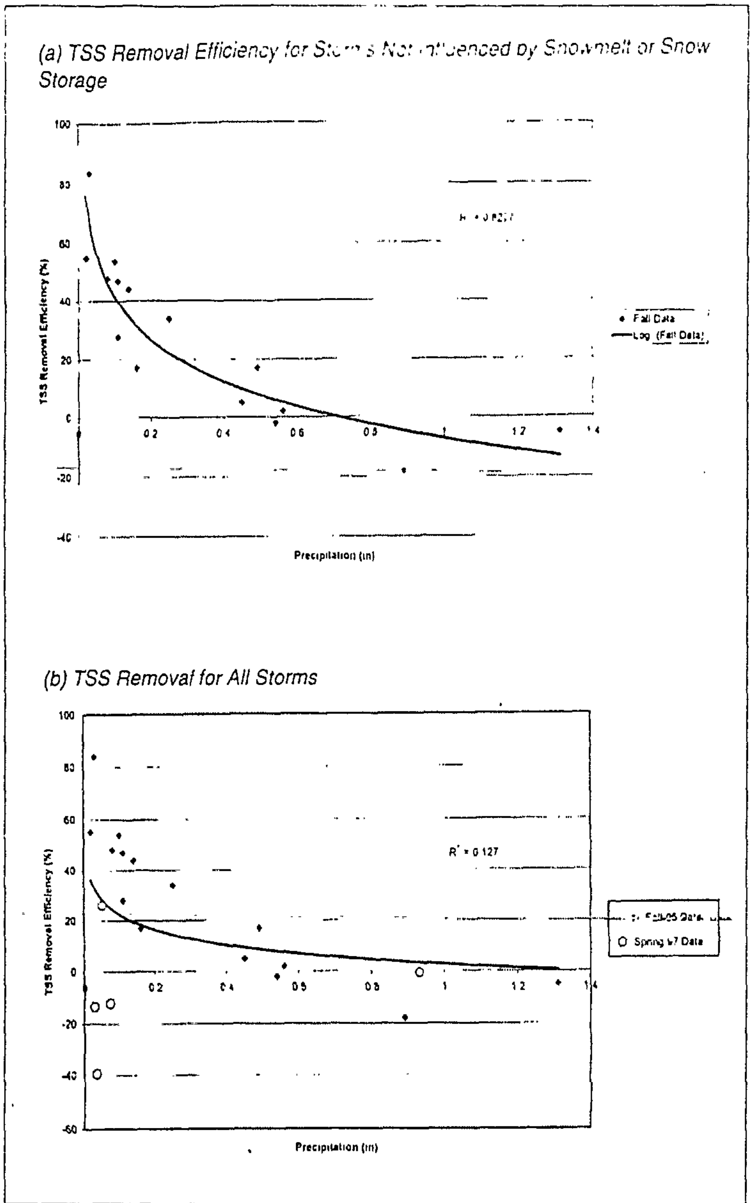

Figure 2: TSS Removal as a Function of Rainfall Depth as a Function of (a) Storms Not Influenced by Snowmelt and (b) All Storm Events

particles. Further, snowmelt from stockpiled snow at the yard increased the inflow to the unit in the winter and spring. By contrast, summer and fall storm events were not influenced by high chloride levels but experienced the greatest rainfall intensity and, consequently, the most storm bypasses.

Second, the sampling methods for measuring TSS could have slightly underestimated the actual removal since it did not fully measure the transport of sand. Sample intakes were located above the bottom of the inflow pipe and therefore could have failed to sample larger sand sized particles moving along the bottom of the pipe. The sampling team was able to calculate the missing bedload by measuring the amount of sediment actually trapped in the tank at the end of the study. They estimated that the unsampled bedload was about 8% of the total sediment load, and the maximum solids removal efficiency would increase to about 29 to 33% if the bedload was included.

Stormceptor Field Tested in Edmonton, Alberta, Canada

A second and more limited independent evaluation of Stormceptor® was performed by the City of Edmonton, Alberta, Canada (Labatiuk, 1997). The City monitored nine storms at a 9.9 acre commercial shopping center. The monitoring protocol required that three consecutive dry days occur before the storm sampler was triggered, in an effort to test the capability of Stormceptor to remove pollutants from "first flush" storms. Table 2 illustrates the pollutant removal rates for several pollutants, based on an analysis of four storm events during the second year of monitoring. Mean TSS removal was about 50%.

During the first year of monitoring, equipment difficulties and improper installation of some plumbing severely limited the validity of the sampling results. The results for the first year included five storms with a mean TSS removal rate of 6.9% and a standard deviation of 11.1%, but these results should be viewed with some skepticism given the monitoring difficulties and the fact that the Edmonton unit may have been undersized. Given the limited number of storms and the lack of on-site rainfall data, it was not possible to determine how pollutant removal rates were related to rainfall depths at the Edmonton site.

Conclusions

While the Madison monitoring effort was certainly comprehensive, more questions need to be answered to fully assess Stormceptor® technology. For example, how well would the Stormceptor® work in a more typical urban installation? Clearly, the Madison maintenance yard was a stormwater hotspot, and the salt and snow storage at the yard may have influenced the performance evaluation. For example, the settling characteristics at the Madison site may have been unusual due to extremely high levels of chlorides in the runoff. Second, the Madison tank may have been too deep. A shallower tank would allow particles to reach the bottom of the settling chamber faster, possibly increasing solid removal.

Interestingly, the Edmonton unit, with a smaller storage capacity, a shallower tank, and larger drainage

R0011497

area, out performed the Madison unit, at least for the limited number of events sampled. This may have been due to the shallow depth of the Edmonton tank, or simply a reflection of the small sample size of the Edmonton study. Clearly, more monitoring data are needed, since the Stormceptor® has been tested in a few locations and a relative handful of storms events. Additional Stormceptor® performance tests are currently underway in Colorado, Texas, and the Pacific Northwest that will expand our understanding of its performance. Based on what is known now, it is not clear whether the Stormceptor® has sufficient sediment and pollutant removal capability to serve as a "stand alone" stormwater management practice in most development situations.

Another perspective on the Madison Stormceptor® can be obtained by comparing its performance to that of the multi-chamber treatment train (MCTT) developed by Robert Pitt. One of the MCTT units also served a maintenance yard in Wisconsin, and sediment removal rates from between 83 to 98% were reported. Removal of other pollutants was on the order of 65 to 95%. The MCTT retains a much larger runoff volume per unit area than the Stormceptor®, and employed advanced techniques for inlet screens, sedimentation and filtration. By way of comparison, the MCTT had about 30 times more runoff storage volume per unit drainage area than the Stormceptor® yet also costs about 20 to 30 times as much as a Stormceptor®.

This initial round of Stormceptor® monitoring indicates that it can be reasonably effective at trapping sand, oil and grease if regular tank clean out occurs. This suggests that it may be useful for pre-treatment for other stormwater practices, particularly those that can easily clog with sediment, and at ultra urban hotspot situations where space is at a premium and designers must go underground.

Article 47

Feature article from Watershed Protection Techniques. 3(2): 647-656

The Benefits of Better Site Design in Commercial Development

Modern commercial development is dominated by the parking lot. Indeed, as much as half of the entire surface area of a typical office park or shopping center is devoted to parking. No one has ever stepped up to claim that they invented the parking lot, and their reluctance is understandable: the parking lot is a prime habitat for the car and not much else.

From an environmental standpoint, parking lots rank among the most harmful land uses in any watershed. Parking lots not only collect pollutants that are deposited from the atmosphere, but also accumulate pollutants that leak, drip or wear off cars. Researchers have found that parking lot runoff can have extremely high concentrations of nutrients, trace metals and hydrocarbons. Parking lots also influence the local air and stream temperatures. In the summer months, pavement temperatures can exceed 120 degrees Fahrenheit, which in turn increases local air temperatures five to 10 degrees compared to a shaded forest. Parking lots can also exacerbate smog problems, as parked cars emit greater levels of smog precursors under extreme heat island conditions (Scott *et al.*, 1999).

Perhaps the greatest environmental impact of parking lots is hydrological in nature. Simply put, there is no other kind of surface in a watershed that produces more runoff and delivers it faster than a parking lot. When this runoff is discharged into a headwater stream, its great erosive power steadily degrades the quality of downstream habitats, unless exceptionally sophisticated stormwater practices are installed.

Is it possible to design a better parking lot? At first glance, there seems to be little opportunity to incorporate better site design into parking lots. However, the better site design techniques described earlier in this issue suggest a key design strategy: *work to incrementally shrink the surface area of the parking lots and then use the space saved to integrate functional landscaping and better stormwater treatment within the parking lot.* Through a series of relatively minor design adjustments, it is possible to reduce the surface area of parking lots by five to 20%. These design adjustments include curbing excess parking, incrementally reducing parking demand ratios, providing credits for mass transit, shrinking stall sizes, narrowing drive aisles, and using grid pavers for spillover parking areas.

In this article, we examine some of the benefits of employing better site design as they apply to commercial development. As with the residential redesign, this analysis also uses the Simplified Urban Nutrient Output Model (SUNOM) to compare actual commercial development sites constructed in the 1990s with the same sites redesigned utilizing better site design techniques. The two commercial developments analyzed include a retail shopping center and a commercial office park.

Our fairly conservative approach to parking lot redesign is intended to reflect realistic opportunities in a suburban setting. For example, we did not utilize shared parking, porous pavement, or structured parking in any of the redesigns, although each of these techniques is very effective. Nor did we reduce the basic footprint or size of the buildings in either scenario, although smaller "boxes" may well have been more appropriate for the zoning. Instead, our basic approach was to make a series of relatively modest changes in parking lot design to shrink parking lot area, and then implement better landscaping and stormwater treatment measures within the saved space.

This article reports on the potential benefits of parking lot redesign in terms of reduced runoff, pollutant export and development costs. It also reviews the initial experience of communities that are experimenting with new and innovative parking lot designs, and concludes with some implications for both the engineer and watershed manager.

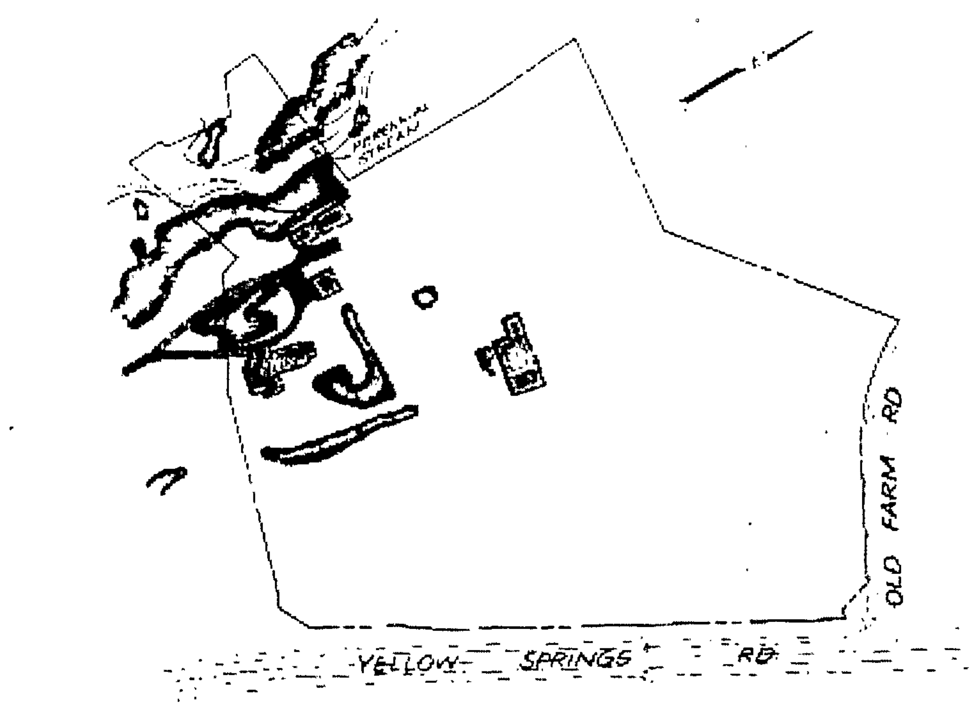

Figure 1: Predevelopment Conditions at the Old Farm Shopping Center Site

Redesign of the Old Farm Shopping Center

The undeveloped Old Farm shopping center, located in the City of Frederick, Maryland, was primarily meadow, with some shrubby forest and a few farm buildings. Bordered by two major arterial roads and served by existing public water and sewer, the site was a prime candidate for commercial development (Figure 1).

Construction of the shopping center site parcel commenced in 1992. The 9.3 acre site is a typical suburban "strip" shopping center with two large retail stores, other retail space, a gas station and a drive-in bank (Figure 2). In terms of surface cover, the shopping center devoted 50% of its total area for parking, as compared to 16% for the actual footprint of the retail buildings. Another 24% of the surface area was devoted to landscaping or stormwater treatment. Less than 10% natural cover was retained on the site, and part of the project encroached on the 100-year floodplain and the stream buffer. The entire site was mass graded during construction. The basic layout was designed to accommodate the car, with generous parking located in front of the stores. The parking lot design provided 5.2 full-size stalls per 1,000 square feet (sf) of retail space, which exceeded the already generous local parking requirement of five spaces per 1,000 sf. According to the most recent national parking research, only 4.0 to 4.5 spaces are needed to serve shopping centers (ULI, 1999).

The stormwater treatment system at Old Farm consisted of an infiltration basin located near the rear of the shopping center that captured runoff from about a third of the site, and three oil grit separators that provide some treatment for the remaining two-thirds of the site. After discharging from the oil/grit separators, runoff traveled through a series of storm drains that extended along the road and eventually discharged to the stream (albeit without detention of any kind). It should be noted that recent performance monitoring has shown that oil grit separators have little or no pollutant removal capability (see articles 119 and 120).

The Redesigned Old Farm Shopping Center

The Old Farm shopping center was redesigned using a "U-shaped" layout that maintained the same amount of gross floor area, but sharply reduced the site area devoted to parking (Figure 3). The new design reduced walking distances, encouraged pedestrian use, and created a more intimate shopping experience. Parking dropped from 50% of the total site area to 38%, primarily because the parking demand ratio was reduced from 5.2 spaces to 4.4 spaces per 1,000 sf of retail area.

The rationale for the lower parking demand was justified in two ways. First, no extra parking spaces were allowed beyond those required by the locality. Second,

R0011500

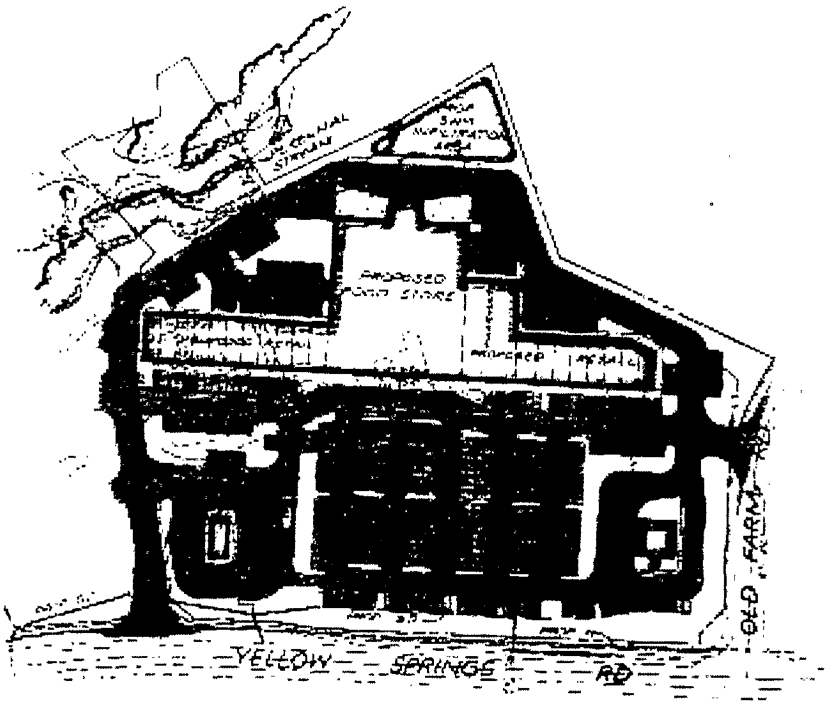

Figure 2: The Conventional Design of the Old Farm Shopping Center

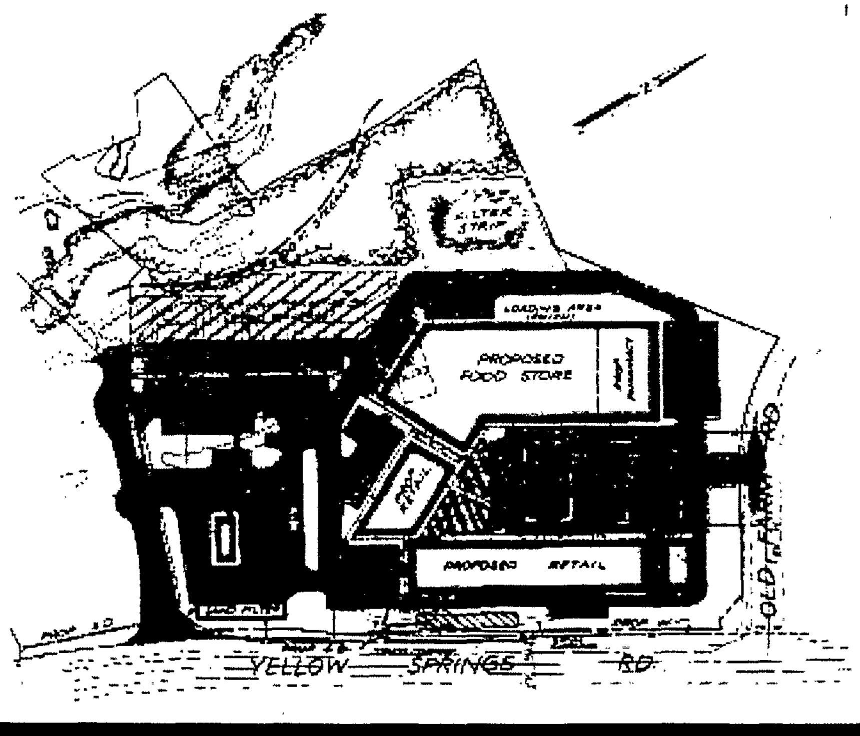

Figure 3: The Innovative Design of the Old Farm Shopping Center

Table 1: Hydrology of the Old Farm Shopping Center Case Study				
		Pre-Developed	Conventional Parking Lot	Innovative Parking Lot
Runoff (inches/yr)	no practice	2.6	24.5	20.6
	practices		18.1	15.1
Infiltration (inches/yr)	no practice	11.8	2.7	3.4
	Practices		9.1	8.9

the existing parking demand ratio was reduced by about 15% to reflect actual parking demand more accurately. As a result, the total number of parking spaces dropped from 343 to 291. In addition, 17% of the parking stalls were designed for compact cars, which require slightly smaller stalls than standard full-sized spaces. Taken together, these changes eliminated slightly more than one acre of parking area, which provided enough space to design a more effective landscaping and stormwater treatment system.

Several parking lot islands were increased in size and converted into bioretention areas to treat stormwater. Other elements of the stormwater treatment system included a sand filter, an infiltration trench, and a filter strip. Furthermore, 25% of the entire parking area was designated for "spillover parking," and grid pavers were used rather than normal paving materials. The grid pavers helped store the first few tenths of an inch of rainfall that would have otherwise run off the parking lot (ICPI, 2000). Lastly, the redesign enabled reforestation and greater protection of the buffer along the stream that runs along the edge of the property. As a result, the proportion of natural cover at the site climbed from 7% to 19% as a result of the parking lot redesign.

Comparative Hydrology at the Old Farm Shopping Center

As expected, the construction of the original shopping center dramatically changed the hydrology of the site (Table 1). The increase in impervious cover from 1% to more than 70% increased annual runoff volume by a factor of nine. The infiltration basin used in the original design helped put some runoff back into the ground, but even so, annual runoff was seven times greater than the pre-development condition. The redesigned parking lot, by virtue of its lower impervious cover and improved stormwater practices, produced about 20% less runoff than the original design. Nevertheless, the stormwater practices at the redesigned parking lot were not able to match the pre-development hydrology.

Comparative Nutrient Output from the Old Farm Shopping Center

The conversion of the meadow into a shopping center greatly increased nutrient export from the site; the SUNOM model indicated that annual phosphorus and nitrogen export would increase tenfold as a result of the development (see Figure 4). Nutrient export from the shopping center was dominated by stormwater runoff, as the model indicated that stormwater runoff contributed about 95% of the annual nutrient export from the site. Nutrient loads were not greatly reduced by the infiltration basin or oil/grit separators that were installed at the conventional parking lot. Nutrient export was still projected to be eight to 10 times higher than pre-development conditions, even after these stormwater treatment practices were installed.

In contrast, the redesigned parking lot sharply reduced nutrient export (Figure 4). In fact, the redesigned parking lot *without* stormwater practices produced about the same nutrient load as the conventional parking lot *with* stormwater practices. This reduction was a direct result of the lower impervious cover associated with the redesigned parking lot. When the redesigned parking lot was combined with more sophisticated stormwater practices (i.e., bioretention, sand filter, infiltration trench and filter strip), the total nutrient export was half that of the conventional parking lot with stormwater practices. It is interesting to note, however, that this load was still about five times higher than that produced by the meadow prior to development.

Comparative Cost to Develop the Old Farm Shopping Center

The cost to develop the redesigned parking lot was marginally lower than the cost for the conventional parking lot — about 5%. Considerable cost savings were realized due to less paving, shorter sidewalks, and fewer curbs and gutters, but these savings were largely offset by added costs for improved stormwater practices, landscaping and grid pavers. Overall, the estimated cost to build the conventional parking lot was $782,500, compared to $746,270 for the redesigned parking lot. The extent of potential cost savings depends heavily on the level of sophistication of the original stormwater treatment system. In this case, the unsophisticated stormwater practices used in the conventional parking design were fairly inexpensive, but were also not effective in removing nutrients.

Summary

Figure 5 summarizes the redesign analysis of the Old Farm Shopping Center. The redesigned parking lot resulted in less impervious cover, stormwater runoff, and nutrient export for a slightly lower development cost than the conventional design.

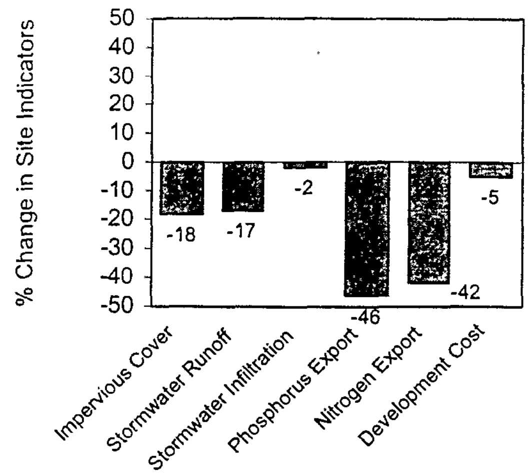

Figure 5: Percentage Change in Key Site Indicators From a Conventional Design of the Old Farm Shopping Center to an Innovative Design, Both With Stormwater Practices

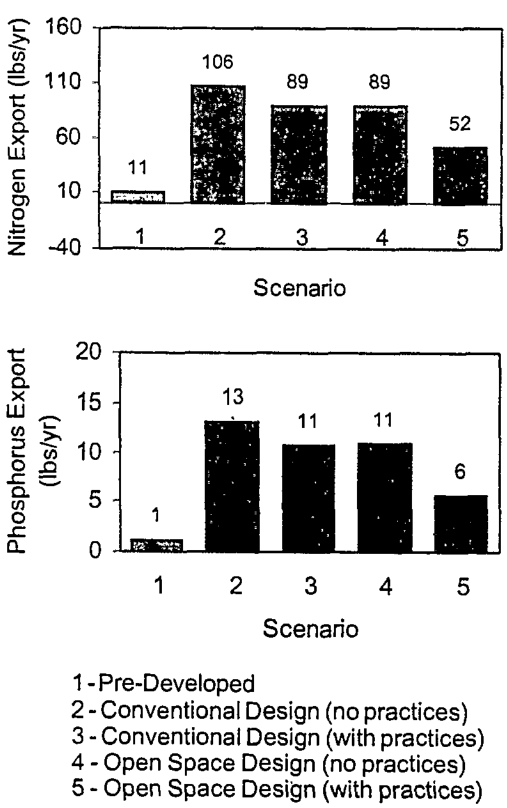

Figure 4: Annual Nitrogen and Phosphorus Export in Each Old Farm Shopping Center Development Scenario

R0011503

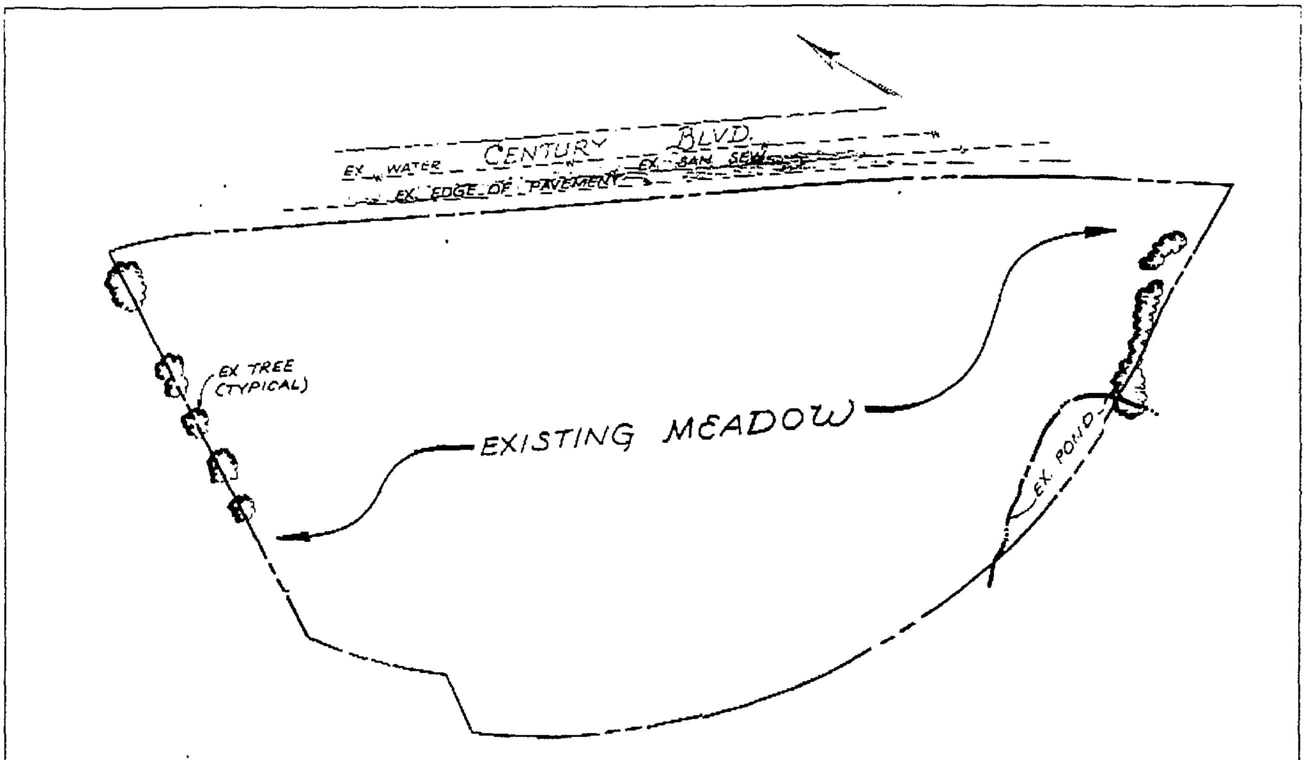

Figure 6: Predevelopment Conditions at the 270 Corporate Office Park Site

Redesigning the 270 Corporate Office Park

The second case study involved the redesign of a typical suburban office park. The 12.8 acre parcel is located in Germantown, Maryland in the mildly sloping terrain of the Piedmont (Figure 6). The existing cover at the site was almost entirely meadow, except for a few trees and an old farm pond that bisected the property boundary. No wetlands or other sensitive natural features were evident on the site. The site was zoned for office development, and existing infrastructure made it an attractive candidate for development. An existing network of public water and sewer, electric, gas, and other utilities ran along the frontage of a large arterial road.

The layout of the conventional suburban office park design is depicted in Figure 7. The project included a pair of five-story office buildings, surrounded by a sea of parking. Over half (52%) of the surface cover at the office park was devoted to parking, as compared to only 11% for actual footprint of the office building. Most of the remainder of the site was utilized for landscaping, stormwater treatment or turf. Only 2% of the natural cover was retained on the site, and nearly all of the parcel was mass graded during construction.

As with many suburban office parks, the location of the building and parking were primarily oriented toward the car. The parking lot was sized using a parking demand ratio of 3.1 spaces per 1,000 sf of building, which slightly exceeded the minimum parking requirements of the locality. As a result, the parking lot created room for 745 standard stalls, along with 33 larger stalls for vans and disabled access. The parking bays also featured roomy aisles between the stalls (24 feet wide). The design was intended to provide some amenities for the office workers, including a short path system between buildings, an ornamental stormwater pond, and some landscaping in required setbacks and parking islands.

The conventional design featured the classic "pipe and pond" approach to stormwater management. Parking lot runoff was initially collected by a curb and gutter system that sent runoff into underground storm drain pipes that, in turn, discharged into two very small wet ponds. Each pond served roughly half of the site and was expected to have a reasonably good capability to remove nutrients.

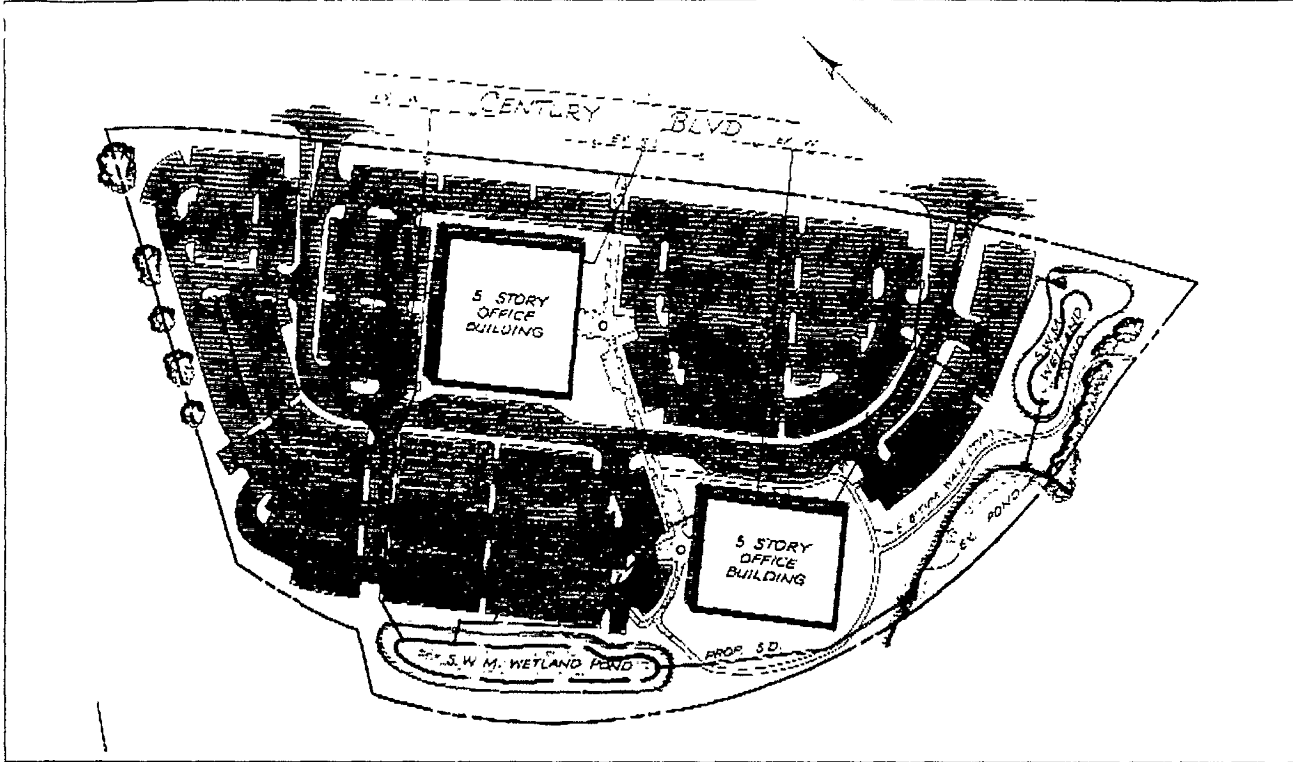

Figure 7: The Conventional Design of the 270 Corporate Office Park

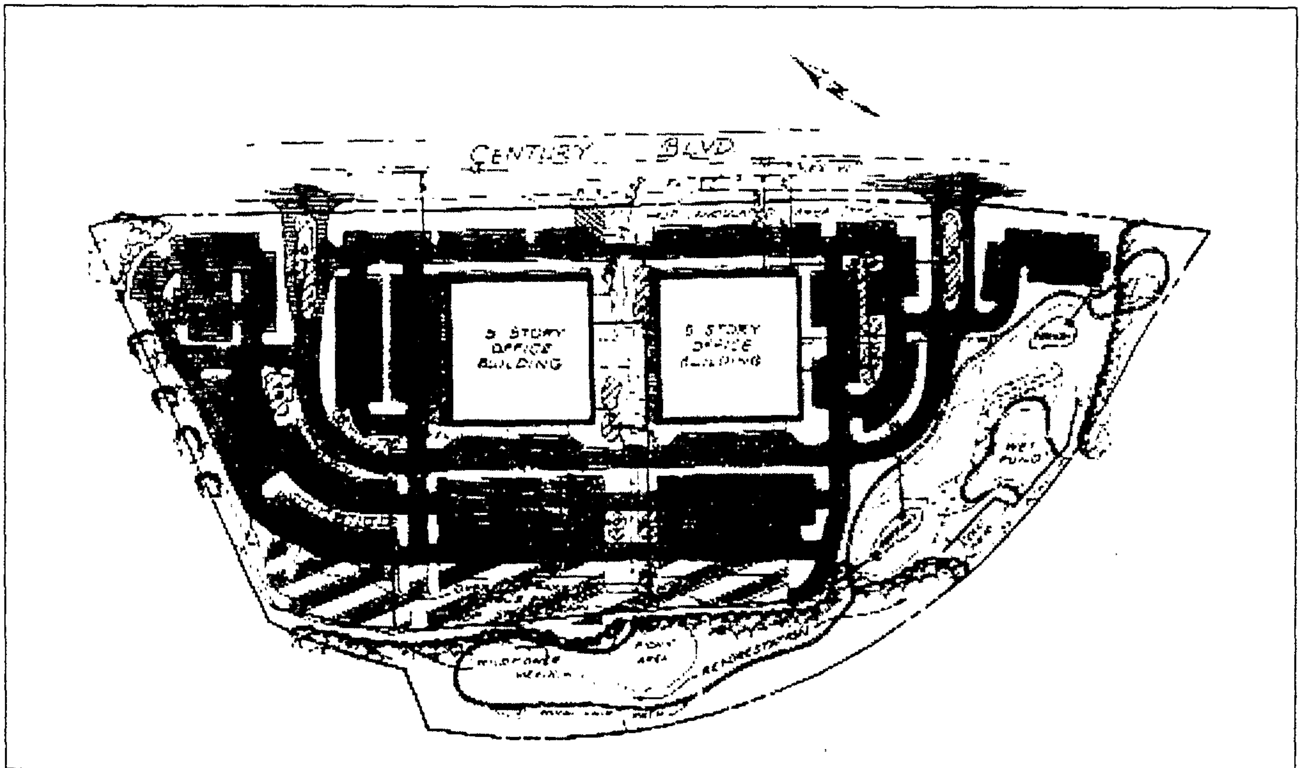

Figure 8: The Innovative Design of the 270 Corporate Office Park

The Redesigned 270 Corporate Office Park

The redesigned site employed a number of techniques to minimize impervious cover and improve stormwater treatment (Figure 8). The office park featured the same amount of office space, but the two office towers were situated closer to the road to shorten utility extensions, and pedestrian access to a bus stop was provided to encourage the use of public transportation.

The key strategy employed in the redesign was to incrementally reduce the size of the parking lot, and this was achieved in five ways. First, no excess parking spaces were allowed over those required by the local parking demand ratio. Second, the local parking demand ratio was reduced by 8% to reflect actual parking demand. Third, the parking demand ratio was reduced by another 10% to reflect the proximity to the bus stop. Fourth, the size of approximately 20% of all parking stalls was downsized to accommodate compact cars. Lastly, drive aisles in many parking bays were reduced from 24 feet in width to 20 feet. Combined, these measures reduced the total parking lot area by nearly 30%, or about two acres. Once again, the savings in paving gave the designer more room to integrate landscaping with more effective stormwater treatment.

For example, larger landscaping islands were installed in the parking lot to plant shade trees, and some of these areas were also converted into bioretention areas to treat stormwater. A dry swale was used to treat stormwater within a landscaped setback area in another part of the site. About 15% of the lot was designated for spillover parking, and grid pavers were used to attenuate runoff in this area. The basic stormwater management goal was to attenuate, treat, or recharge as much runoff from smaller storms as possible in the parking lot itself. Runoff from larger storms was treated in a wet detention pond near the outlet of the property.

As a result of the redesign, roughly 14% of the office park was either retained in natural land cover or reforested (compared to 2% under the conventional design). This green space, combined with the water features and a walking path, created a more tranquil environment for office workers. Overall, the total impervious area associated with the redesigned office park dropped from 68% to 53%.

Comparative Hydrology for the 270 Corporate Center Office Park

The hydrological story was much the same for the 270 Corporate Center as for the shopping center. Construction of the conventional design sharply increased annual runoff volumes and decreased infiltration (Table 2). Runoff did not increase as much in the redesigned parking lot, primarily because its impervious cover was much lower. Annual runoff volumes were 21% lower in the redesigned parking lot compared to the conventional design, and infiltration volumes were 42% higher. Despite these improvements, the redesigned parking lot was unable to mimic the hydrologic conditions prior to development.

Nutrient Output at the 270 Corporate Center Office Park

As expected, the conversion of the meadow into an office park greatly increased nutrient export. Annual phosphorus and nitrogen export increased roughly tenfold, according to the SUNOM model (Figure 9). As with the shopping center, stormwater runoff was found to generate about 95% of the annual nutrient export from the site. The two wet ponds were reasonably effective in removing nutrients at the conventional office park, but still resulted in nutrient export that was seven to eight times higher than pre-development conditions. In contrast, the redesigned parking lot sharply reduced nutrient export (Figure 9). The combination of lower impervious cover and more effective stormwater practices reduced nutrient export by about 40 to 50%, when compared to the conventional parking lot design *with* stormwater practices.

Table 2: Hydrology of the 270 Corporate Office Park Case Study

Hydrologic Factor	Pre-Developed	Conventional Parking Lot	Redesigned Parking Lot
Runoff (inches/yr)	2.7	23.9	18.9
Infiltration (inches/yr)	11.8	2.6	3.7
Note: no change in the annual volume of runoff or infiltration was calculated as a result of the stormwater practices installed at either the conventional or redesigned parking lot.			

Comparative Cost to Develop the 270 Corporate Office Park

The cost to develop the redesigned office park was approximately the same as the cost to develop the conventional office park, although the component costs were somewhat different. Less was spent on paving, sidewalks and utility pipes, but these savings were largely offset by higher costs for improved stormwater treatment practices, landscaping, grid pavers and curiously, curbs and gutters (the higher cost for this last item was due to the wider parking islands used for bioretention areas). Overall, the estimated cost to build the conventional parking lot was $948,900, compared to $921,200 for the redesigned parking lot.

Overall Summary: Office Park Redesign

The redesigned parking lot at the 270 Corporate Office Park resulted in less impervious cover, stormwater runoff, and nutrient export for about the same development cost as the conventional design. The results are summarized in Figure 10.

The Limits and Potential of Parking Lot Redesign

To our knowledge, no one has yet tried to quantify the potential economic and environmental benefits of better parking lot design at new commercial developments. This initial analysis provides compelling evidence that better site design is an important, if not indispensable, tool for managing the quantity and quality of stormwater runoff from parking lots.

In each of the case studies, the redesigned parking lot resulted in less impervious cover, stormwater runoff, and nutrient export for about the same or even slightly lower cost than the conventional design. Taken together, better site design techniques reduced impervious cover by at least 15% in each case. While this is an impressive reduction, about half of each site remained impervious after the redesign. Perhaps the most critical benefit of each redesign was that it created more room to locate more effective stormwater treatment practices. When smaller parking lots were combined with better stormwater practices, the resulting nutrient export was almost half that of a conventional parking lot.

In each case study, the critical ingredient was an incremental reduction in the local parking demand ratio. Without this capability to shrink the surface area devoted to parking, designers have little ability to devise the more sophisticated stormwater treatment and landscaping systems that can help mitigate the impact of the parking lot. Therefore, the first and most important step in implementing better site design for commercial developments *is to reduce local parking demand ratios, even if only by*

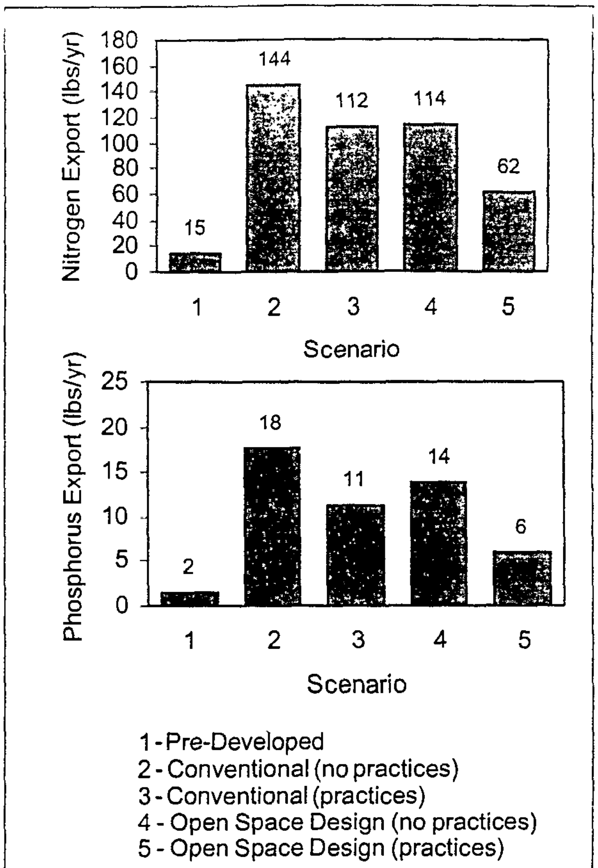

Figure 9: Annual Nitrogen and Phosphorus Load in Each 270 Corporate Office Park Development Scenario

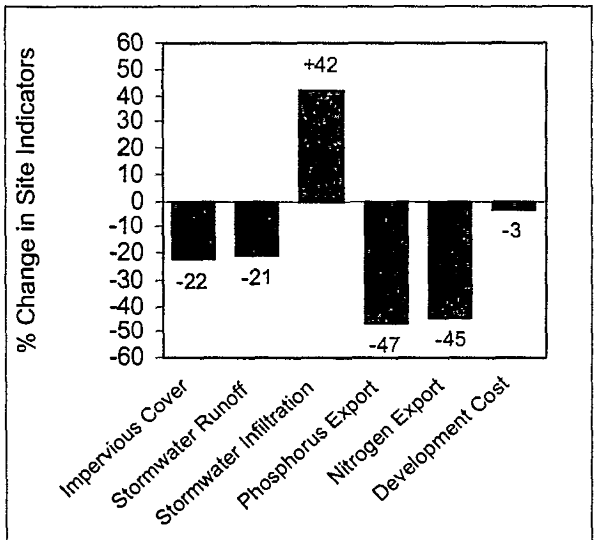

Figure 10: Percentage Change in Key Site Conditions from a Conventional Design to a Redesigned Parking lot at the 270 Corporate Office Park, Both With Stormwater Practices

five or ten percent. For many communities, however, this modest step may seem like a terrifying leap, possibly off a cliff.

Developers, bankers, retailers and drivers all have a shared interest in abundant and convenient parking, and it is hard to convince them that any attempt to downsize parking lots, however modest, will not work against this goal. This kind of thinking is quite understandable. Most people can easily recall the rare situation where parking was hard to find, but the more common situation where parking is plentiful generally escapes our everyday notice.

Small wonder, then, that so many communities are prone to inertia when it comes to changing parking codes. Perhaps the only way watershed advocates can overcome this inertia is to document the existence of excess parking capacity in each community. Indeed, it is a rather simple step for volunteers to count cars and photograph empty stalls during peak times at similar commercial land uses to demonstrate how generous local parking requirements actually are.

A small but growing list of communities are now experimenting with their parking standards and parking lot designs, including cities like Scarborough, Ontario; Oakland, CA; Olympia, WA; Sacramento, CA; Bellevue, WA; Davis, CA and Prince George's County, MD. Each community has worked in different ways to redesign their parking lots, and many of their successful experiences are recounted in *Better Site Design: A Handbook for Changing Development Rules in Your Community* (CWP, 1998a).

Given the prevalence of parking lots in our urban landscape and the environmental harm they cause, we need to fundamentally change the way that parking lots are sized and designed. The modest ideas presented in this article are merely an initial step in this direction. A wide range of professions collectively influence the form and function of parking lots, including engineers, hydrologists, landscape architects, urban foresters, soil scientists, developers, leasing agents, plan reviewers, transportation researchers and many, many others. Working together, these groups can move us closer toward the goal of a truly sustainable parking lot, i.e., one that not only provides car habitat, but also prevents damage to other habitats, as well. - ***JAZ***

EPA

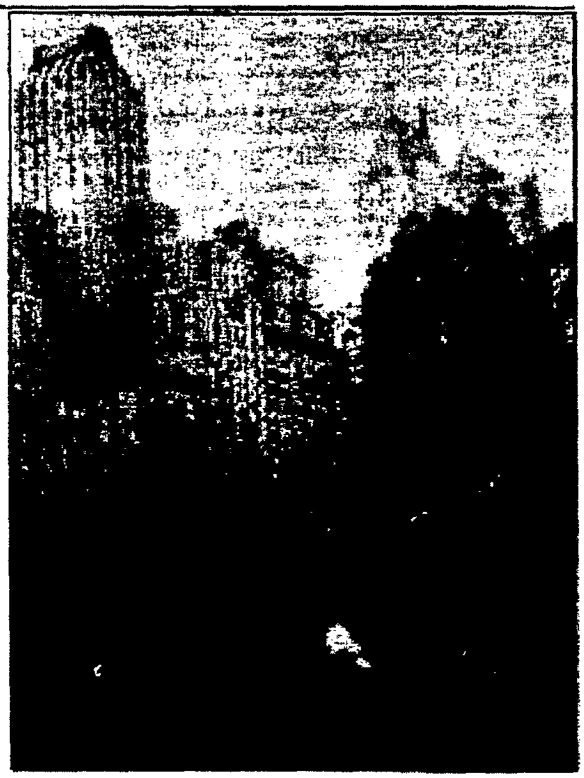
Urban Runoff Impacts to Receiving Waters

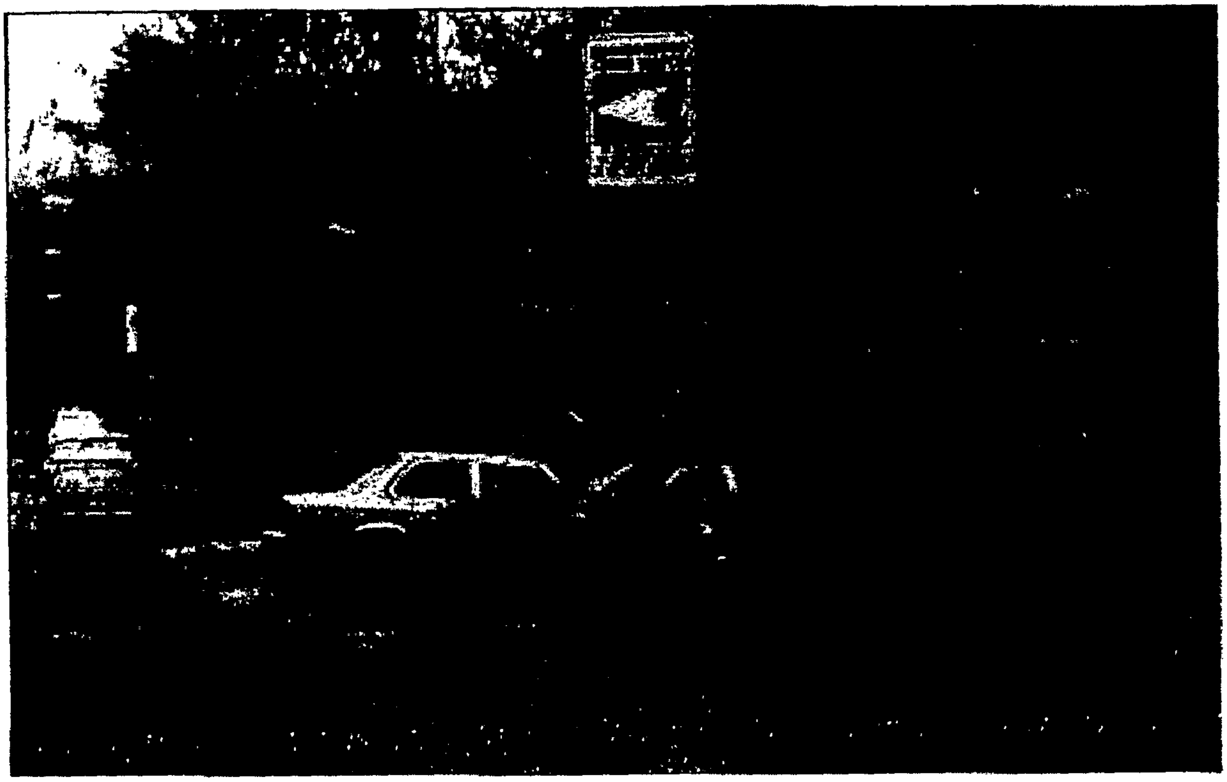
Introduction

The EPA-sponsored National Urban Runoff Program (NURP) identified the potential of stormwater to adversely affect receiving waters and aquatic biota through increased frequency and duration of peak flow rates, erosion/sedimentation, eutrophication, or toxic impact. Assessments completed under state clean lakes and nonpoint source programs have identified the extent to which urban runoff is impairing water use.

Stormwater Contaminants

The state assessments identified several categories of potential urban stormwater pollutants: suspended solids, nutrients, bacteria, oils/grease, toxic organics, and toxic inorganics (heavy metals). Critical pollutants were identified by: (1) frequency of occurrence within the stormwater database, and (2) high concentrations relative to the EPA water quality criteria. An additional consideration was the degree to which urbanized stormflow hydrology alone impacted biota in natural stream courses. Potential impacts resulting from the presence of the above pollutants include: (1) physical impairment or habitat disruption to biota, (2) enrichment and subsequent eutrophication of receiving waters, and (3) exposure and physiological response to toxic substances by aquatic biota. The presence of such impacts are considered an impairment of the receiving water resource.





Automobile traffic is a major source of pollutants resulting from urban stormwater runoff.

High Flows/Erosion/ Suspended Solids

Various urban runoff studies have effectively demonstrated the impacts of high flows, erosion, and deposition on urban streams and other sensitive receiving waters. Increased frequency and duration of high flows result in increased erosion-related impacts to (1) eroded sites, (2) conveyance systems including streams, and (3) sites of deposition. In-stream impacts are related to increased streambank erosion during high flows, increased turbidity and suspended solids concentrations, scouring habitat, and downstream depositional impacts that degrade habitat and reduce hydraulic channel capacities. Increased suspended solids concentrations and turbidity in streams can be detrimental to aquatic life (primary producers, benthic invertebrates, and fish) by interfering with photosynthesis, respiration, growth, and reproduction. The deposition of relatively fine-grained sediments in stream beds can dramatically reduce their value for insect production and fish spawning. Erosion/ sedimentation impacts can be costly, requiring removal of deposited materials to restore water supply storage, flood control, habitat, and recreational benefits of impacted resources.

Nutrients

Increased nutrient (phosphorus, nitrogen) concentrations in stormwater have been shown to result in greater nutrient enrichment and associated algal productivity in lakes, embayments, and other quiescent receiving waters, often creating undesirable excessive growth conditions. Phosphorus is often emphasized as the nutrient controlling algal growth; phosphorus loading rates from urban areas have been determined to be three to seven times greater than undeveloped woodland. However, a preponderance of stormwater inflow has been demonstrated to inhibit algal growth as a result of the presence of toxic substances, despite elevated nutrient concentrations.

Toxic Organics

Toxic organic pollutants that are prevalent in urban runoff include pesticides, phenols, phthalates, and polynuclear aromatic hydrocarbons (PAHs). While some exceedances of EPA freshwater chronic water quality criteria have been reported, concentrations in general are sufficiently low to preclude significant impacts to aquatic biota. However, their potential for bioaccumulation and status as human carcinogens warrants continued consideration as pollutants of concern.

Toxic Metals

Toxic metals are the pollutants of greatest concern in urban runoff. Lead, zinc, copper, and cadmium have both a high frequency of occurrence and high absolute concentrations in stormwater; numerous exceedances of water quality criteria for these metals have been reported. Metals have the potential to bioaccumulate and persist in the environment.

EPA water quality criteria have been developed for both acute and chronic toxicity values from bioassays on representative biota; criteria are designed to protect 95 percent of aquatic species. Physiological effects of metals exposure include algal growth inhibition and zooplankton/fish mortality through gill adsorption and respiratory impairment.

Uncertainties of Toxic Impacts

While stormwater impacts related to aesthetics, hydrologic changes to stream habitat, elevated fecal coliform counts, and eutrophication have been adequately demonstrated, the adverse effects of toxicants have been more difficult to establish. Although some water quality degradation may be occurring, such degradation has generally not been perceived to result in significant impairment to aquatic biota. For example, of over 10,000 fish kills investigated by EPA during the period 1970-1979, less than 150 were attributable to urban runoff. If present, potential toxic impacts have been more subtle and more easily overshadowed by larger, definite impacts associated with scour and sedimentation. Other sources of uncertainty regarding toxic pollutant impacts include the following:

1. Water quality metals criteria and most stormwater analyses are based on total concentrations, whereas only the smaller dissolved fraction is directly related to toxicity. Criteria are therefore conservative as they also assume dissolution of the inert particulate fraction.

2. Criteria are based on continuous bioassays for the defined exposure period. In reality, stormwater toxic exposure is intermittent and of short duration, whereupon receiving waters recover to relatively acceptable quality. These are recognized by EPA under the term "Estimated Effect Levels for Intermittent Exposure."

3. Bioassays and water quality criteria are based upon end-of-pipe stormwater concentrations. Criteria therefore do not assume dilution capability by the receiving water.

4. Pollutant forms and concentrations are dynamic relative to product and use trends. For example, lead concentrations in stormwater have declined in recent years with the progressive conversion of the motor vehicle fleet to lead-free combustion engines. Similarly, some pesticide products are being retired in favor of new products being introduced to the market.

Summary Assessment of Urban Runoff Impacts

The majority of pollutant loading attributed to urban stormwater originates from endemic sources such as motor vehicle traffic and atmospheric fallout. While toxic metal criteria established from continuous exposure bioassays are regularly exceeded in stormwater, receiving water resources and local perception often do not reflect a corresponding beneficial use impairment of the resource. Possible reasons for this disparity are due to the conservative nature of water quality criteria designations and the complexity of biochemical cause and effect relationships. Instead, perceived or documented impairments focus on aesthetics from oil and floatable debris, species displacement from erosion/sedimentation in conveyance streams, and enhanced eutrophication potential from nutrient enrichment.

Foreword

Despite the gains achieved by Clean Water Act requirements and the installation of municipal sewage treatment systems in most communities, water pollution still remains a problem. Although industries and municipal treatment systems continue to affect water quality, states estimate that nonpoint source pollution causes one- to two-thirds of the impairment or threats to waterbodies.

Nonpoint source pollution results from land runoff, precipitation, atmospheric deposition, drainage, seepage, and hydrologic modifications. In urban areas nonpoint source pollution is created when sediment, toxic substances, nutrients, pathogens, and even garbage wash off fields, lawns, and impervious surfaces into our nation's waterbodies.

This guide is intended to help decisionmakers, such as local government officials and planners, understand the causes of nonpoint source pollution and design and implement a program to control this pollution. The guide provides a framework for developing a nonpoint source program tailored to an individual community. It includes examples of successful runoff management programs that illustrate the variety of strategies state and local governments have adopted.

Technical guidance and expertise, however, are essential components in this process. *Urbanization and Water Quality* lists a number of sources for such expertise: publications, contacts, and summaries of several federal programs mandated by the Clean Water Act and Coastal Zone Management Act. Applied within the community's structure, this information can help improve and protect the quality of nearby waterbodies.

Chapter 1

How Urban Runoff Affects Your Community: The Problem

The thirsty earth soaks up the rain,
And drinks, and gapes for drink again.
Abraham Cowley (1618-1667)

While centuries of poets have praised the virtuous qualities of rain, urban decisionmakers are forced to face the harsh reality — rain and its close relative, snow, are the major carriers of nonpoint source pollution. Such pollution occurs in developed areas when water runs off the land and streets — gathering pollutants in its path and depositing them in nearby waterbodies.

Urban runoff carries pollutants from many sources and activities — automobiles, oil and salt on roads, atmospheric deposition, processing and salvage facilities, chemical spills, pet wastes, industrial plants, construction site erosion, and the disposal of chemicals used in homes and offices. In fact, pollutant levels in urban waterbodies are generally much greater than in forested watersheds.

Runoff water quality worsens as urbanization increases:

- Trees that once intercepted rainfall are gone.
- Natural dips or depressions that had formed temporary ponds for rainwater storage are lost by grading and filling for development.
- Thick, absorbent layers of natural vegetation and soils are replaced by paved (impervious) surfaces such as roads and roofs.
- Eroded paths such as streambanks become channels, increasing the amount of sediment carried by runoff.

As asphalt and concrete replace vegetation, runoff increases and reaches waterbodies faster and with greater force. And when the land loses its capacity to absorb and store rainwater, the groundwater table drops and stream flows decrease during dry weather.

The Symptoms

Local governments must be alert to the obvious symptoms of water pollution. They include

- scum and algal mats floating near lake shores,
- excessive plant growth choking waters used by boaters and swimmers,
- sediment-clogged drainage ditches and sewers,
- decreasing depth of a lake,
- fewer fish and wildlife,
- contaminated water supply for drinking, recreation, or industry,
- fish kills that may destroy sport fisheries or close beaches,
- fish advisories caused by bacteria or toxic substances found in fish, and
- extreme flooding or streambank erosion.

The Sources

Pollution from urban runoff can affect water in various ways, depending on the pollutant. The impacts and sources of pollutants have been researched by many organizations, including the Metropolitan Washington Council of Governments, from which much of this information was extracted (see Table 1).

■ Sediment. Sediment — organic and inorganic material suspended and settling in water — clogs storm drains; fills river channels, lakes, wetlands, and reservoirs; and increases the potential for flooding downstream. Sediment may fill in water supply reservoirs, eventually requiring costly dredging or new water sources.

These suspended solids make the water appear muddy, decreasing its value for fishing and recreation. As sediment settles to the bottom, phytoplankton, fish, and invertebrates have difficulty feeding and reproducing. Other aquatic life may be smothered or deprived of essential sunlight. Sediment can also carry other materials — such as nutrients, pesticides, and trace metals — that can harm both aquatic life and human health.

Sediment and erosion are at their peak when the soil is disturbed along with the vegetation that stabilizes it. And once sediment enters a stream, it can take many years to travel through the waterway. As silt, clay, and sand move downstream, they erode the streambank, affecting fish and wildlife habitat along the way.

■ **Nutrients.** Nutrients — excessive levels of phosphorus and nitrogen — pose a severe problem as urban development intensifies. Nutrients encourage undesirable algal blooms and excessive aquatic weed growth. This nutrient-rich process, called eutrophication, greatly decreases the water's quality.

In lakes, for example, decomposing plants can cause surface scums and unpleasant odors, discolor water, and decrease oxygen. This breakdown limits swimming, boating, fishing, and other recreational uses; reduces fish and wildlife habitat; and contaminates water supplies. The water-holding capacity of lakes and reservoirs may also decrease.

Urban runoff carries nutrients from roads, sidewalks, and parking lots, and from lawns, golf courses, parks, cemeteries, homes, and commercial sites. In some areas, improperly maintained household septic systems add to the problem.

■ **Bacteria.** Urban runoff often contains high levels of harmful bacteria and viral strains, including fecal streptococcus and fecal coliform from human and animal wastes. When these levels exceed public health standards, as they often do, water is unsafe to drink, beaches are closed, and harvesting shellfish beds is restricted.

Older, more intensively developed areas produce the most bacteria from organic wastes and sanitary sewer overflows. In addition, pet and bird wastes increase the nutrient and bacteria content of runoff.

■ **Oil and grease.** Oil, grease, and other petroleum-based substances contain hydrocarbons, some of which are harmful to sensitive animal species and aquatic life. Hydrocarbons attracted to sediment settle in the bottom of waterbodies, where they may harm bottom-dwelling organisms and be transferred through the food chain.

Hydrocarbons also degrade fisheries habitats and damage the appearance of the water's surface. They lower dissolved oxygen by limiting the interaction of water and air. Oil and grease problems are highest in the runoff from parking lots, roads, and service stations. Oil held in the soil can eventually seep through to the groundwater and be carried to the streams.

■ **Heavy metals.** Heavy metals — including lead, copper, cadmium, zinc, mercury, and chromium — can be toxic to aquatic life and contaminate drinking water supplies. Heavy metals affect sensitive animal species, plants, and fisheries and enter the food chain through animal tissue ingested by humans and other animals.

R0011518

Table 1.—Pollutants typically found in urban runoff.*

COMMON URBAN RUNOFF POLLUTANTS	SOURCE	AVERAGE CONCENTRATIONS	NONPOINT SOURCE IMPACTS
Sediment	Urban/ Suburban	average 80 mg/L	Fills in ponds and reservoirs with mud; contributes to decline of submerged aquatic vegetation (SAV) by increasing turbidity and reducing the light available for photosynthesis. Acts as a sink for nutrients and toxicants and as a source when disturbed and resuspended.
Total Phosphorus	Urban Suburban	1.08 mg/L 0.26 mg/L	A contributing factor cited in eutrophication (nutrient over-enrichment) in receiving waterbodies and subsequent algal blooms. Algal blooms contribute to the decline of SAV by reducing light available for photosynthesis, further degrade water quality by decreasing the level of dissolved oxygen (DO), and may cause changes in the composition of plankton and fish species.
Total Nitrogen	Urban Suburban	13.6 mg/L 2.00 mg/L	Like total phosphorus, contributes to eutrophication and algal blooms.
Chemical Oxygen Demand	Urban Suburban	163.0 mg/L 35.6 mg/L	Decreases the concentration of dissolved oxygen. Low DO concentration and anaerobic conditions (complete absence of DO) can lead to fish kills and unpleasant odors. Primarily released as organic matter in the "first flush" of urban runoff after a storm.
Bacteria	Urban Suburban	average — 200 to 240 000 MPN/L	High concentrations can lead to closure of shellfish harvesting areas and prevent swimming, boating, or other recreational activities.
Zinc	Urban Suburban	0.397 mg/L 0.037 mg/L	Most commonly found toxic metal in the mid-Atlantic coastal region; chronically exceeds EPA water quality criteria. Primary cultural source is the weathering and abrasion of galvanized iron and steel.
Copper (Nationwide Urban Runoff Program average)	Urban Suburban	0.105 mg/L 0.047 mg/L	Chronically exceeds EPA water quality criteria. Primary cultural source is as a component of antifouling paint for boat hulls and, in urban runoff, from the leaching and abrasion of copper pipes and brass fittings. An important trace nutrient, it can be bioaccumulated and, thereby, create toxic health hazards with the food chain and increase long-term ecosystem stress.
Lead	Urban Suburban	0.389 mg/L 0.018 mg/L	Lead from gasoline burning in automobiles is less of a problem today because of unleaded gasoline use. However, lead from scraping and painting bridges and overpasses remains. Chronically exceeds EPA water quality criteria. Attaches readily to fine particulates that can be bioaccumulated by bacteria and benthic organisms (e.g., oysters and mussels) while feeding. Lead has adverse health impacts when consumed by humans.
Oil and Grease	Urban/ Suburban	average 2-10 mg/L	Toxicity contributes to the decline of zooplankton and benthic organisms. Accumulates in tissues of benthic organisms, a threat to humans when consumed directly or when passed through the food chain. Primary cultural source is automobile oil and lubricants.
Arsenic	Urban/ Suburban	average 6.0 µg/L	An essential trace nutrient. Can be bioaccumulated, creates toxic health hazards within the food chain and increases long-term stress for the entire ecosystem. Accumulates within tidal, freshwater areas, increasing the toxicity for spawning and juvenile fish. Primary cultural source is fossil fuel combustion.
Cadmium	Urban/ Suburban	average 1.0 µg/L	Urban runoff contributes a major portion to the mid-Atlantic coastal region. Primary cultural source is metal electroplating and pigments in paints. Can be bioaccumulated; creates toxic health hazards within the food chain and increases long-term toxic stress for the entire ecosystem.
Chromium	Urban/ Suburban	average 5.0 µg/L	Primary cultural source is metal plating and as a component of paint pigments. An essential trace nutrient, it can be bioaccumulated, creating toxic health hazards within the food chain and increasing long-term toxic stress for the entire ecosystem.
Pesticides	Urban/ Suburban	average <0.1 µg/L	Primary urban source is runoff from home gardens and lawns. Can bioaccumulate in organisms and create toxic health hazards within the food chain. Observed levels currently below standards.

Based on mid-Atlantic Coast data.** ***Source: Metropolitan Washington Council of Governments, 1993.

R0011519

Most metals found in urban runoff come from corroding, decaying surfaces, often accelerated by acidic rain, and from dissolving or leaching materials. Among the sources of metals are roofing materials, downspouts, leaded gasoline, galvanized pipes, metal plating, paints, wood preservatives, catalytic converters, brake linings, and tires. Maintenance of bridges and other structures can also contribute paint scrapings and abrasives.

■ **Toxic substances.** Toxic chemicals, including pesticides and polychlorinated biphenyls (PCBs), can seriously impair water quality and threaten human and animal health. In addition to pesticides, toxic wastes are found in fertilizers, herbicides, and household substances such as paints and cleaning materials. Proper use and disposal of these substances are mandatory.

■ **Chlorides.** Chlorides or salts are toxic to many freshwater aquatic organisms, which can tolerate only a certain level of salinity. Increased levels of sodium and chloride in surface and groundwater can also affect soil structure, stressing plant respiration and lessening viability.

The main source of chlorides is road salting to remove ice and snow. Chlorides run off roads, parking lots, and sidewalks, and find their way into wetlands, streams, lakes, and groundwater. Because of their high mobility, chlorides can have a major impact on groundwater.

■ **Temperature.** Even a slight rise in water temperature can adversely affect some aquatic life and insects in and around a waterbody, including stoneflies, mayflies, and trout. This is particularly true of streams that alternate between cold and warm water.

Runoff can raise stream temperatures as a result of passing over an urban landscape warmed by structures and paved surfaces. Less shade because of fewer trees also raises stream temperature. Runoff stored in shallow ponds and heated by the sun between storms, especially pollution controls that hold runoff for extended periods, can also harm aquatic life.

■ **Trash and debris.** Floatable wastes collect at impasses in streams and lakes, disturbing water flow and impairing the aesthetic quality of the environment. This debris, from street litter and careless disposal practices, washes into waterbodies both over land and through the storm drain system.

■ **Impervious surfaces.** Paved surfaces absorb less rainfall, thus directly increasing water velocity. More sediment will be deposited downstream; and the rapid, forceful flow may drastically erode streambanks, making the area vulnerable to flooding. Increases in paved surfaces can be directly linked to the accelerated loss of aquatic habitat. Heavier sediment loads clog streambeds with sand and silt, destroying habitat. Pool and riffle stream areas also become severely degraded, leaving poor conditions for both the fish community and the macroinvertebrate insect community on which fish depend for food.

■ **Disturbance of stream habitats.** Development inevitably requires that roads and pipelines cross streams, rivers, and wetlands. Construction activities can upset ecosystems and habitats; permanent structures such as culverts can block the movement of fish, preventing recolonization.

Wildlife habitat may also be affected by the replacement of vegetation by roads and structures. Installation of concrete-lined storm drainage channels, for example, often requires removing tree canopies and results in a loss of riparian and aquatic habitats.

Open spaces play an important role in controlling nonpoint source pollution in most urban areas. Therefore, the whole watershed should be considered in making conservation decisions. Maryland, for example, has a Forest Conservation Act that protects existing forests while allowing continued development. It requires a developer to map existing forests and submit a forest conservation plan. This type of program can serve as a reference for urban communities facing similar decisions.

In the past, communities have treated pollution crises as they arose. They have built treatment plants to control point sources of pollution, and used various best management practices (BMPs) to address urban runoff (see Chapter 4). But today, communities are realizing that the hydrology and ecology of their entire watershed influence water quality (see Fig. 1).

Communities are also recognizing that the greatest loss from water pollution is that people can no longer use and enjoy the natural resource. They can't swim, boat, fish, picnic, or just enjoy a lake or river. As a result, the economic impact on the community is significant — people must go elsewhere for recreation, taking with them dollars that could be spent on gas, food, lodging, and entertainment. Pollution may also cause property values to fall, eroding the tax base.

With this increased awareness and knowledge, communities of all sizes are building two-pronged water quality programs: (1) they are identifying and correcting existing problems, and (2) they are focusing on preventing future problems. Communities are finding that a comprehensive nonpoint source management program will help them avoid many of the problems caused by urban pollutants *before* they occur.

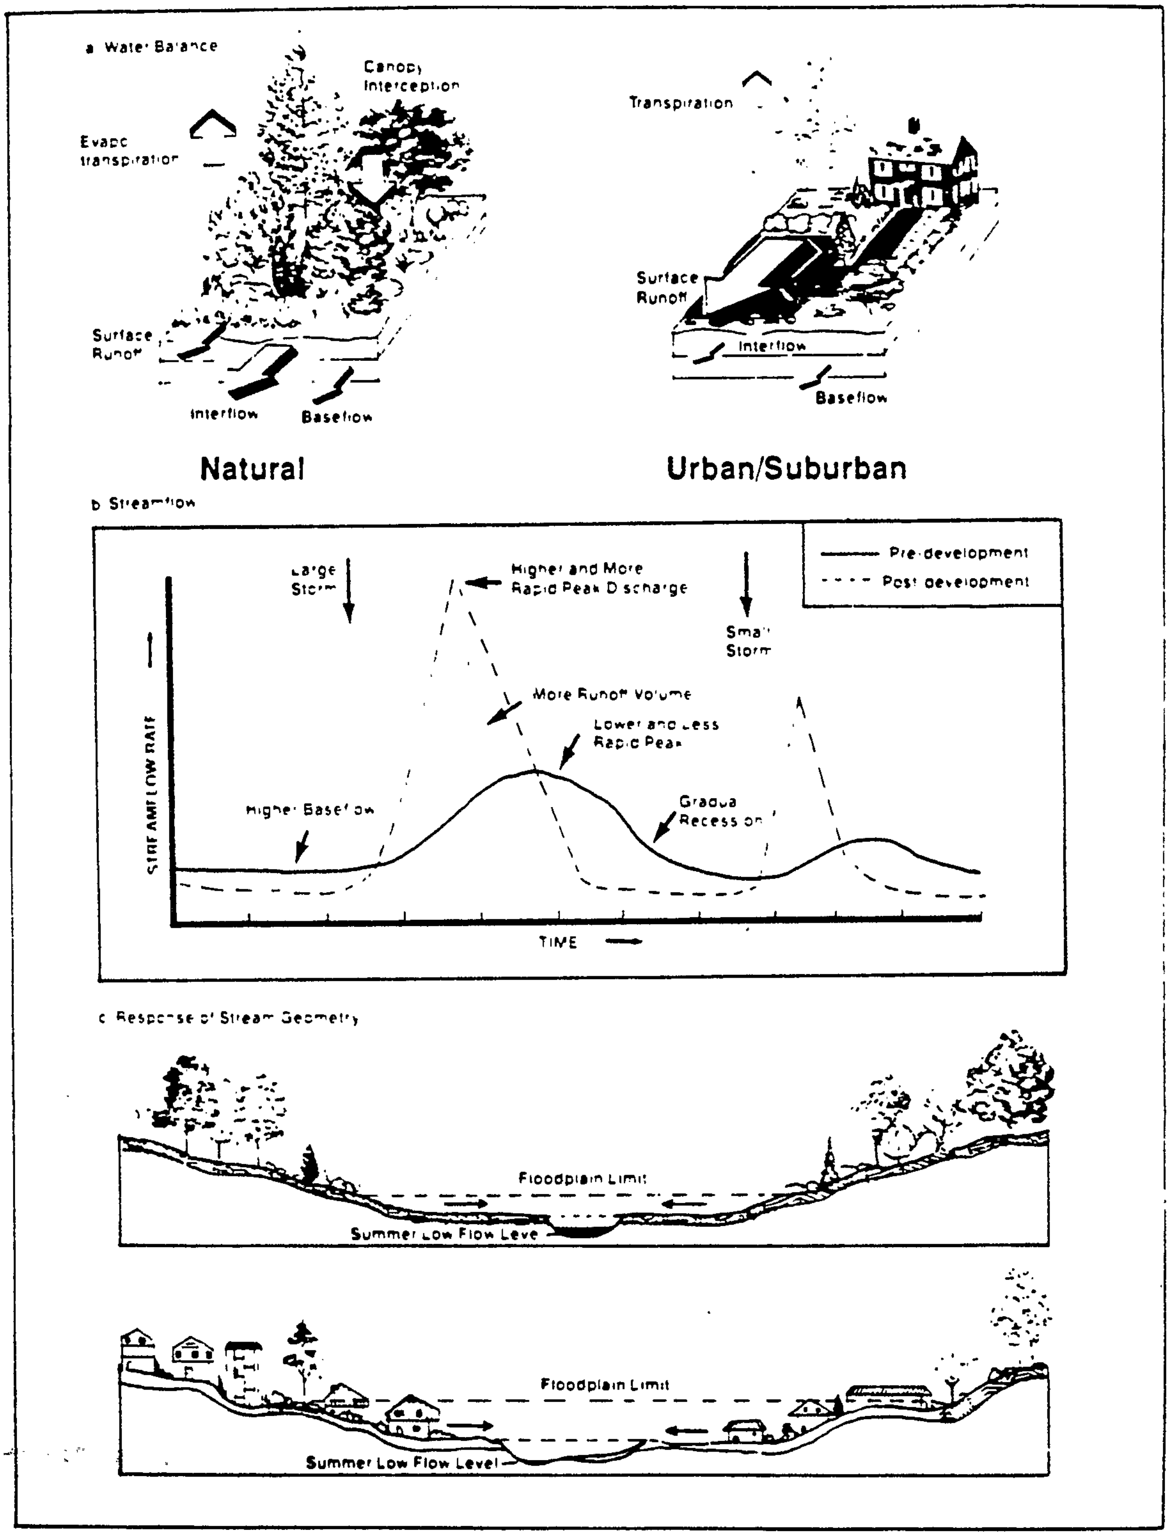

Figure 1.—Changes in watershed hydrology as a result of urbanization. ***Source: Metropolitan Washington Council of Governments, 1987.***

R0011521

Chapter 2

Controlling Urban Runoff: Designing a Nonpoint Source Management Program

With urbanization inevitably comes nonpoint source pollution. This pollution stems from the basic processes of urbanization and the individual lifestyles of citizens.

A nonpoint source management program is one element within a community's overall management plan, just as the effects of urban runoff are one concern. But each piece connects within the community puzzle, if only within the budget. Therefore, the task of controlling nonpoint source pollution must be accomplished by the entire community, planning and working together.

Conservation techniques on undeveloped land — floodplains, wetlands, stabilized streambanks, and slopes — go far in assuring water quality. These natural features play important roles in managing nonpoint source pollution in local communities and should be included in any comprehensive management approach.

This chapter describes a step-by-step approach to designing a nonpoint source management program, a process that a community can adapt to its own situation. Subsequent chapters contain information on the pollution prevention and control methods that can be applied to managing urban runoff.

Figure 2 charts some of the elements of a successful nonpoint source management program. While most programs begin with defining the problem, a program requires continued revisiting, reevaluating, and adjusting. A central element in all phases of program development and implementation is educating and involving the public. In fact, the program's success depends on public support and buy in. Chapter 5 discusses techniques to be incorporated at every phase of the program to keep the public aware and supportive.

The following is a step-by-step guide to constructing a successful nonpoint source management program:

Step 1: Define the current or potential problem.

Step 2: Evaluate existing programs and resources.

Step 3: Build program infrastructure.

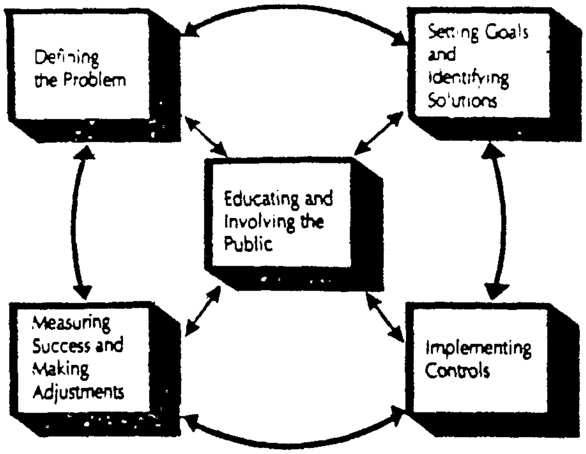

Figure 2.—Elements of a successful watershed project. *Source: U.S. Environmental Protection Agency, The Watershed Protection Approach: A Project Focus, 1994.*

Step 4: Identify potential options.

Step 5: Evaluate options and alternative strategies.

Step 6: Set program goals.

Step 7: Select a final strategy.

Step 8: Develop a work plan.

Step 9: Adopt and implement the work plan.

Step 10: Monitor, evaluate, and revise the program.

A Nonpoint Source Management Program

Step 1: Define the current or potential problem.

Whether you are reacting to citizen complaints or planning ahead to prevent potential problems, you will need substantive, reliable data to define your community's current or future problems.

Enlist staff, interns, and/or volunteers to determine what information is needed, why it is important, and how to obtain it. Emphasize accuracy in collecting data and keep meticulous records on when, where, and how the data were collected.

Organize and store data for ease of use and accessibility, preferably in a computer database, complete with backup copies.

Your most important task is to first get to know your entire community to evaluate it for actual and potential nonpoint source pollution problems. All factors are important — from the people who live there to the community's physical position within its watershed.

Research and inventory your resource area and community to completely understand the community's strengths and weaknesses in relationship to the watershed. You'll find most of this information at your local soil and water conservation district or your state water quality authority. The U. S. Geological Survey, your regional planning commission, and local universities can also help. Table 2 lists further sources of various data.

Table 2.—Sources for natural resource assessment, inventories, and other data.

TYPE OF INFORMATION NEEDED	CONTACTS
Water Quality Data	U.S. Geological Survey, U.S. Environmental Protection Agency, U.S. Army Corps of Engineers, U S Fish and Wildlife Service; state water quality agencies, fish and game departments, departments of health; and tribal environmental offices
Land Use Data	U S. Department of Agriculture's Soil Conservation Service and Agricultural Stabilization and Conservation Service, U S. Forest Service, Bureau of Indian Affairs, U S Bureau of Reclamation, U.S Bureau of Land Management; state cooperative extension services, land office; tribal environmental or agricultural offices, local government offices such as city planners and county commissioners
Economic Data	County extension service, councils of government, economic research services, chambers of commerce; state department of commerce; tribal councils; real estate agents, private consultants
Demographic Data	Councils of governments, census reports, chambers of commerce, state statistics bureaus, almanacs

Source: Terrene Institute, Clean Water in Your Watershed: A Citizens Guide to Watershed Protection, 1993.

An important resource for community programs is section 319 of the Clean Water Act. This provision requires each state to assess and design a management program to control potential nonpoint source pollution problems. Contact the responsible state agency to pinpoint local problems and determine if resources have been allotted.

■ **Identify and map your watershed.** Include smaller watersheds within its jurisdiction and specific sites needing attention because of development or other special circumstances (see Fig. 3).

- Locate wetlands and other critical areas.
- Identify vegetation strips and other areas that can control pollution or urban runoff.
- Map your community's drainage pattern downstream and the location of groundwater aquifers and those used for drinking water (see Fig. 4).

■ **Identify the land uses within the watershed.** Map and calculate the number of acres within the watershed for each type of use. Check with your zoning commission first, and if you need more detail, go to

- land ownership and variance zoning records,
- site approvals,
- building permits, and even
- aerial photos.

You may not be able to obtain comprehensive, absolutely accurate and precise land use information — but the more details you gather now, the better your community will understand the land use in and around its watershed.

Categories can be defined broadly — residential, commercial, industrial, agricultural, and open space — and further subdivided as necessary.

For example, low-density residential has a different impact on water quality than high-density residential. Among industrial uses, a mining company may cause more nonpoint source pollution than a sugar processing plant. And forests differ from wetlands.

Some questions to ask:

- How much of the agriculture is dairy, soybeans, pasture, rangeland, or other?
- Are open spaces forest, meadow, or wetlands?

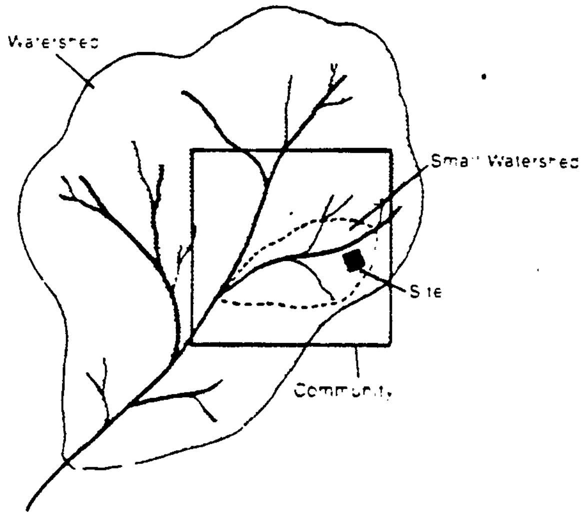

Figure 3.—Watersheds nest within each other; a site within a small watershed lies within the community and is part of the larger watershed.

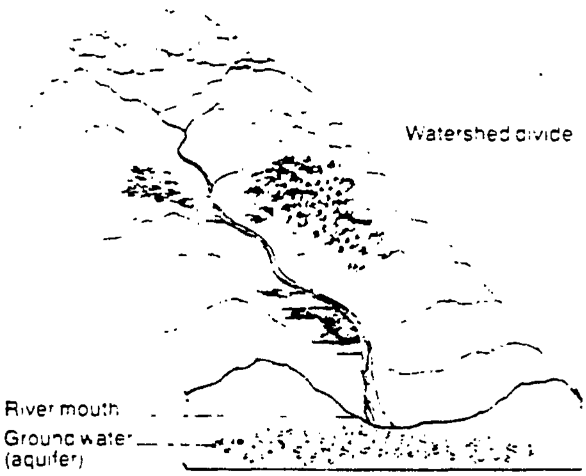

Figure 4.—A watershed graphically depicted. ***Source: Puget Sound Water Quality Authority.***

- How rapidly are the urban areas developing?
- How are urban areas divided for development (commercial, residential, industrial, other uses)?

■ **Investigate environmental factors.** Assess geology, topography, soil characteristics, vegetation, groundwater recharge areas, flood-prone sites, and hydrologic and biological characteristics.

Get help in determining what principles of geology, topography, soil, and vegetation are important in

R0011525

understanding water quality. Study USDA Soil Conservation Service (SCS) soil maps, Federal Emergency Management Agency (FEMA) floodplain maps, and U.S. Geological Survey topographic maps. You can find assistance locally from the USDA Extension Service, soil and water conservation district, and university and high school science departments.

■ **Determine current waterbody quality.** Obtain basic information on your waterbodies — pollutant concentrations, vegetative cover, and aquatic life — and determine if the state has monitored or designated them by classes. Water quality standards specify the concentrations of various pollutants allowable according to how the waterbody is used. Water quality designated uses include fishing, boating, water supply, priority wetlands or floodplains, and productive or open shellfish beds.

The state water quality agency should be able to provide current data, including documentation of any known water quality problems. If the state has information for your waterbody, a baseline database on its water quality may exist. If not, determine how to establish baseline data; perhaps your local college or university can help.

Investigate ongoing efforts to collect data, such as those obtained from citizen monitoring groups (see Chapter 5).

■ **Determine actual threats to surface and groundwater.** Is an industrial park being developed with the potential for construction runoff and, later, operational discharges from high traffic parking and maintenance lots? Is land use changing significantly — or at a rapid rate? Is there a known trouble spot?

Threats to groundwater include high water tables, uncapped abandoned wellheads, discharges associated with industrial development, and failing and inappropriately located septic systems.

■ **Identify other problem areas.** Identify specific sites that need attention, using land use maps to define areas of greatest imperviousness. Additional actions can include

- researching water quality and biological resources;
- walking along streams to visually assess excessive erosion, lack of riparian cover, water quality conditions, and physical stream conditions;
- identifying point sources by obtaining copies of National Pollutant Discharge Elimination System (NPDES) permits for discharge levels;
- obtaining data related to flood control or stormwater best management practices;
- obtaining information from local resource managers familiar with water resources; and
- checking sections 319 and 314 (Clean Lakes) assessments and 305(b) reports made by your state water quality agency on impaired waterbodies (EPA requires these reports from each state).

■ **Research the local economy.** An accurate picture of the local economy is important to make growth projections and to assess what funds might be available to protect water quality.

- Determine what portion of the watershed's population is rural and what portion is urban.
- Describe factors specific to the area, such as a large plant opening or a long-time employer closing.
- Assess the growth trends in the community and in the watershed. Development is a major cause of both short- and long-term nonpoint source pollution. Understanding population and growth trends also helps determine the areas most vulnerable to water quality deterioration.
- Assess income levels compared to national and regional averages and calculate the local tax base and revenues available from government grants and other sources. Current and projected tax revenues and other income sources will determine the amount of resources available to manage water quality.

■ **Evaluate industry and infrastructure.** Are industrial plants and infrastructure, such as sewage and stormwater systems, potential nonpoint source polluters? Assess age, state of environmental technology and practices, and other features. Seek guidance from experts in this assessment.

Assess the condition of roads, bridges, airports, marinas, and other parts of the transportation network.

- Note needed or ongoing repairs or new construction, and specify possible nonpoint source pollution hazards.
- Observe current road and ditch maintenance practices and note opportunities for improvement.

DETERMINING FINANCING STRATEGIES

Communities must answer several questions before selecting the best financing option for the situation:

- *Are funds sustainable? Will they last over the long term or are they only a short-term band-aid approach?*
- *Are funds easy to obtain? Is the application complicated? Does it require multiple approvals?*
- *Are funds difficult to administer? Will you need additional staff to track and prepare reports or assess and collect fees?*
- *Does a correlation exist between the funding and the problem? Will those who pay for the benefits receive them?*
- *Will the funding be used appropriately? Will it be a quick fix or will it have secondary benefits?*
- *Have legal restrictions been placed on the use of the funds?*

Step 2: Evaluate existing programs and resources.

■ **Identify existing ordinances and enforcement authorities.** Identify state and local laws that authorize government to proceed with control methods. For example, zoning ordinances might authorize setbacks or buffer strips, limit development on impervious areas, or establish erosion and sediment controls. Existing programs and authorities should be used — and strengthened — to benefit water quality.

Determine if your governmental unit has the legal authority to protect its floodplains and enforce ordinances using fines, permits, inspections, stop work orders, or other methods to make a nonpoint source program work. Communities often set fines for septic violations, for example.

■ **Investigate funding options.** Review funding options and select those that best suit your community. For an overview of traditional and innovative funding mechanisms, refer to EPA's "A State and Local Government Guide to Environmental Program Funding Alternatives" (Appendix B).

STORMWATER UTILITY FINANCING

The stormwater utility is a creative approach to funding that also addresses political and institutional questions. One of the most important benefits of a stormwater utility is that it can provide a steady stream of funds to develop, operate, and maintain a comprehensive stormwater management system. This, in turn, permits the development of integrated, long-range planning from one source.

Establishing a stormwater utility can be complicated. It requires collecting water and analyzing its quality, assembling land use and economic information, and establishing an equitable billing system. Moreover, establishing the utility can prove expensive because of costs for engineering, legal, and financial studies; new staff, and information management systems. Local officials must educate citizens to overcome public resistance to a new utility charge.

Many cities have such programs, including Bellevue, Washington, and Billings, Montana (see Appendix C for contact information).

Federal sources

- Federal Construction Grants Program — States provide seed money loans to local governments for water quality projects to be repaid from local fees or taxes. This program, however, is being gradually replaced by the State Revolving Loan Fund.
- State Revolving Loan Fund — Administered by a state agency, loans can be used to fund projects to control nonpoint pollution and be repaid from local revenue.
- EPA Clean Lakes Program Grants — Publicly owned lakes may qualify for federal grants available through state environmental agencies.
- Section 319, Clean Water Act — EPA provides grants to specific nonpoint source projects that demonstrate progress in controlling and abating nonpoint source pollution.

State and local sources

- Special use taxes — State or community levies, fees, or taxes on cigarettes, boat licenses, hotel rooms, or permits.

CALIFORNIA NONPOINT SOURCE STATE REVOLVING FUND LOANS

California was one of the first states to use state revolving funds for nonpoint source projects. Projects included demonstration projects, retention/detention basins, wetlands for stormwater treatment, and a variety of best management practices. Eligible programs also include training, public education, technology transfer, and development of ordinance and management practices.

Loans can cover 100 percent of the project cost. Repayment, which can take as long as 20 years, begins one year after the program begins. Interest rates are determined by the state's general obligation bond rate.

The loan request begins with an eight-page application and background information. The local government passes a resolution establishing repayment arrangements. The State Water Board places the project in the SRF Intended Use Plan approved through a public hearing process.

- BMP tax credits — Used for installing best management practices or similar controls.
- Drainage fees — Used to compensate for excessive runoff from a site.
- Bonds — Paid for by fees from developers or users.
- Special assessments — Levied through utility districts established by communities.

Step 3: Build program infrastructure.

■ **Identify all participants and determine their objectives.** Participants with a vested interest might include state and local agencies, governing bodies such as legislatures and city/county councils, local or national public environmental groups, trade associations, citizens, and business leaders. Establishing a working relationship with the lead state nonpoint source pollution agency is particularly important for information, resources, and support.

■ **Match the resources with the problems.** Determine what governmental units fit into your proposed plan and which methods of funding will work best. You may not need a staff as much as you need the ability to coordinate the available resources.

TYPES OF NONPOINT SOURCE PROGRAM FINANCING

A number of creative strategies for financing water quality programs have been implemented in recent years. Examples of the most successful are

- **Real estate transfer fee:** *Nantucket, Massachusetts, has funded a land purchase program through a 2 percent transfer fee on all property sold on the island. From the land bank's beginning in 1984 until June 1993, the fee has collected nearly $27 million.*
- **License fees:** *In Iowa, the Groundwater Protection Fund includes revenue from increases in pesticide dealer license fees. Chemical manufacturers are also assessed a 75 cent per ton tax on nitrogen-based fertilizers.*
- **Impact fees:** *In Florida local governments can assess development impact fees when issuing permits to cover infrastructure costs associated with new development.*
- **Sales tax:** *Washington increased state sales tax on cigarettes by 8 cents a pack to finance water pollution control programs. 50 percent for marine, 10 percent for nonpoint source, 10 percent for freshwater, 10 percent for groundwater, and 10 percent for discretionary programs.*
- **Stormwater utility fees:** *Some governments have created a stormwater utility service to achieve multijurisdictional solutions. Charges are based on the amount of a property owners' impervious surface and generally range from $1 to $4 a month.*
- **Environmental trusts:** *Minnesota established a trust with proceeds from the state lottery; half of the net proceeds will remain in the fund for five years.*
- **State revolving funds (SRF):** *These funds were authorized by the Water Quality Act of 1987 specifically to improve water quality. The SRF money is loaned to local governments, who repay it with revenue raised from local fees or taxes. SRF funds recycle a set amount of money to finance numerous projects over an extended period.*

Local governments. Identify the units within your community with the authority, knowledge, and resources to coordinate a nonpoint source control program — for example, departments of public works, public health, or the environment. In small communities, the conservation commission, planning board, or code enforcement office might have the authority. Other relevant governmental units might include regional planning commissions or the departments of park maintenance, road maintenance, waste disposal, or health.

Existing municipal programs can be modified to address urban runoff concerns. For example, a pretreatment inspection program for a publicly owned treatment works (POTW) can be expanded to look at runoff at each industrial facility. Similarly, fire and safety programs can be expanded to inspect runoff collection points. This coordination should be high priority since it can be much more cost effective to use existing program resources than to start a new program.

Find out what actions neighboring cities and counties, particularly in your watershed, are taking to control nonpoint source pollution. While you cannot control other jurisdictions, even though their actions might affect your water quality, you should be well informed of their problems and methods of controlling them.

State agencies. Determine agencies responsible for nonpoint source management, groundwater, water quality standards, floodplains, wetlands, coastal zone management, land conservation, land planning, endangered or threatened species; and scenic and wild river protection.

Find out what help the lead nonpoint source agency can offer and fit this resource into your control strategy. State nonpoint source coordinators may not be able to help with all problems — they have their own agendas, determined by state and federal priorities. With the diversity of funding sources for nonpoint source control, the community may need to enlist the support of several different agencies.

Federal resources. U.S. EPA and USDA can provide technical advice and materials. In addition, the Army Corps of Engineers can provide technical guidance, information, and permits. The U.S. Fish and Wildlife Service is a source for biological information, and the National Park Service and U.S. Geological Survey can provide watershed information.

VIRGINIA STORMWATER MANAGEMENT

Virginia's stormwater management ordinance is an example of state-enabling legislation (Code of the Commonwealth of Virginia: Title 10.1, Chapter 6, Article 1.1). Municipal ordinances can be established by reference to the state law or tailored to local needs. Specifically, the components of Virginia's legislation are

- *statement of purpose;*
- *definition of terms;*
- *authorization for local programs;*
- *guidelines for developing technical criteria and administrative procedures;*
- *statement on the status of state projects and lands;*
- *specification of the state's oversight responsibilities;*
- *authorization for establishing more stringent local requirements;*
- *procedures for submitting plans and approving and exempting land uses;*
- *authorization for collecting performance sureties, recovering administrative costs, and assessing service charges;*
- *description of the appeals process;*
- *specification of civil penalties and enforcement options;*
- *authorization for cooperation with federal and state agencies; and*
- *statement exempting the legislation from limiting the authority of other agencies.*

The Virginia legislation includes all minimum critical elements and provides the legal authority for local governments to adopt their own stormwater management ordinances. The Virginia law places the primary burden on new development by defining existing runoff levels and the corresponding level of water quality effects, erosion, and flooding as a point of reference. Local governments can require performance bonds or escrow accounts for development. If proper stormwater controls are not installed, resources will be available to complete required activities without burdening taxpayers.

Cognizant of EPA's municipal stormwater requirements, the Virginia law also authorizes local governments to cooperate with federal agencies.

Appendix C lists these and other information sources, including some interstate programs or compacts, such as the Chesapeake Bay Program, the Gulf of Mexico Program, EPA's National Estuary Program, FEMA's National Flood Insurance Program, and NOAA programs.

■ **Determine public attitudes and perceptions.** Alert citizens can be your best allies and informants. Use citizen complaints about water quality to spot current problems. Citizens often express such complaints in phone calls or letters to council members or the local newspaper editor. Look for newspaper articles on local lake or river problems.

If necessary, use a survey to assess public attitudes and perceptions regarding water quality issues and to determine the level of support and cooperation the program might elicit. Formal citizen monitoring projects are extremely successful components of many state and area water quality programs.

Step 4: Identify potential options.

The following chapters will help you think about your options for controlling urban runoff. Add to them the information you have garnered through your exploration of the agencies and organizations already working in the nonpoint source pollution arena. Your state nonpoint source coordinator can point to techniques that will work in your area.

- List each option to be considered for your plan (and your specific problems).
- For each option, list reasons favoring its use and those in opposition.
- Estimate the cost, including maintenance and longevity, for each option.

Step 5: Evaluate options and alternative strategies.

By now, you should have mechanisms in place to share information and thoughts about the process with many groups and individuals — both those knowledgeable in the field and interested citizens. At this point, you certainly need to know how your community is thinking. In addition to local stakeholders, make sure to include federal and state landowners and other groups such as the Department of Defense and the Conservation District.

Some jurisdictions use the consensus method, requiring support from all members, to make water policy decisions. Collecting information, airing viewpoints in group discussions, and analyzing the problems and solutions lead to acceptable compromises. The consensus process frequently produces a more creative and binding outcome, important when a community commits to a long-term project.

In exploring the merits of each option for controlling nonpoint source pollution, carefully consider the following issues:

- benefits and costs to the community;
- feasibility of implementation;
- public support and/or opposition;
- funding sources;
- staff to administer, enforce, and monitor;
- potential for problems and adverse reactions;
- technical support; and
- long-term maintenance ability.

■ **Models.** Computer models can be used as a design tool to project possible scenarios for pollution control programs, but they should be used with care and expertise. Modeling can be an expensive exercise that does not always relate to the real world. Models now in use include several versions of SWMM, a Storm-water Management Model developed by EPA, and its companion, RECEIV, and AGNPS, the Agricultural Nonpoint Source Model. Many states and regional governmental units are using GIS (Geographic Information System), another computerized tool, to predict erosion and other factors. Local governments can adapt GIS to their own needs.

Step 6: Set program goals.

After analyzing the information collected, determine the focus of your program. This step takes you back to the original premise: Does your community have an immediate problem, or has it simply recognized the wisdom of preventing future nonpoint source problems?

Thus, your program goals will be driven either by the need (1) to take immediate action, or (2) to achieve community support for a long-term preventive program. Of course, you may have to balance both concerns.

The basic steps in setting realistic goals, however, are based on setting priorities and matching them with available resources:

- Identify and list your community's most serious problems.
- List all other problems, both immediate and potential.
- Rank all problems for immediate, medium-range, and long-term action.
- Establish a series of objectives and a timeline for achieving each goal.

Visible progress is important to build community support. As you set program goals, try to identify at least one objective that can be accomplished quickly to assure your community that progress is being made.

Step 7: Select a final strategy.

The strategy selected should meet several objectives. At a minimum, it should

■ **Establish the legal, financial, and administrative framework for the nonpoint source management program.**

■ **Develop a comprehensive public education/participation program that ensures community buy-in to the nonpoint source management process.** Far from being an isolated element, public education, understanding, involvement, and support are vital elements in each stage of a project—from defining a problem, to developing workable solutions, to adjusting and monitoring the progress (see Fig. 5).

■ **Restrict construction/development in highly erodible areas — steep slopes and erodible soils.** Some slopes are not amenable to runoff control and some soils are impermeable — unable to absorb runoff. These areas should be identified and conventional ground-disturbing construction prohibited.

■ **Reproduce predevelopment hydrological conditions.** In addition to controlling runoff, a nonpoint source control program should, to the extent possible, diminish the hydrological changes brought about by development. Successful planning requires recognizing and addressing the serious implications of such changes.

■ **Reduce or remove pollutants.** Because control methods differ markedly in removal mechanisms, their performance in removing pollutants can vary significantly. Applying best management practices is one method of achieving goals (see Chapter 4 for discussion of BMPs). However, BMPs change with time and conditions and should be monitored and modified as necessary. Retrofitting includes constructing new BMPs or modifying existing practices in developed areas. Control practice effectiveness should constantly be reevaluated considering new technology, maintenance, repair, or upgrading needs.

■ **Use strategies appropriate to the watershed and the site.** Many control methods do not work because they are unsuited to the geographic area or site. Inappropriate methods can cause maintenance problems or nuisance conditions; in some cases, inappropriately located methods may not function at all. Decisionmakers need to understand a site's special characteristics. For example, plans may need to be modified after field reviews of the site's physical condition.

TARGETING

Implement a comprehensive management program by stages based on water quality problems — particularly when resources are limited. By ranking problems according to your specific area needs and targeting them for control, you can realize the greatest water quality benefits for resources expended. See Chapter 4 for discussion of best management control practices.

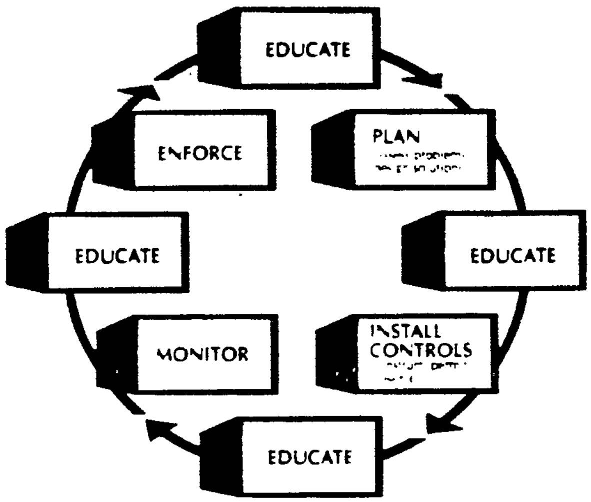

Figure 5.—Comprehensive public education/participation program. *Source: Terrene Institute, Clean Water in Your Watershed: A Citizens Guide to Watershed Protection, 1993.*

R0011531

■ **Protect and preserve vegetative treatment systems with nonpoint source benefits.** Buffers and natural systems filter out many pollutants in urban runoff before they become a problem. Communities should identify and preserve these natural vegetative treatment systems, because once they are altered, they cannot be easily replaced.

■ **Protect critical aquatic habitats and natural wetlands.** Determine the aquatic species most threatened by nonpoint source pollution in the watershed. What can be done to protect their habitats? Is the preferred technique compatible with other uses of the water? Should more than one control method be used?

■ **Be responsible for maintenance of controls.** Controls are effective only if regularly maintained, and maintenance costs can be significant. Over 20 years, structural BMPs can exceed their initial construction costs, passing on costs to future residents or taxpayers. While some effective BMPs require significant maintenance, others — particularly some nonstructural BMPs — are not expensive to maintain. Anticipate future maintenance needs and consider the cost factor compared to other needs and resources.

■ **Positively affect the environment.** Control methods significantly affect the natural environment and adjacent community, either positively or negatively. Small investments in design, landscaping, and maintenance can make a control method an attractive, or at least an unobtrusive, feature in a community. Without such effort, controls can become unsightly nuisances. If that occurs, public support for nonpoint source control is jeopardized.

Step 8: Develop a work plan.

After defining the goals and the strategy, develop a specific work plan. The work plan should express the community's goals in definitive terms, yet be broad and flexible in their execution. It should ultimately be a practical, easy-to-use guide to decisionmaking over the long term.

The work plan should also include specific measurable objectives to meet community goals (e.g., nitrogen concentration will drop 10 percent by 2000 from 1990 levels) and fit into the existing infrastructure. The plan should complement existing plans, translating local goals, priorities, and resources into action.

Consider other plans in developing a work plan for your community:

- comprehensive land use plan
- stormwater management plan
- roadway/transportation plan
- zoning map
- water and sewer network
- open space conservation plan
- preservation of critical areas

Also consider

- legal authorities
- local/state agencies
- existing land use patterns and zoning

The following is an outline for developing a nonpoint source pollution control work plan:

I. Formulate goals, objectives, assumptions.

II. Describe the size and scope of plan.

III. Identify legal authority.

IV. List the responsible agency or agencies.

V. Describe staff and training needs.

VI. Describe existing conditions and resources, using data relating to the community, including water quality problems and opportunities for improvement.

VII. Describe demand pattern for water. Analyze how water use patterns relate to demographic and economic groups; measure impact on residents, nonresidents, and tourists; assess impact of fees and other charges on demand patterns; analyze why existing opportunities (i.e., recreation, fishing) are not being used.

VIII. Provide needs analysis. Analyze supply and demand relationship; develop program standards; describe water quality needs, state need for a plan/program, and local government's ability to meet program needs.

IX. Analyze present policies and programs as they relate to program goals and outcomes. Recommend and justify the option selected.

X. Appendix. Include background studies (pertinent information collected), data and methods, bibliography (sources), and acknowledgments and credits.

Step 9. Adopt and implement the work plan.

The work plan must be adopted by the community's governing body. Information gained in developing the work plan should be used to further the effort to educate and involve the public and community decision-makers. Whether a public referendum is required to pass the plan and financing mechanism or a committee or city council will make the final decision, inevitable differences of opinion can be resolved through a continued program of public information, education, and political savvy.

■ **Implementation.** After local adoption, follow an implementation plan that describes the necessary actions and who is responsible. Schedule actions by time period, group, and responsible agency. Relate costs to the general budget. Describe needs for training, legislation, public participation, and state approval process, if necessary.

■ **Training.** A successful water quality program requires a high degree of staff involvement. A program must have technical staff to develop specific controls, administrative staff to oversee the project, clerical staff to maintain records, and volunteers to carry out citizen education and monitoring functions. Staff and volunteers should help develop the plan and begin training soon after its adoption.

Workshops sponsored by federal, state, regional, and county agencies and by private environmental groups are good ways to gain expertise. In addition, local university extension curricula may offer courses that relate to the program. On-the-job training can also be effective if supervised by professional water quality specialists (see Appendix C).

Step 10: Monitor, evaluate, and revise the program.

While some revisions will occur early in the planning process, evaluation and modification should continue indefinitely. Incorporate a monitoring and evaluation plan into the work plan and see that staff or volunteer programs are in place to carry out this ongoing process.

To make sure the control method is working, develop a monitoring program that relates results to initial goals set early in the planning process. The monitoring program must have clear goals, such as

- evaluating BMP efficiency;
- specifying problems with receiving water quality;
- identifying priority sources (for example, gas stations or malfunctioning septics);
- validating results against other studies or models; and
- complying with applicable regulations, including local requirements.

Compliance may be a good area in which to involve citizens. Citizens have made valuable contributions to local monitoring programs. However, volunteer monitors must be well trained, supervised, and motivated to ensure that the data is accurate and useful. The local government should carefully supervise program activities and conduct the analyses (see Chapter 5).

A monitoring program should consider, at a minimum, the following parameters:

- beneficial uses that need protection;
- expected impacts on water resources and assorted habitat; and
- an approach to measuring impacts.

Prepare an annual report of your progress for the county or city council and other governing bodies. This serves not only as a program evaluation tool but also keeps the community informed. In addition, the state government may be able to include the report as part of its annual report required by the Clean Water Act.

Chapter 3

Planning to Prevent Urban Runoff

A successful nonpoint source management plan begins by identifying general concepts and goals in the total community development or comprehensive plan. Specific controls (see Chapter 4) to prevent pollution should be part of each site plan.

Damage that occurs as part of the development process is, at worst, irreparable and, at best, costly to clean up. Therefore, urban runoff pollution prevention should be part of the overall plans for roads, parks, utilities, and other public facilities as well as for each site.

Such plans should consider the larger drainage basin, the immediate watershed, the municipality, and, finally, the specific site. Water quality plans must work in harmony with local legislation and programs of other political jurisdictions.

Developing a Land Use Plan

Land use planning begins with the local government, but it must also adhere to state mandates and comprehensive planning. A good nonpoint source program coordinates federal and state laws with local programs in a plan that improves and protects water quality according to community needs. Local government should provide the broad legal authority to develop comprehensive plans and programs.

Land use planning can prevent pollution problems by protecting water quality, open spaces, stream valleys, and floodplains. At the same time, planning should support local economic needs. Through comprehensive planning, communities can address water quality issues by setting development goals — for environmental quality, a sustainable economy, viable commercial areas, population density, housing patterns, recreational facilities, tourism, and property values — that work together to ensure the overall "quality of life."

Land use planning reduces pollutant loads in two ways:

- by controlling the type, size, and location of development in a given area, and
- by reducing pollution generated at specific levels of development.

While comprehensive planning provides general guidance in managing nonpoint source pollution, specific practices are put in place through zoning laws that regulate development.

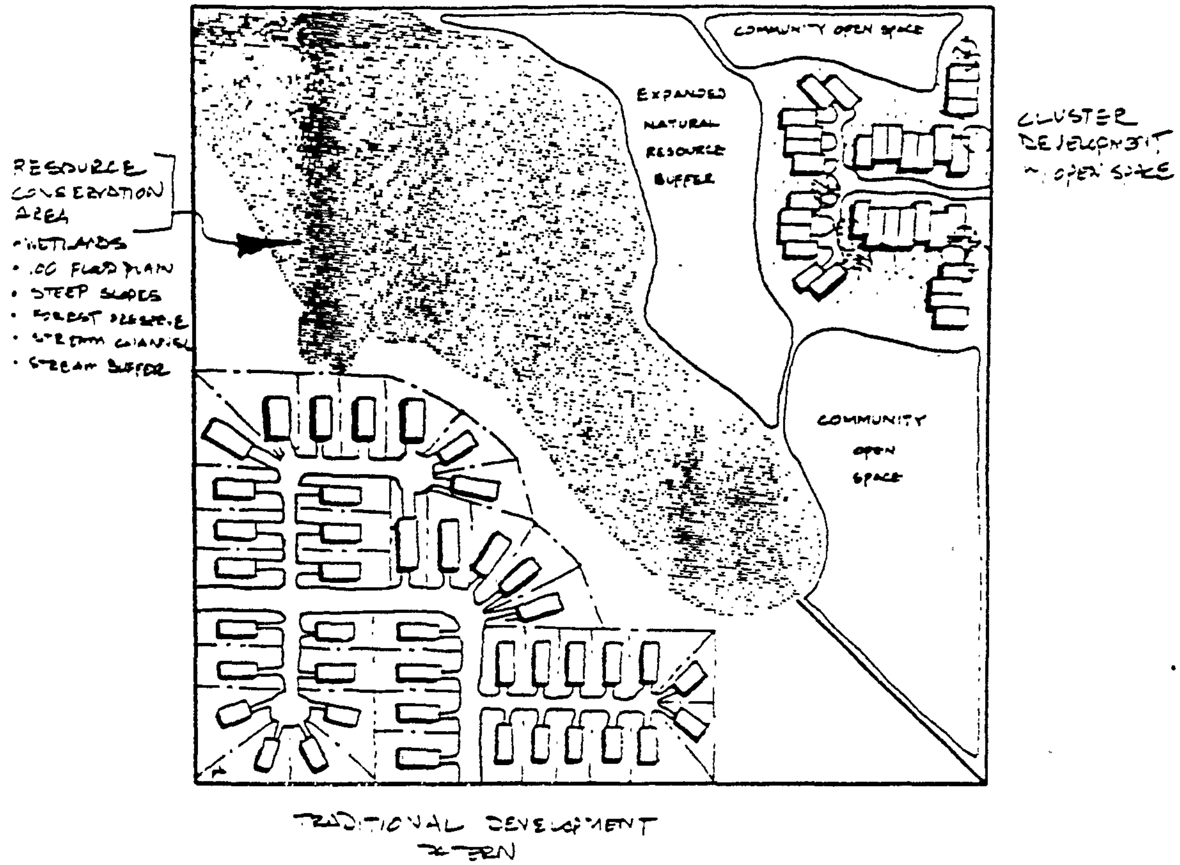

Figure 6.—Cluster versus traditional development preserves open space and reduces land disturbances.
Source: Metropolitan Washington Council of Governments, 1993.

■ **Zoning process.** Zoning specifies the density and type of land use that can occur in a given area. It is the working arm of a comprehensive plan that controls overall local development and considers water quality and other environmental goals along with a myriad of community concerns. Zoning ordinances apply only to uses that begin after the ordinance is enacted, and therefore affect only future practices.

Because zoning ordinances also regulate authorized uses (e.g., building, lot sizes, designs), they can be structured to control nonpoint source pollution. This control is particularly relevant on highly erodible steep slopes and shores or in high-density areas where developers must provide adequate drainage systems for their projects.

Several types of zoning apply to water quality issues:

Cluster development. Clustering preserves the existing topography and provides the community with more open green space by concentrating residential development on a limited portion of the site. This leaves substantial area for amenities such as playgrounds, parks, and woods (see Fig. 6).

Preserving open space and the existing tree canopy reduces impervious surfaces and the resulting runoff. Further, following the land's natural contours reduces disturbances that cause erosion, improves aesthetics, and preserves sensitive habitats.

Keeping the same population density, developers can save on necessary facilities such as roads and utility lines, since cluster development reduces the lengths of paved roadways and utilities needed.

Cluster development minimizes the need to convert agricultural land to residential use. It also allows development to match actual site capacity. Homeowners and the public can enjoy many of the amenities of rural living within an urban environment. Cluster development also helps maintain property values, one of zoning's basic goals.

R0011536

Planned unit development (PUDs). Through comprehensive development planning, PUDs provide a mix of zoning classifications including compatible commercial, residential, and even light industrial development. PUDs, which sometimes include clustered development, range in size from a few acres to over 1,000.

PUDs harmoniously blend varying uses to create an attractive, interrelated unit that preserves both property values and aesthetics. As with cluster development, a PUD's goal is to maintain density while maximizing open space. The ideal PUD locates residences and offices within walking distance of each other, dramatically reducing traffic.

A PUD's main water quality benefit is large-scale urban runoff management planning. Local governments control PUDs through negotiations between the developer, the public, and the public review authority. PUDs must maintain open space to facilitate stormwater drainage and sometimes require developers to provide special structures to handle runoff.

Incentive or bonus zoning. This method is used to promote cluster development. It permits the developer higher density than normal in return for maximizing open and/or public use space or other amenities.

Downzoning. Downzoning changes an established zone to a lower density level or less intense use. Typically, industrial zoning permits the most intense land use, followed by light industrial, commercial, and residential.

Downzoning is used on strips of land adjacent to waterways to provide a buffer between industrial sites and the streambank or on a whole area surrounding a waterbody to reverse or prevent pollution.

Phase-in zoning. Phase-in zoning is used when present development is incompatible with water quality goals but abrupt change would be too disruptive to the economy and the community. For example, to protect a lake surrounded by heavy industrial development, the community might close and decontaminate plants when their useful life is finished, rather than allowing them to be sold or leased to another industry, and prohibit new plants from opening.

Large-lot zoning. Large-lot zoning applies to large residential developments, generally 5 to 20 acres. Regulations call for designs that take advantage of common management to achieve water quality goals. These may include reducing the quantity and impact of septic system leachate to a water supply, building stormwater detention basins, or preserving open land to facilitate aquifer recharge.

Conditional zoning. Conditional zoning can be used in a standard zone or where zones are not clearly delineated. It carefully monitors and limits potentially harmful activities by permitting certain activities only under special conditions. For example, a conditional zoning might allow multiunit apartments in a single-family housing zone only if no septic tanks were used.

Floating zone. A floating zone is defined by characteristics rather than geographical location. The proposed use must be compatible with the surrounding uses and conform to the zone's expressed purposes.

Under a floating zone, for example, multifamily dwellings that conform to specific code requirements regarding septic tanks, grading, and open space preservation could be acceptable in an area zoned for single-family dwellings. Alternatively, a floating zone might restrict certain development in a wetland or around a well or aquifer recharge zone. A developer would need to show that the project does not fall within the area subject to floating zones or take adequate steps to protect water quality within the zone.

Overlay zoning. An overlay zone is a mapped district that places restrictions or requirements in addition to those of the underlying zone. Overlay zones are used to meet a special public interest that is not met by the existing zone or by rezoning. For example, these zones can protect specific water sources such as ponds, wells, or wetlands lying within residential, commercial, or industrial zones. In Figure 7, the stream valley corridor buffer overlay zones provide special protection for water resources located within the existing zones, reducing the impact of uses on water and natural habitat.

In another example, Maryland counties use overlay zoning within the Chesapeake Bay Critical Area — a 1,000-foot land buffer surrounding the tidal portion of Maryland's bay tributaries — to protect land and water resources. The critical area overlay zone is designed to foster more sensitive development activity for shoreline areas while minimizing the adverse impacts of develop-

R0011537

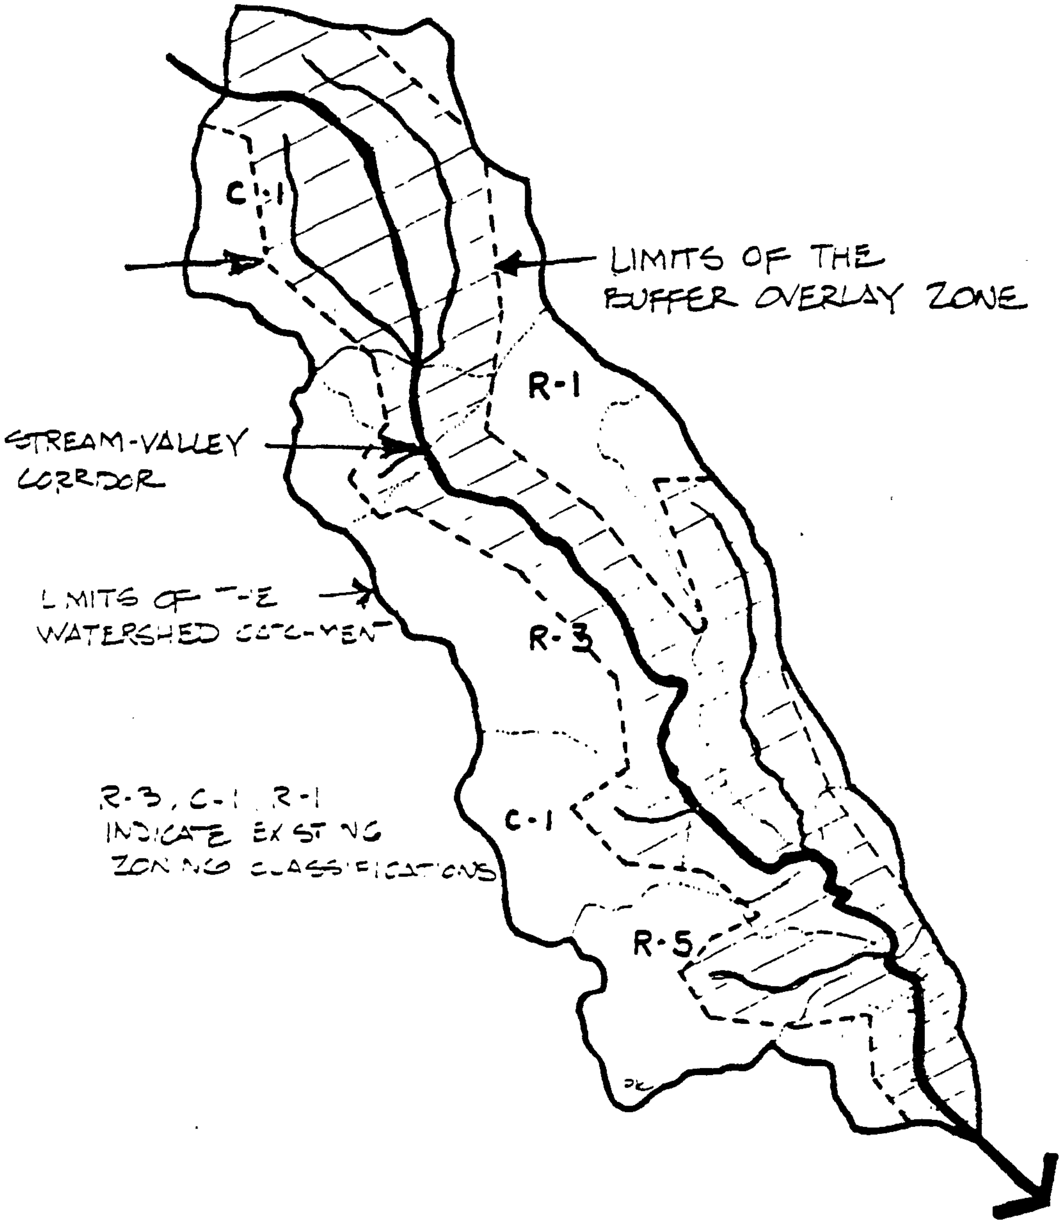

Figure 7.— Overlay zoning adds another measure of protection to critical resources. ***Source: Metropolitan Washington Council of Governments, 1993.***

ment on water quality and natural habitats. Zones are known as intensely developed areas (IDAs), limited development areas (LDAs), and resource conservation areas (RCAs).

Floodplain zoning. Building in floodplains — areas subject to periodic inundation by runoff — is considered unsafe. Except for roads or other transportation facilities, development is generally restricted. Local governments or FEMA can provide floodplain maps.

Open space preservation. This zoning protects community open spaces by creating public parks or undeveloped strips of land adjacent to waterbodies. This important zoning provides open space to allow urban runoff to seep into the ground and recharge the water table. Open space preservation also protects critical aquatic habitats such as wetlands, reduces flooding, and enhances aesthetics.

Not all open space uses benefit water quality. A zoo, for example, requires high maintenance to dispose of manure, care for parking lots, and clean up litter. In addition, open space should be used differently depending on its location within the watershed.

Aesthetic zoning. Aesthetic zoning places design restrictions on new or historic buildings, preventing development or renovation from blighting the community or destroying its style or scale continuity. Aesthetic zoning can also protect water quality by requiring open space or limiting development size and the pressure it places on the watershed. For example, restrictions can protect attractive shores and swimming, boating, fishing, and other recreational uses.

Performance zoning. Performance zoning limits development to the resources of the specific property. While the overall intensity of use meets zoning requirements, the gross density can vary, depending on the property's characteristics. Performance zoning can set a maximum use intensity (density factor) on the buildable portion of the site. This avoids many small zoning districts providing different levels of protection. The environment is protected from disturbance of unstable or rare resources, but flexibility is allowed in less sensitive areas.

In using zoning as part of an environmental program, planners should consider all options to ensure that the zoning solution is appropriate and feasible. For example, downzoning a heavily developed area to protect a waterbody might not be economically feasible, but incentive zoning could be applied to future development or an overlay zone used to augment existing zoning.

Zoning regulations promote legal issues and challenges. Courts often strike down unnecessarily restrictive or discriminatory ordinances. In addition, zoning is a political issue, often requiring a referendum or other formal adoption mechanism. Therefore, zoning plans must be carefully structured to address a variety of needs and constituencies.

■ **Subdivision review.** Land use is regulated by many zoning categories. However, before separately owned parcels of land can actually be developed, they are subject to subdivision review.

The subdivision review process includes several stages in which various government entities and agencies review development plans to ensure that the developer has met all the standards and requirements placed on the land and has obtained all necessary permits and approvals.

ZONING + SITE PLAN REVIEW

A small, primarily rural Maryland community is devising a plan to protect the water supply of its rapidly growing town.

Subdivision regulations have been amended to give the town council authority to regulate the density of development based on anticipated demands and effects on the water supply and quality. Aquifer recharge areas have been identified and an overlay zoning district established.

A site plan for a development must be prepared by a professional hydrogeologist for review and approval by the town council and the planning commission. The plan must delineate the development within the recharge area and project water demand and its effect on aquifer recharge. If the council determines that the development does not lie within any recharge area, the development plan may proceed through normal processing.

The council or planning commission may reject any plans that

- *impose adverse effects upon the aquifer recharge rate or water quality (the developer may resubmit modified plans),*
- *would create a water demand on the site greater than the groundwater recharge rate, or*
- *cause more than a 10 percent decrease in a site's recharge rate (immediate rejection).*

Other economic and water quality considerations may also be grounds for rejection.

These requirements include building lots, streets, sewers, grading, and relationships to other properties and the comprehensive plan. The review can also include runoff control, drainage, and erosion control requirements, and provisions for parks, buffer areas, open spaces, and maintenance responsibility. These features are often phased in as the project progresses, with completion required by the time the lots are sold.

Before subdivision review was part of the normal planning process, developers often sold lots without such basic design features as roads, parks, and open spaces. The community had to pay for further improvements. Reviews guarantee that developers meet requirements before construction can begin or proceed.

Subdivision review is a good time to review the design of permanent urban runoff management structures. This allows the entire parcel to be reviewed as a whole rather than in small separate parcels that may not individually require comprehensive treatment.

Site plan review is a stage in the subdivision process. It enables government to review the technical aspects of a proposed development. While not always required, site plan review ensures that new development or expanding current uses comply with zoning, environmental, health, and safety requirements. A site plan shows the proposed development in context and provides a good picture of how it will fit in with the surrounding areas. It shows existing topography, natural features, wetlands, and runoff facilities. The detailed project site includes internal roads and parking areas, building placement, recreational areas, and landscaping.

■ **Land acquisition.** To protect water quality and the environment, jurisdictions can purchase property uniquely valuable to the community. Land purchases protect wells, wetlands, and strips bordering waterways. Publicly owned land is used for parks and recreation and preserved as open space to recharge the groundwater.

While acquiring land to gain control of critical areas can be an effective technique, it is costly. Acquiring contiguous pieces of property often takes many years. Converting private lands to public ownership also removes them from the tax rolls — and requires ongoing management and maintenance expense.

In addition, land purchase is a divisive issue because of the cost and the frequent resistance to taking land out of development. Communities should prioritize potential land purchases and carefully evaluate each parcel's importance, such as ability to recharge groundwater, existing land uses, and development trends. Communities can then plan to fully purchase lands most critical to preserving water quality, and use partial purchase arrangements for less critical land.

Several types of purchase arrangements and financing mechanisms are possible.

Fee simple interest. The most expensive type of acquisition is outright purchase, where the jurisdiction gains full or "fee simple" title and the maximum measure of control over land uses. The community can benefit by establishing parks, recreation facilities, or a conservation district.

WISCONSIN STEWARDSHIP PROGRAM

The Stewardship Program, created in 1989, is part of Wisconsin's century-old history of acquiring and protecting environmentally sensitive lands.

Through the program's streambank protection category, the Wisconsin Department of Natural Resources (DNR) or nonprofit conservation organizations protect water quality and fisheries from urban and rural runoff through land purchases and easements along streams.

In 1992, for example, the department purchased a 43-acre corridor easement for $39,500. The corridor included a 7,000-foot frontage along the Milwaukee River and 27 acres of wetland and lowland woods. The easement protects water quality and fish habitat and assures public access to the shoreline.

While landowner resistance has resulted in only a modest number of easements, DNR has reported a renewed interest in the program, with some 40 landowners giving permission for easement appraisals. The addition of a fee acquisition authority by the legislature should also enhance landowner acceptance.

Source: Wisconsin Stewardship Program Progress Report, April 1993.

Partial interests. More limited interests can be tailored to specific public objectives, including environmental protection. Partial interests generally take several forms:

- *Conservation easements and restrictions.* The easement holder can prohibit actions on the property, such as restricting certain high-density development or prohibiting hazardous materials or septic tank systems. Easements apply to all subsequent landowners for the full term, which might be specified, or in perpetuity. Property owners gain benefits because easements take land off the tax roles or assess it at sharply reduced levels.

Conservation easements — such as the Maryland Environmental Trust, Eastern Shore Conservancy, Western Maryland Conservancy, and Wisconsin's Stewardship Program — are becoming more prevalent.

- *Purchase of development rights.* In this case, the right to develop the property is purchased, while ownership remains with the landowner. The landowner cannot develop the property, based on the restrictions in the deed.

- *Restrictive covenants.* A restrictive covenant attaches to the property and applies to future landowners. However, unlike an easement in which a local government can enforce restrictions, a restrictive covenant can be enforced only by other property owners similarly restricted.

  To protect water quality, a local planning board might require a restrictive covenant limiting paved surfaces as a condition to granting site plan approval for a proposed subdivision. Or, a government might purchase a parcel outright, place restrictive covenants on the title limiting future development rights, and sell the deed-restricted property back to a private party. Such restrictions can be used to prohibit specific land uses, densities, or activities that pose a threat to water quality.

While partial interests do not provide governments with total control, they have certain advantages:

- the community is not burdened with maintaining the property;

- the property remains on the tax rolls; and

- lower costs allow the community to obtain interests in more parcels.

Financing. Since full or partial purchase of land is costly, the community should carefully consider the alternatives. A number of strategies can be used to finance purchases, including those listed in Chapter 2.

- *Donations or "bargain sales."* Motivate individuals by allowing a charity or tax deduction to donate or take a loss on property sold to the local government.

FINANCING LAND ACQUISITION

Through a land bank program, Nantucket Island — off the coast of Massachusetts — has acquired 1,105 acres from purchase or gift as of June 1993. This represents 3.5 percent of the island's total acreage (see page 17, Nonpoint Source Program Financing). The land bank has targeted two coastal preserves with a large amount of shore frontage for acquisition as open space public lands. The program, funded by a 2 percent real estate transfer fee, receives favorable support from residents.

- *Purchase by conservation groups.* Encourage private conservation groups to purchase the land.

- *Increased water and sewer fees.* Dedicate "user fees" added to utility bills to land purchase.

- *Increased local property or property transfer taxes.* Levy fees on real estate transfers and trust funds set up to acquire land with the proceeds, placing the burden on developers.

- *Municipal bonds.* Issue bonds to raise money for land acquisition, depending on state law and federal limitations

Protecting Critical Resources

■ **Floodplains.** Floodplains provide flood storage, runoff infiltration, vegetative filters, and protection for wildlife and streambanks. Naturally vegetated floodplains are a valuable habitat for plants and wildlife and allow streams to find their natural courses.

Generally, state and local governments work through FEMA's National Flood Insurance Program to preserve national floodplains. States have passed enabling legislation providing various levels of assistance and coordination to local governments, which adopt measures to reduce or eliminate flood damage in return for flood insurance. When enforced, these measures prevent and/or limit development in floodplains, allowing them to continue to provide flood storage, runoff infiltration, and erosion protection.

R0011541

NATIONAL FLOOD INSURANCE PROGRAM

NFIP was created by Congress in 1968 to reduce the loss of life and property and the cost of rising disaster relief from flooding. These goals are achieved by

- *requiring that new and substantially improved buildings be constructed to resist flood damages;*
- *guiding future development away from flood hazard areas; and*
- *transferring the costs of flood losses from the taxpayer to floodplain property owners through flood insurance premiums.*

The courts have consistently upheld the land use management criteria of the NFIP and over 18,000 communities participate in the program.

The floodway, which maintains the flood-carrying capacity of rivers and streams, is the most important provision of the NFIP. The floodway is the area of the watercourse plus adjacent floodplain land that must be preserved to allow the base flood (100-year flood) discharge without increasing flood heights more than a designated amount. Communities must prohibit any development within a floodway that would increase flood heights.

A floodway — a de facto preservation tool — also protects critical riparian habitats, minimizes degradation of surface water quality, and provides for groundwater recharge.

A community that preserves and manages its floodplains also preserves a natural control for nonpoint source pollution and a no-cost alternative to detention basins and other structural controls (see Chapter 4). As an added benefit, homeowners may also enjoy lower flood insurance rates.

■ **Wetlands.** Once considered wastelands, wetlands are now highly valued for a multitude of benefits. In some cases, wetlands are even being constructed to control nonpoint source runoff. Wetlands support plants that remove suspended sediment and dissolved nutrients from runoff and provide a habitat for a variety of wildlife. They also store excess runoff and absorb destructive waves that can erode shorelines. Section 404 of the Clean Water Act protects the nation's wetlands by requiring permits to fill and dredge them.

Although wetland protection and use are critical to any comprehensive plan to reduce nonpoint source pollution, using wetlands to filter pollutants has drawbacks. Wetlands can easily become sinks, allowing trapped toxic pollutants to seep into groundwater. A nonpoint source management plan should, therefore, consider wetlands in the context of the entire drainage system.

■ **Stream buffers.** These undeveloped zones at the edge of waterbodies preserve vegetation to reduce erosion and trap sediment, nutrients, and other pollutants before they reach the water. Buffers can also shade streams to reduce temperature, improving fish and wildlife habitat. Local jurisdictions usually pass laws to establish these buffers.

■ **Stabilized hillsides and steep slopes.** Vegetative or structural controls secure banks by retaining soil, holding back runoff, and maximizing infiltration. To protect slopes, local governments have purchased the land, used a site plan review process, or passed special ordinances.

■ **Aquifers or wellheads.** A valuable water resource, these structures require protection to preserve water quality. Sources as diverse as toxic wastes, manure, pesticides, road salt, and oil can cause contamination.

EPA has estimated, for example, that 20 percent of the one million underground petroleum storage tanks may be leaking and could contaminate water supplies. Since municipal pumping systems draw substances discharged toward the well, areas surrounding wells are particularly vulnerable. Toxins can easily enter an aquifer through an open, unsealed wellhead, making wellheads a chief source of groundwater contamination. Therefore, many county health departments are identifying abandoned wellheads without adequate caps or seals.

Many jurisdictions protect areas around wells, ranging from a few hundred feet to several miles, with special ordinances, permits, and prohibitions against specific types of development and activities. In some cases, communities have purchased the land surrounding a well to assure protection. The Wellhead Protection Program, part of the 1986 Safe Drinking Water Act Amendments, provides technical assistance to communities to protect wellheads.

Intensely Developed Area

Characteristics

- Dense residential, institutional, commercial or industrial uses
- 4 or more dwelling units per acre
- Public sewer and water serving 3 or more housing units per acre

Applicable Criteria

- Reduce pollutant loadings by at least 10% from predevelopment loads
- Reduce nonpoint impacts to streams and tidal waters from redevelopment
- Protect remaining wildlife and fish habitats

Limited Development Area

Characteristics

- 1 dwelling unit per 5 acres up to 4 per acre
- Areas with public sewer or water or both
- Mixture of land usage—not dominated by agriculture, wetlands, forest, or open space

Applicable Criteria

- Replace cleared forest land on an acre for acre basis
- Restrict removal of existing forest land to 20% when development occurs
- Restrict impervious areas to 15% of the land area being developed
- Encourage clustering of dwelling units to conserve natural habitats

Resource Conservation Area

Characteristics

- Housing density of less than 1 dwelling unit per five acres
- No public sewer or water
- Primarily open fields, wetlands, forest, and agriculture

Applicable Criteria

- Limit residential development to an overall density not to exceed 1 dwelling unit per 20 acres
- Encourage agriculture and forestry

Successful Land Use Programs

While land use controls vary according to location, a number of communities have successfully used these strategies to curtail nonpoint source pollution.

As mentioned earlier in this chapter, Maryland's Chesapeake Bay Critical Areas Program is one way local communities can implement state programs designed to protect water quality. The Critical Areas Commission, which established criteria to classify and protect lands in a 1,000-foot strip surrounding the tidal portions of the bay's tributaries, requires jurisdictions to write and adopt local programs. They must include both state and local comprehensive plan requirements for zoning, site planning, subdivision review, and other activities. The Critical Areas program addresses development, resource use, and resource protection.

Local jurisdictions must assign their lands in the critical area to one of the following development categories (see Fig. 8):

- intensely developed — four or more dwelling units per acre;
- limited development — one to four dwelling units per 5 acres; or
- resource conservation — less than one dwelling unit per 5 acres.

These definitions also include other characteristics, such as land usage and sewerage. Development requirements have been specified for all three categories. For example, only 5 percent of the land in a limited development or resource conservation area may be reclassified to more intense use.

Dade County, Florida, has developed a Wellfield Protection Ordinance that prohibits underground storage tanks and other potentially polluting activities in the recharge zone of public wells. The ordinance is based on a mathematical groundwater flow model that predicts the speed that groundwater travels in recharge areas. In Massachusetts, the Cape Cod

R0011543

Planning and Economic Development Commission is using a similar principle to protect its well fields.

In 1988, Washington state developed a Local Planning and Management of Nonpoint Source Pollution administrative code (chapter 400-12) that outlines procedures for state watershed management. The state code was originally developed by the Puget Sound Water Quality Authority that monitors an environmentally sensitive area encompassing 12 watersheds.

The Washington program stipulates local watershed plan development, to be funded primarily through grants from the state Department of Ecology. Under the regulation, a watershed management committee prepares plans and addresses all major watershed nonpoint sources. Unlike traditional citizen advisory committees, these local bodies have significant decisionmaking responsibility. They operate under the general aegis of a lead agency — usually a county — responsible for convening the committee and overseeing plan development. The planning committee, government entities affected by the plan, and the Department of Ecology must approve each plan.

Chapter 4

Urban Nonpoint Source Control Methods

Construction and development activities can be one of the worst sources of urban nonpoint source pollution. Improper construction erosion and sediment control can cause large volumes of sediment to impair sewers, streams, lakes, and stormwater control devices. When this excessive sediment enters small streams, wetlands, and lakes, it can damage or destroy wildlife habitat by smothering stream and lake bottoms, filling impoundments with sediment, increasing dredging costs, and impeding navigation.

After construction is complete, many changes in land use and site drainage characteristics can cause a host of additional problems. Changes include increased impervious surfaces and pollutant loadings, as well as different runoff patterns and increased volumes and temperature. Cold water fisheries may be destroyed, streambank erosion and flooding may be increased, and beneficial uses of waterbodies — such as swimming, fishing, and boating — may be impaired. To avoid or reduce these problems, a dual focus on proper construction site erosion and sediment control and postdevelopment runoff control is necessary.

A number of control practices can be used to reduce the impact of development or redevelopment. Local conditions will determine what practices are appropriate for a given situation. In most cases, standard erosion and sediment control practices can be used, although they may need to be adjusted for areas with steep slopes, intense rainfall, or highly erosive soils. Management strategies for postconstruction runoff controls are generally site specific — they must be specifically designed to fit the individual development site and local conditions. Often a combination of techniques offers the most protection.

Practices used to control sediment and erosion during construction, when the soil is not stabilized, are different from practices used for long-term runoff control after construction. During the site development process — before construction begins — an erosion and sediment control plan should be developed for each activity during construction. This plan should be developed in conjunction with a stormwater management plan to address the runoff from the newly completed project or development.

Tools of the trade are usually referred to as best management practices (BMPs). The term BMP is used to describe the most effective practice or combination of practices to control runoff and nonpoint source pollution. A BMP may be a system that reduces the pollutants that enter urban runoff or a method that reduces the amount of pollutants in the runoff before it enters a waterbody. BMPs are generally grouped into categories — structural or nonstructural — depending on the operating principle or physical mechanism used to reduce nonpoint source pollution. Nonstructural controls decrease erosion potential, while structural controls prevent and mitigate erosion and sediment movement.

Nonstructural BMPs are a cost-effective way to manage stormwater runoff and prevent nonpoint source pollution. These controls take advantage of the land's natural features and use, relying on planning, design, maintenance, education, economic incentives, and even regulation to prevent runoff contamination (see Chapter 3).

A variety of urban BMPs can be used to mitigate some of the adverse impacts caused by development. More detailed information on selecting and using BMPs can be found in the resources listed in Appendix B.

Preconstruction Planning

■ **Basic development practices.** Land use strategies for local government to plan an overall nonpoint source control program were discussed in Chapter 3. But requirements for developers before construction begins, particularly at the site plan review stage, can help prevent problems from occurring on individual sites. A developer can be required to submit a detailed plan for managing runoff and for returning the site to a predetermined hydrological condition after completing construction.

Since few control methods can handle the large loads of sediment that erode during construction, a combination of control systems should be planned for and put in place. In some cases, the measures used during construction can be modified to control runoff over the long term.

Use the following check list, singly or in combinations, to develop an urban runoff management plan.

- Respect contours and natural features of the landscape — for example, avoid stream valleys and steep slopes.
- Use downzoning to restrain development.
- Specify minimum lot sizes.
- Limit development by soil type or proximity to waterbody.
- Restrict or prohibit development in sensitive areas identified in the comprehensive plan.
- Limit density of development.
- Limit percentage of lot that can be disturbed.
- Limit percent of impervious cover.
- Preserve natural 100-year floodplain (area that will receive a flood at least once within 100 years); allow no modification of the natural floodplain; and ensure that development is consistent with the comprehensive plan.
- Prohibit clearing or grading on steep slopes (more than 25 percent recommended) and limit road grades (equal to or less than 7 percent recommended).
- Prohibit development in nontidal wetlands and require a buffer zone for these areas.
- Retain upland and riparian trees as a certain percentage of predevelopment tree cover.
- Require waterway disturbance permits for structures such as roads and utilities so they do not restrict fish migration or riparian areas.
- Reserve a minimum percent of open space on each new development site.
- Designate the percent of the land that can be exposed at one time during construction; specify the duration of exposure and the developer's revegetation/stabilization responsibilities.
- Impose time restrictions on construction — e.g., prohibit disturbances during spawning season.
- Revegetate immediately or as soon as possible following construction.
- Provide for stormwater collection or treatment, such as use of sediment control basins, wetlands, or wet ponds, to accommodate large storms.
- Route clean water around the site.
- Maintain infiltration capacity, using natural drainage conditions where possible. This may mean limiting impervious area to a fixed percentage of lot size and limiting runoff to predevelopment rates and characteristics.
- Control erosion and sediment through the watershed protection ordinance.

- Limit the grade of constructed slopes.
- Stabilize existing steep slopes by sodding and pegging to establish grass cover, building retaining walls, and planting woody vegetation on the most extreme slope.
- Dispose of construction wastes such as oil, cement, and debris.
- Require inspection during and after construction.
- Require long-term maintenance and review of plans for adjacent parcels.
- Ensure that development plan meets all existing ordinances.

■ **Groundwater considerations.** When considering options for postdevelopment stormwater control, groundwater should be considered in choosing a BMP. Activities that have a significant impact on groundwater should be controlled by design standards. For example, a standard could require runoff collection systems for roads and parking lots to control at least the first flush — the first 1/2 inch of rainfall that typically contains most contaminants — during any storm.

Controlling Development

Local governments should consider the total environment in selecting a nonpoint source pollution strategy that will provide the maximum benefit to the environment and to consumers. These benefits usually depend not only on the method itself but also on its design, maintenance, and congruence with the surrounding landscape.

A community's success in preventing pollution depends largely on how well it has planned for controls during and after the development process (see Fig. 9).

■ Site conditions. In developing a comprehensive nonpoint source water quality protection plan, the first step is to assess the site's geographic elements and morphology (see Fig. 10).

Soil. Permeability — the ability of the soil to absorb runoff — is crucial in selecting an appropriate control method. This characteristic particularly affects infiltration methods, which can affect groundwater quality (see Fig. 11).

Slopes. Steep slopes preclude the use of several types of control methods and certain types of development. For example, porous pavement and grassed swales must be situated on sites with slopes of 5 percent or less, whereas infiltration trenches are not practical when slopes exceed 20 percent.

Size of the watershed area. The success of some control methods depends on the watershed size. For example, detention ponds normally do not work unless the watershed area is greater than 10 acres. Alternately, infiltration and vegetative controls are most successful in areas less than 10 acres (see Fig. 12).

Water table. A high water table can reduce the effectiveness of an infiltration basin. If a seasonally high water table extends to within 4 feet of the bottom of an infiltration basin, the site generally is not considered suitable. The depth of infiltration and pond controls are limited by their proximity to the water table.

Distance to bedrock. As with a high water table, a bedrock layer too close to the surface (2 to 4 feet from the bottom of an infiltration basin) will prevent the infiltration basin from draining properly. Similarly, controls that use ponds generally will not work if the bedrock lies within an area that must be excavated to provide stormwater storage.

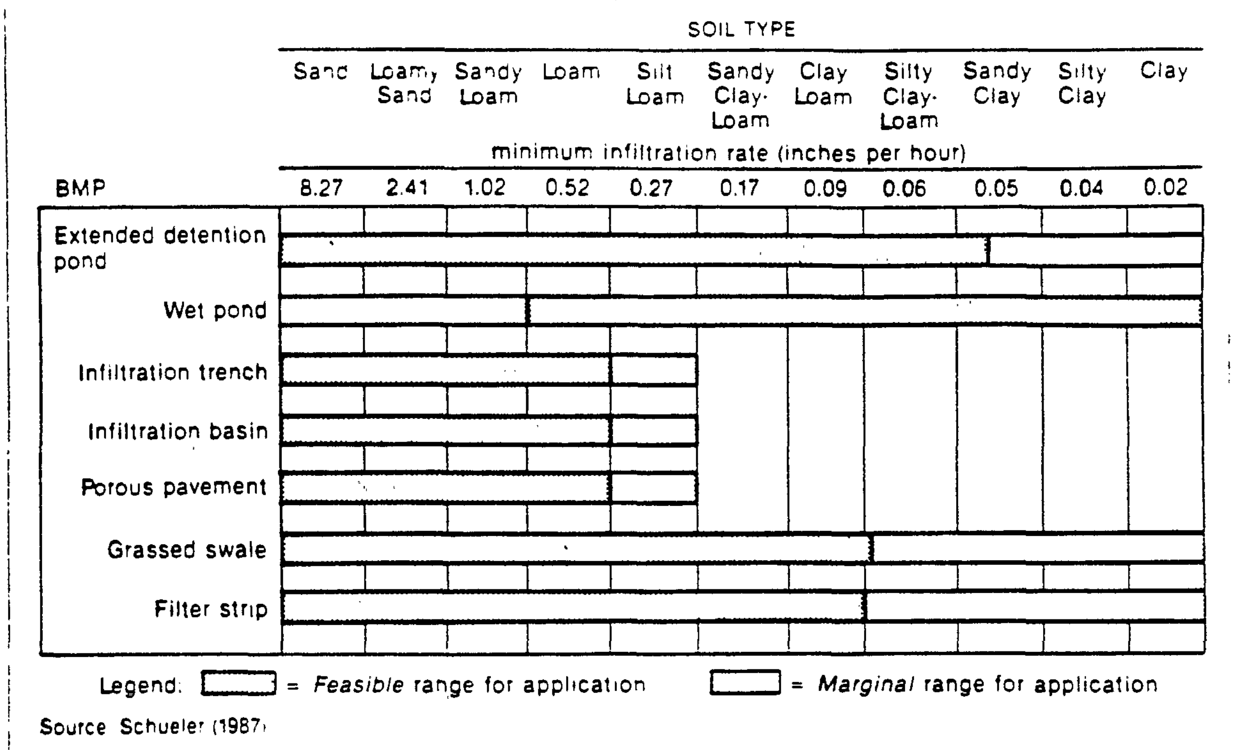

Figure 11.—Restrictions for BMP application based on soil permeability. *Source: Schueler, 1987.*

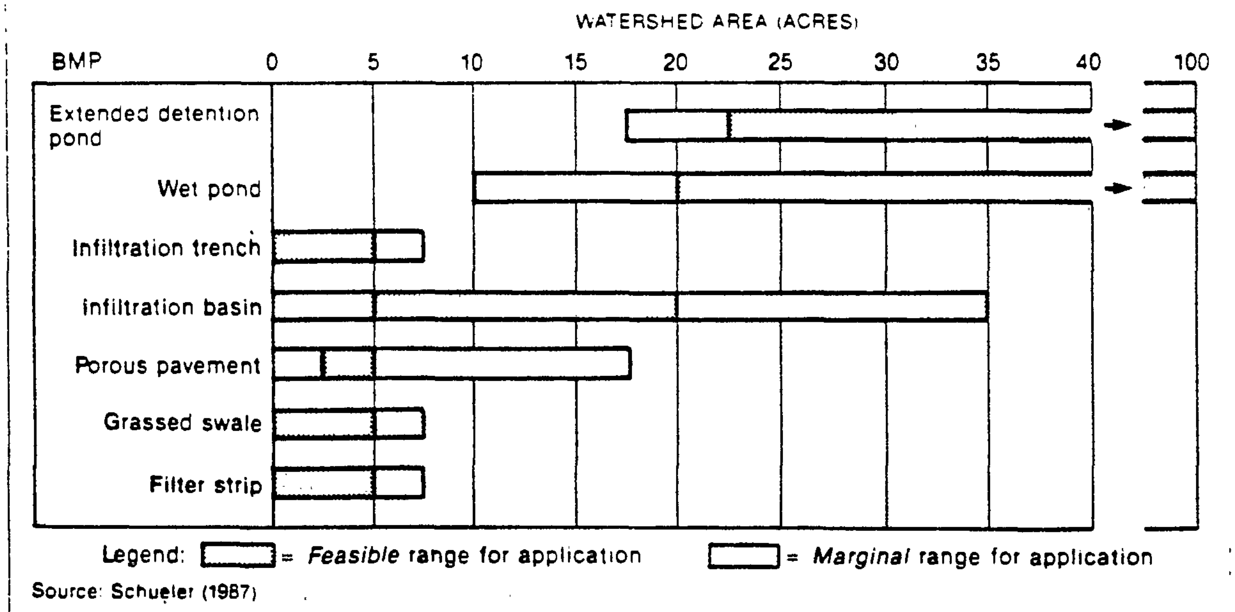

Figure 12.—Feasible BMPs for different watershed sizes. *Source: Schueler, 1987.*

Proximity to foundations and wells. Infiltration basins should be at least 100 feet away from drinking water wells to prevent groundwater contamination. Wellhead protection areas may require even greater distances to properly protect public water supplies. To prevent seepage, they should be installed at a reasonable distance (100 feet) from a building foundation.

Land use. A very small or intensively developed site may preclude the use of space-consuming controls such as detention ponds and porous pavement. In addition, some controls are appropriate only to particular types of land uses. For example, sand filters are suitable for parking lots, while grassed swales are effective only in low density residential areas.

Effects of temperature. Shallow marshes and wet ponds heat up rapidly during the summer, and their runoff into colder streams can harm aquatic life.

■ **Predevelopment status.** The second step in selecting a control method is to determine which option comes closest to duplicating the site's hydrology prior to development. Consideration involves a number of factors:

Control of peak flows. Some local regulations require that a nonpoint source control method be able to control the peak flow from a two-year storm — a storm expected to produce a flood every two years. Some jurisdictions require control of even larger storms. Ponds are an excellent method for achieving this goal; infiltration basins are somewhat less effective.

Control of first flush. First flush is the disproportionately large amount of pollutants usually found in runoff during the early part of a high intensity or large volume storm, caused by the rapid runoff of accumulated pollutants. First-flush control — the first 1/2 inch of rainfall — can also be required for a runoff area. However, if storms in an area are frequent, the first flush may not be significant and further monitoring may be needed.

Volume control. Infiltration basins can reduce the runoff volumes of smaller storms by diverting much of the runoff back into the soil.

Groundwater replenishment. Infiltration basins provide an excellent way to replenish groundwater lost because of development; however, this benefit must be weighed against the potential for groundwater contamination.

Streambank erosion control. While some nonpoint source pollution methods control streambank erosion to some extent during a two-year storm if properly designed, installed, and maintained, more severe storms require large extended detention ponds and infiltration controls to prevent downstream erosion.

■ **Pollutant removal.** The third step is to determine which control method will remove the greatest volume of pollutants. Important interrelated factors are the removal mechanisms, types and percentage of runoff to be treated (first flush versus total runoff), and the type of pollutant being removed.

The nature of the pollutant is the most important factor in a control method's effectiveness. For example, most control methods are extremely effective in removing sediment and trace metals, which are usually adsorbed into sediment surfaces. However, vegetative systems are more effective in removing soluble pollutants such as phosphorus, nitrogen, and chloride. Systems that combine nonvegetative and vegetative features are generally highly effective.

■ **Cost.** A final step in selecting a control method is estimating the cost by taking into account all factors associated with the method. Construction and both short- and long-term maintenance are, of course, the major cost components. Costs may include

- labor,
- materials,
- land purchase,
- loss of tax revenue on acquired lands, and
- downstream mitigation.

Flood Control and Retrofitting

In the past, flood control efforts have focused primarily on decreasing the volume of water that abruptly enters waterbodies. Traditional methods to reduce flooding include using dry detention basins that temporarily store excess runoff, constructing channels, streambank hardening, and floodplain restrictions that limit development along or in flood-prone stream areas.

These flood control measures were not originally designed to control pollution caused by increased urbanization. The historical focus was on quantity control — not quality control. Urban planners and water quality professionals now recognize that these issues must be incorporated into an overall strategy that assesses both flooding and pollutant removal. Existing flood control BMPs are now being redesigned or retrofitted to protect water quality. New flood control BMPs are almost universally being built with this dual focus.

A comprehensive watershed protection strategy, which uses nonstructural and structural BMPs, will reduce the long-term costs of both controlling floods and protecting water quality.

Identifying and preserving buffers and natural systems is an important component of a watershed management plan. These areas serve as nonstructural controls, filtering out many pollutants in urban runoff that might reach the waterbodies. However, in existing developments, they have often been altered. When nonstructural controls are impossible or impractical because of existing development, a community may turn to structural practices — constructing new runoff treatment structures or retrofitting existing runoff management systems.

Retrofitting requires modifying runoff control structures or conveyance systems, originally designed to control flooding, to also control water quality. Modifications might include enlarging structures, changing the inflow and outflow patterns, and increasing detention times.

Retrofitting costs are a major hindrance in improving water quality in developed areas. Therefore, communities may need to identify the most insidious pollutants and then select the most cost-efficient and effective solutions to deal with them, thus improving water quality in urban runoff.

Urban Best Management Practices

BMPs should be selected as part of an erosion and sediment control plan during the site development process, with long-term runoff management part of the objective. The best system of practices to control nonpoint source pollution after construction is completed may be a modification of the practices used during the construction process.

Selecting the proper BMP system is critical in achieving the ultimate goal — reducing the pollutants in urban runoff. In selecting the most appropriate BMPs for a specific site, consider the following:

- the site's physical condition and development status;
- runoff control benefits provided by each BMP option;
- the pollutant removal capability of each BMP option under several design scenarios;

URBAN RUNOFF CONTROL PROGRAMS

Several states and localities have made significant advances in developing and implementing runoff controls. Two particularly noteworthy examples are in Maryland and Florida.

- **Maryland** *began its stormwater management program with the passage of a 1982 state law requiring each county and municipality to adopt a stormwater management ordinance based on state criteria. Criteria call for maintaining predevelopment hydrological conditions and reducing erosion and pollution.*

  The state Sediment and Stormwater Administration reviews and approves local ordinances and develops stormwater management programs for state and federal construction projects. The ordinances must include an approved stormwater management plan, criteria and procedures for stormwater management, proper implementation of the plan (including design criteria for specific proposed controls), maintenance and inspection procedures, and penalties for noncompliance. The ordinances are required for any new construction projects, with a few exceptions for single-family homes on small parcels of land.

- **Florida's** *stormwater management program applies to all new development. Administered through a stormwater rule that serves as a performance standard, Florida's program ensures that runoff volume, speed, timing, and pollutant loads are close to predevelopment levels.*

  The standard requires that a stormwater management system remove at least 80 to 95 percent of the annual pollutant load of sediments, nutrients, and many heavy metals. If permit applicants show that they can meet the standard, the state assumes that water quality requirements will not be violated. But if violations occur, the state can impose more stringent requirements, even if the basic performance standard has been met.

- the environmental and human advantages of each BMP option; and
- the long-term maintenance cost of the BMP.

Table 3 compares the effectiveness of a number of currently used urban best management practices. Urban BMPs are generally grouped into four categories based on the operating principle or physical mechanism used to reduce the amount of runoff pollutants — detention basins, retention/infiltration devices, vegetative controls, and source controls.

■ **Detention basins.** Detention basins are most popular and effective in reducing suspended solids and particles by temporarily holding the runoff and allowing the sediment to settle.

In addition to reducing the pollution in runoff, detention basins also delay the amount of runoff released into receiving waters, thus reducing flooding and streambank erosion and lessening the stress on the physical habitat. The slow release also dilutes the runoff, thereby reducing the concentration of pollutants entering the stream.

With proven success in controlling runoff, detention basins can reduce suspended solid concentrations by 50 to 95 percent. These basins can be used for large drainage areas, be incorporated into new development site plans, and enhance the value of the surrounding property.

Often, however, finding suitable land for a detention basin is difficult and constructing basins in developed areas may not be possible. One solution may be to convert dry ponds previously installed for flow control; they can usually be economically retrofitted to detention basins.

Routine maintenance is required for detention basins. Solids should be removed regularly, because removing accumulated solids after 10 to 20 years can be expensive.

Detention basins are generally of three types:

Dry ponds. Used for flood and erosion control, dry ponds remain dry and available to catch water following large storms. While intended to control water quantity, they can be retrofitted to improve water quality.

Wet ponds. Designed to hold water permanently, wet ponds can be highly efficient in removing sediment and in reducing nutrients through biological activity such as algal growth if properly constructed.

Extended detention dry ponds. These ponds catch stormwater and retain it for 24 to 40 hours, remaining dry at other times. They remove pollutants by trapping sediment particles and allowing them to settle.

■ **Retention/infiltration devices.** Retention or infiltration devices allow runoff to percolate into the ground, reducing the amount of pollutants released into the receiving water. The filtration and adsorption mechanism traps many pollutants — particularly suspended solids, bacteria, heavy metals, and phosphorus — in the upper soil layers and prevents them from reaching the groundwater.

Infiltration devices can remove up to 99 percent of runoff pollutants, depending on the percolation rate and area, soil type, pollutants present, and available storage volume. Success also depends on the rainfall. Not only do infiltration devices have high pollution removal rates, but they can also be built in developed areas and effectively reduce the volume of runoff.

However, poor site conditions such as impermeable soils, a high water table, and bedrock can lessen the effectiveness or cause failure of retention/infiltration devices. These devices must also be installed carefully to prevent soil compaction from heavy machinery, and they require such pretreatment devices as grass filter strips to remove coarse sediment from the infiltration surface. Operation and maintenance are also critical. Many infiltration BMPs have failed from lack of maintenance. Devices must be designed for ease of access, maintenance, and operation.

Retention devices fall into the following categories:

Infiltration basins. An infiltration basin is a natural or excavated large open depression. It temporarily stores runoff until the water percolates through the bottom or sides. Excess runoff can overflow through elevated outlets to maximize the storage volume. Because runoff usually percolates in a day or two, these basins can be dry.

Infiltration trenches and dry wells. Similar in design, infiltration trenches and dry wells are excavated holes filled with coarse stones and then covered. Dry wells are used primarily for roof drainage; trenches are used on larger areas such as streets and commercial parking lots. In both designs, runoff infiltrates the surrounding soil or is collected by perforated underdrain pipes and routed to an outflow. Infiltration trenches preserve the natural hydrology of an area and can fit on small sites. However, they require considerable maintenance and can contaminate groundwater under certain conditions.

Table 3.—A comparative assessment of the effectiveness of current urban best management practices.

URBAN BMP OPTIONS*	RELIABILITY FOR POLLUTANT REMOVAL	LONGEVITY*	APPLICABLE TO MOST DEVELOPMENTS	WILDLIFE HABITAT POTENTIAL	ENVIRONMENTAL CONCERNS	COMPARATIVE COST	SPECIAL CONSIDERATIONS
STORMWATER WETLANDS	Moderate to high, depending on design	20+ years	Applicable to most sites if land is available	High	Stream warming, natural wetland alteration	Marginally higher than wet ponds	Recommended with design improvements and the use of micropools and wetlands
EXTENDED DETENTION PONDS	Moderate, but not always reliable	20+ years, but frequent clogging and short detention common	Widely applicable, but requires at least 10 acres of drainage area	Moderate	Possible stream warming and habitat destruction	Lowest cost alternative in size range	Recommended with design improvements and the use of micropools and wetlands
WET PONDS	Moderate to high	20+ years	Widely applicable, but requires drainage area of greater than 2 acres	Moderate to high	Possible stream warming, trophic shifts, habitat	Moderate to high compared to conventional	Recommended, with careful site evaluation
MULTIPLE POND SYSTEMS	Moderate to high; redundancy increases reliability	20+ years	Widely applicable	Moderate to high	Selection of appropriate pond option minimizes overall environmental impact	Most expensive pond option	Recommended
INFILTRATION TRENCHES	Presumed moderate	50% failure rate within five years	Highly restricted (soils, groundwater, slope, area, sediment input)	Low	Slight risk of groundwater contamination	Cost-effective on smaller sites; rehab costs can be considerable	Recommended with pretreatment and geotechnical evaluation
INFILTRATION BASINS	Presumed moderate, if working	60 – 100% failure within 5 years	Highly restricted (see infiltration trench)	Low to moderate	Slight risk of groundwater contamination	Construction cost moderate, but rehab cost high	Not widely recommended until longevity is improved
POROUS PAVEMENT	High (if working)	75% failure within 5 years	Extremely restricted (traffic, soils, groundwater, slope, area, sediment input)	Low	Possible groundwater contamination	Cost-effective compared to conventional asphalt when working properly	Recommended in highly restricted applications with careful construction and effective maintenance
SAND FILTERS	Moderate to high	20+ years	Applicable for smaller developments	Low	Minor	Comparatively high construction costs and frequent maintenance	Recommended, with local demonstration
GRASSED SWALES	Low to moderate, but unreliable	20+ years	Low-density development and roads	Low	Minor	Low compared to curb and gutter	Recommended, with checkdams as one element of a BMP system
FILTER STRIPS	Unreliable in urban settings	Unknown, but may be limited	Restricted to low-density areas	Moderate if forested	Minor	Low	Recommended as one element of a BMP system
WATER QUALITY INLETS	Presumed low	20+ years	Small, highly impervious catchments (<2 acres)	Low	Resuspension of hydrocarbon loadings; disposal of hydrocarbon and toxic residuals	High, compared to trenches and sand filters	Not currently recommended as a primary BMP option

* **Based on current designs and prevailing maintenance practices.** ***Source: Metropolitan Washington Council of Governments, 1992.***

Sand filter. Sand filters, used to pretreat runoff before it enters another stormwater structure, are suitable for small sites in highly impervious areas and can be retrofitted into existing urban areas. To use sand filters, drainage areas must be stabilized against erosion. Designed mainly to enhance water quality, sand filters are also used to control first-flush water quantity in smaller drainage areas.

Porous pavement. Most practically used for parking lots, porous pavements increase infiltration of water into the soil, maintaining the water balance at nearly the same level as before the land was paved. Runoff rapidly permeates the pores of several layers of different permeable materials and filters the pollutants into the underlying subsoil or perforated drain pipes. The rate of pollutant removal depends on the amount of filtered runoff and underlying soil type.

A study by the Metropolitan Washington Council of Governments found that porous pavement removes as much or more suspended sediment and other pollutants — phosphorus, nitrogen, bacteria, lead, and zinc — as detention/retention basins. Porous pavements can also moderate runoff rate and volume so that drainage patterns and surrounding vegetation remain normal, improving erosion control and enhancing water quality.

Operation and maintenance must be considered in the use of porous pavements, however. They do eventually clog and should be routinely vacuumed.

Oil/grit separators. Also known as water quality inlets, oil/grit separators are designed to remove sediment and hydrocarbons from runoff before it is released to the storm drain network or infiltration system. Runoff passes through long, rectangular concrete chambers — modified to remove sediment, grit, and oil — before exiting through a storm drain pipe.

Oil/grit separators are used infrequently because of their limited ability to remove pollutants caused by low average detention times and the possibility that pollutants removed during one storm could reenter runoff from later storms. However, oil/grit separators can remove coarse-grained sediments from urban runoff and treat runoff before it enters underground filtration systems. They are unobtrusive, compatible with storm drain networks, and easily accessed.

OPERATION AND MAINTENANCE OF URBAN BMPS

Proper operation and maintenance of urban BMPs are critical to their success. A 1990 study of four Maryland counties showed that in 434 wet and dry detention ponds, 70 percent were not operating properly. Poor maintenance was the most frequently cited reason.

To ensure that stormwater management facilities are an asset to the community, not a liability, maintenance must include

- *periodic inspections;*
- *debris and sediment removal from basins and channels;*
- *pipes, pumps, and structure maintenance;*
- *general housekeeping, such as grass cutting and repairs;*
- *mosquito control;*
- *fish stocking; and*
- *vegetation control.*

Before adopting a nonpoint source program using urban BMPs, include sufficient funding for regular maintenance to ensure proper functioning.

Maintenance can be performed by private corporations, individuals, or local government staff. While homeowners' associations and individual property owners can do some maintenance, depending on private citizens to maintain urban BMPs is risky. Legal maintenance and monitoring agreements can be negotiated between a developer and the local public works department. When maintenance is clearly its responsibility, local government may choose to contract with a private company.

A realistic cost estimate is vital to making the community aware of its responsibility for nonpoint source pollution. Maintenance requires staff time to record and assess routine maintenance checks and on-site visits to perform the routine checks.

■ **Vegetative controls.** Vegetative BMPs decrease the velocity of stormwater runoff, promoting infiltration and settling of suspended solids and preventing erosion (see Fig. 13). For maximum effectiveness,

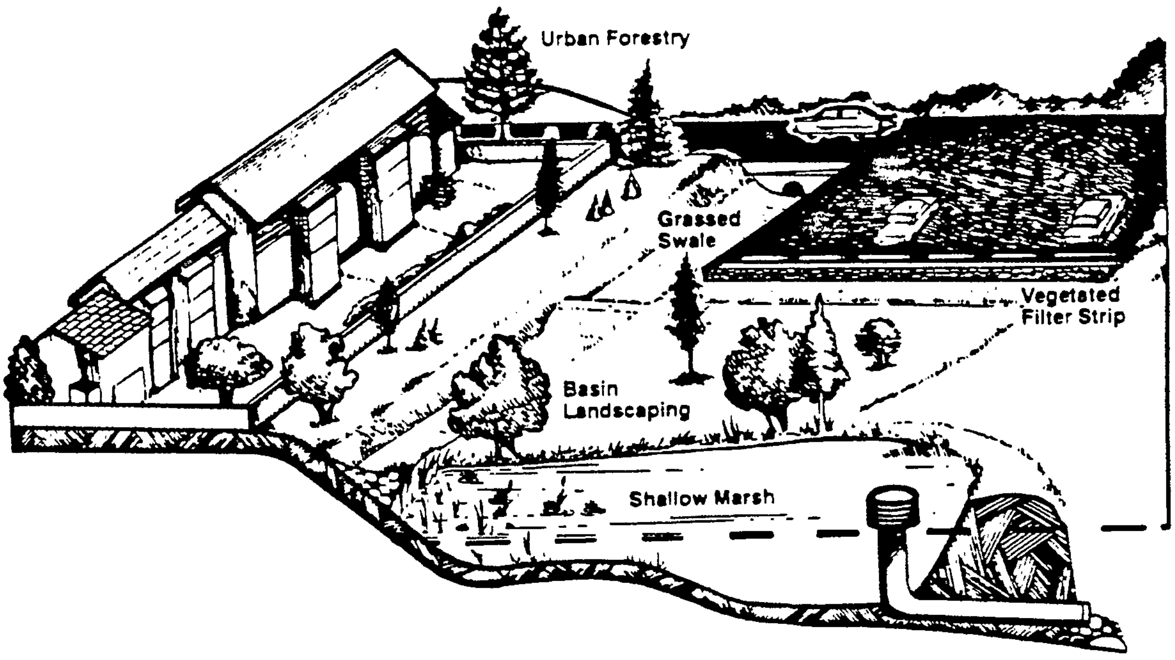

Figure 13.—Vegetative BMPs take many forms and are used for various purposes. *Adapted from Schueler, 1987.*

vegetative controls must be used in combination with other BMPs as a first line of defense in removing suspended solids before more intensive treatments take over. Vegetative BMPs also remove organic material, nutrients, and trace metals.

Less costly than other control practices, vegetative controls enhance the attractiveness and value of sites. Using vegetative controls to pretreat runoff improves the operation and maintenance of other BMPs.

The ultimate performance and practicality of vegetative controls depend on the site's physical features. Plant material must be selected carefully and regularly maintained. Because they have limited ability to control runoff, and effectiveness varies according to the season, vegetative controls should not be a site's only control practice.

Several types of vegetative controls are as follows:

Basin landscaping. Landscaping can improve a stormwater basin's effectiveness in removing pollutants. Landscaping around a basin reduces the amount of impervious surface area, provides an attractive, green buffer along streambanks, and protects and enhances the use of existing wetlands. Proper landscaping can route stormwater runoff through green areas and away from erosion-prone steep slopes and other areas.

Grassed swales. Grassed swales are depressions, such as gullies, that infiltrate and transport runoff water. They are often used in residential developments and on highway medians as an alternative to curb and gutter drainage systems.

Swales control peak discharges by reducing runoff velocity. The swale allows some runoff to infiltrate the soil, thus diminishing the volume of water passing downstream. Swales are easy to construct, attractive, and a potential habitat for wildlife. However, effectiveness varies considerably from site to site; swales may encourage mosquitos, ragweed, dumping, and erosion.

Filter strips. While similar to grass swales, filter strips are shallower and distribute runoff across a wider area. Their efficiency depends on strip length, slope, and size; soil porosity; normal runoff velocity; and vegetation type. Grassy strips supplemented with shrubs and small trees increase the ability to absorb and retain nutrients.

Riparian reforestation. Trees planted near streambanks can stabilize soil, cool water, and benefit many forms of aquatic life.

R0011555

■ Pollution prevention. Local governments should establish ongoing programs to reduce the generation and exposure of pollutants that accumulate on streets and other surfaces, and eventually wash into lakes and streams. These source reduction programs are usually called pollution prevention programs.

In most cases, pollution prevention is more cost effective than structural BMPs in reducing pollutant loadings. However, a combination of source reduction efforts and structural BMPs is generally needed to fully control the effects of urbanization.

Pollution prevention controls — also known as nonstructural controls — include land use planning and zoning strategies, as well as public education efforts. Storm drain painting, recycling, and household hazardous waste collection offer high value for the initial investment. Incentives to use public transportation or otherwise lower emissions that generate pollutants are also considered source controls. (See *Clean Water in Your Watershed: A Citizens Guide to Watershed Protection* for more information on source reduction controls and areas to target for community participation.)

Pollution prevention controls can generate a sense of community; in addition, they have aesthetic or economic benefits. To be effective, source reduction practices require a combination of education, regulation, and guidance. Chapter 5 more fully discusses these issues relating to citizen involvement and education.

Listed below are common pollution prevention controls communities can consider. Local governments can

- collect and recycle crankcase oil;
- begin leaf and other yard waste collection programs;
- establish catch basin drainage programs;
- redesign road salting programs to minimize the salt quantity and, where feasible, use an alternative deicer;
- educate the public about the hazards of fertilizers and pesticides used in commercial lawn care and grounds maintenance operations and the alternative organic treatments;
- start remedial erosion control programs;
- educate the public on how to reduce litter and properly dispose of pet wastes and household pollutants;
- remove illegal and improper industrial and commercial connections to storm drains that discharge directly into receiving waters without prior treatment; and
- plug or seal abandoned wells and cisterns that are conduits for nonpoint source groundwater pollution.

Other administrative strategies may include hazardous waste restrictions or contingency plans. Source prohibitions — barring storage or use of dangerous materials in a defined area — are common ways to protect health and the environment. Many jurisdictions, for example, now prohibit handling or storing toxic chemicals where a spill could threaten groundwater supplies. Jurisdictions also offer hazardous waste amnesty days, which provide residents the opportunity to properly dispose of hazardous waste.

Many commercial and industrial users produce hazardous wastes that threaten water quality. They include dry cleaners, auto service stations, industrial plants, trucking and railroad facilities, and airports. Other activities — such as agriculture, junk yards, machine shops, landfills, and septic systems — also use hazardous materials.

Most of these activities are controlled by NPDES industrial or municipal stormwater permits, but local governments should check with their permitting authorities to determine the degree to which permit requirements are being met and controls inspected.

Chapter 5

Community Education and Citizen Involvement

Even the best planned nonpoint source pollution program cannot succeed without community participation and cooperation. Citizen monitoring groups and solid public information and education programs are invaluable tools to be planned for and nurtured.

Because nonpoint source pollution is a continuing issue related to development and individual life styles, a water quality program must be established and embraced to succeed. Organization and ordinances mean nothing without community support. The community must buy in and accept the program, just as it does a sewage treatment system.

To gain support, you must understand your community. Is your community small or large? Are residents primarily retired or parents with young children? Are residents commuters or do they earn their living in the community? Do most residents stay in the community all year or seasonally? How much do residents know about nonpoint source pollution? How will they be affected by a nonpoint source management plan? How can they be expected to react to the proposed plan?

A public opinion survey or series of well-publicized public hearings throughout the watershed and in your immediate community will help you get to know the community and give you a basis for measuring public opinion.

■ **Public awareness.** Public information and education are important ways to curb nonpoint source pollution, since the solution lies largely in changing individual behaviors and lifestyles. An informational program must educate citizens about the problem and make citizen involvement part of the solution.

■ **Framing the message.** An initial step in developing a public awareness program is to frame your message. Determine what information about nonpoint source pollution you wish to convey, and stress this message at every opportunity. The tone and level of complexity of your message depend on the community's composition and sophistication. The program should include concrete information about using and disposing of toxic substances in homes, yards, farms, and work places.

■ **Targeting the audience.** Nonpoint source pollution affects everyone in the community. On the issue of control, business people, developers, and homeowners each have an individual agenda. Make sure your public awareness program considers these individual needs and interest.

Tailor your messages and presentations to specific groups — for example, college faculty, city employees, developers, civic organizations, or youth groups. Involve environmental groups such as the Izaak Walton League, state associations of conservation districts, and other public or private organizations.

■ **Reaching your audience.** A targeted public awareness campaign uses a variety of tools to convey your message and attain your goals. Some of the tools include

- *Media.* Techniques include press releases, articles, photos with captions, talk shows, news programs, public service announcements, newsletters, and public notices to publicize your message.
- *Community events.* River/lake festivals, county/city fairs, and other special events are educational and public awareness opportunities to make your message known to a variety of audiences.
- *Awards.* Broaden your visibility, recognize good work, and gain a variety of advocates for your program through conservation awards for young people, public service awards, and participation and sponsorship awards.
- *Meetings.* Use public gatherings, club meetings, special conferences, and workshops to explain your program; customize your message to the needs and interests of your audience.
- *Speakers' bureau.* Face-to-face communication to a specialized audience provides a powerful opportunity to deliver your message, answer questions, and clarify ambiguities.
- *Educational materials.* Brochures and posters obtained from EPA, the state water authority, or other groups can be distributed to schools, civic groups, and businesses to further support your message.

■ **Using a variety of information/education tools.** The numerous techniques available to make your community aware of the nonpoint source problem and its solutions are limited only by your imagination and budget. See the following list and Table 4 for ideas to ensure support from your community:

- Publicize your program in all possible ways — use fact sheets inserted into utility statements, flyers, radio, TV, newspapers, public hearings, group meetings; develop personal contacts with reporters — offer story and photo opportunities.
- Tailor your message to various levels of knowledge — from those who understand the concept of nonpoint source pollution to those who have never heard of it.
- Form committees to work on specific aspects of the program; include representatives from all interest groups.
- Offer field trips to groups. Seeing the watershed's problem has much more impact than reading about it.
- Distribute drafts of the plan to interested groups for review.
- Set up meetings using existing organizations such as 4-H or Extension Service and organize community informational watershed workshops.
- Involve schools — make presentations to classes or conduct field trips.
- Set up nonpoint source pollution displays at every opportunity — county fairs, local Earth Day events, conferences, school events.

■ **Citizen monitoring.** Environmentally conscious citizens have made great contributions to local programs nationwide. Groups such as the Chesapeake Bay Watch and the Streamwalk Committee in Seattle, Washington, have become integral parts of the water quality program. Citizen groups can collect valuable information on basic parameters — they can monitor and identify problems, collect surface water samples, and measure turbidity.

Table 4.—Community education and citizen involvement methods.

METHOD	MOST EFFECTIVE USE	RESULTS
Newsletters	Announce meeting time and dates, update information on actions already taken, list issues to be discussed at upcoming meeting	Public awareness
Newspaper articles	Same as newsletter — provide additional detail about local success stories, photos of citizen activities, feature articles provide information about problems and solutions	Public awareness
Demonstration sites	Exhibit innovative technology — should be accompanied by signs, brochures, or permanent on-site interpretive staff	Public awareness, knowledge, understanding
Printed and taped material (e.g., factsheets, videos)	Explain new technology, describe case studies, provide training information for new employees, outline facts to stakeholders	Public awareness, knowledge, understanding
Signs	Mark watershed boundaries, identify critical areas, promote specific behaviors in specific places, identify cooperators in project, explain adjacent project and its BMPs, provide interpretive natural resources information	Public awareness, knowledge, understanding
Meetings	Share information, plan actions, evaluate progress	Public awareness, knowledge, understanding, desire/ability to act
Field trips	Observe resources to be protected, view installed BMPs, learn how BMPs operate, monitor (assessment or compliance type) BMPs	Public awareness, knowledge, understanding, desire/ability to act
On-site inspections	Identify problems, recommend corrective actions, evaluate effectiveness of pollution controls, identify noncompliant stakeholders, educate individuals	Action
Training	Provide new skills to stakeholders	Action
Technical assistance	Identify problems, recommend solutions, assist with installation of BMPs, educate individuals, evaluate effectiveness of solutions	Understanding, desire/ability to act, action

***Source:** Terrene Institute, Clean Water in Your Watershed: A Citizens Guide to Watershed Protection, 1993.*

Local officials see two advantages to citizen monitoring. First, these activities are an economical way to gather high quality data. Second, citizen monitoring is a valuable tool to build grassroots interest in water quality issues. In addition to helping officials identify and avert potential water problems, citizen groups build public support for nonpoint source programs and remedial actions, when necessary.

Despite these benefits, a volunteer program needs careful handling. Everyone is not suited to be a volunteer monitor. Groups and individuals may have difficulty staying motivated throughout an entire sampling project. Inappropriate training or procedures can result in useless data. Sampling also involves a slight risk of injury; local governments must have sufficient liability insurance to cover such situations.

Consider the following recommendations concerning volunteer monitoring programs:

- Citizen monitoring projects should not stand alone but should be integrated into a total water quality management program.
- A qualified water quality specialist should develop the sampling design, analyze the data, and prepare the final report.
- A qualified water quality specialist should train and supervise volunteers in the field, review data frequently, and work closely with the state water quality agency.

R0011559

*TVA RESERVOIR LANDS PLANNING PROGRAM**

The Tennessee Valley Authority manages some 300,000 acres of public reservoir lands, spanning seven states and including 23 multipurpose reservoirs with more than 11,000 miles of shoreline.

When he established TVA in 1933, President Franklin D. Roosevelt charged it with "the broadest duty of planning for the proper use, conservation, and development of the natural resources of the Tennessee River drainage basin."

TVA uses the land for activities ranging from generating electrical power to managing recreation, forestry, and wildlife areas. Communities and the public use TVA's reservoir lands for industrial and navigation facilities, agriculture, community parks, and recreation.

Since it receives more than 1,500 requests for land use each year, TVA considers planning a land management priority. To accommodate the growing demand for development on its lands, TVA initiated a planning process to balance competing demands for public and private uses with environmental needs and national, regional, and local values.

TVA uses planning teams to determine how the land should be used. The team considers public comment, compatibility with existing and adjacent land uses, and legal requirements in making its decision. Plans approved by the TVA Board are continually revised to keep up with growth pressures, economic trends, public needs, environmental conditions, and changing laws. A Geographic Information System (GIS) keeps track of an endless amount of resource data on which the team bases and updates its recommendations.

As part of its planning process, TVA developed a three-step public participation plan. First, TVA identified why and how the public should be involved; next, it identified its audience; and finally, it planned how to involve the public. During public meetings, for example, private citizens and local, state, and federal agencies identify regional concerns and local land use issues. This information is incorporated into the GIS data and used to make social, cultural, and environmental planning decisions.

TVA's land planning process provides a continuing opportunity for local governments and citizens to offer their views on how public reservoir lands should be used, with public acceptance an added benefit. This objective assessment of regional needs guides TVA in handling a multitude of land use request.

Constant public involvement and reevaluation give TVA an insight into early problems, avoiding later crisis management. In addition, local governments and interest groups have a clear understanding of TVA's land use and development intentions. Finally, this process provides warnings of potential detrimental impacts to water quality from proposed uses.

**Adapted from TVA Reservoir Lands Planning and Land Management Planning Applications of a Geographic Information System fact sheets.*

- The sample design should be relatively simple and not dependent on precise measurement.
- Volunteers should be carefully recruited and trained; periodic training may be necessary to replace drop-outs and refresh monitoring skills of current volunteers.
- The water quality specialist should encourage frequent reports, personal presentations at group meetings, and media coverage to keep the group motivated.

The Missing Link — Community Partnership

The optimum situation — informed watershed planning to identify and correct existing problems and prevent future problems — will achieve the best environment possible. But all planning, no matter how complete, must be done *with* your community, not *for* it.

The advantages of the prevention/restoration ethic are impressive and would tempt any community — clean, usable waterbodies attract business and recreational dollars and measurably improve the economic health of the community. Remedial measures, designed to address current environmental conditions, can return water resources to an acceptable purity level.

However, billions of dollars are lost on public works projects, declining property values, and missed revenues from tourism, recreation, and other uses because of the missing link — community partnerships. Without community buy-ins by educated citizens who understand their individual responsibility and the community's needs, remediation will need to be repeated in each generation, if not more often.

Planning and prevention within the total community and watershed area comprise a vital permanent solution to water quality issues. In some cases, eliminating the cause of pollution may not be enough — the waterbody will still need rehabilitation. In other cases, communities must restore the quality of a waterbody even as they prevent further harm.

So plan for the optimum, seeking guidance and cooperation from your community along the way. When the community agrees to implement the plan you know will work, you will have served them — and the environment — well.

Appendix A

Federal Water Quality Program Summary

Coastal Zone Management Act of 1972 (CZMA)

This act established a program to encourage states and territories to develop comprehensive programs to protect and manage coastal resources, including the Great Lakes. To receive federal approval and implementation funding, states and territories had to demonstrate programs and enforceable policies sufficiently comprehensive and specific to regulate land and water uses and coastal development and to resolve conflicts between competing uses. They also needed authority to implement the enforceable policies.

Under federally approved state and territorial programs, the program must protect and manage important coastal resources, including wetlands, estuaries, beaches, dunes, barrier islands, coral reefs, and fish and wildlife and their habitats. Resource management and protection are accomplished through state laws, regulations, permits, and local plans and zoning ordinances.

Water quality protection was not specifically cited as a purpose or policy of the original statutes. The Coastal Zone Act Reauthorization Amendments of 1990 specifically charged state coastal programs, and state nonpoint source programs, to address nonpoint source pollution affecting coastal water quality.

Coastal Zone Act Reauthorization Amendments of 1990 (CZARA)

In these amendments, Congress recognized that nonpoint pollution is a key factor in the continuing degradation of many coastal waters and established a new program to address this pollution. Congress further recognized that the solution to nonpoint pollution lies in state and local action. In enacting CZARA, Congress called upon states to develop and implement state coastal nonpoint pollution control programs.

EPA developed the technical guidance to help states develop control programs. The guidance specifies management measures for sources of nonpoint pollution in coastal waters — agriculture, silviculture, urban, marinas, and hydromodification. Management measures are economically achievable measures to control the addition of pollutants to coastal waters; that is, they reflect the greatest degree of pollutant reduction achievable through the application of the best available nonpoint pollution control practices, technologies, processes, siting criteria, operating methods, or other alternatives.

National Pollutant Discharge Elimination System (NPDES)

Traditional point sources of water pollution are regulated by EPA and the individual states under the NPDES permit program established by section 402 of the Clean Water Act, which establishes permit requirements for certain municipal and industrial stormwater discharges.

Under Phase I, NPDES permits are required for municipal separate storm sewers serving large or medium-sized populations (greater than 250,000 or 100,000 people, respectively) and for stormwater discharges associated with industrial activity. Permits are also issued, case by case, if EPA or a state determines that a stormwater discharge contributes to a violation of a water quality standard or significantly contributes pollutants to U. S. waters.

Under Phase II, EPA is to prepare two reports to Congress that (1) assess the remaining stormwater discharges, (2) determine, to the maximum extent practicable, the nature and extent of pollutants in such discharges, and (3) establish procedures and methods to control stormwater discharges to the extent necessary to mitigate impacts on water quality. Then EPA is to designate stormwater discharges in addition to those addressed in Phase I that must be regulated to protect water quality and establish a comprehensive program to regulate those designated sources.

Section 319 of the Clean Water Act

This statute establishes a national program to control nonpoint sources of water pollution and to protect groundwater. Under section 319, states address nonpoint pollution by assessing the problems and causes within the state, adopting management programs to control the pollution, and implementing the management programs.

States are required to submit an assessment of state waters not expected to meet water quality standards because of nonpoint source pollution and a management program for controlling nonpoint source pollution. Section 319 authorizes EPA to issue grants to states to assist them in implementing management programs or portions of management programs that have been approved by EPA.

National Estuary Program

Administered by EPA under section 320 of the Clean Water Act, this program focuses on point and nonpoint pollution in geographically targeted, high-priority estuarine waters. In this program, EPA assists state, regional, and local governments in developing comprehensive conservation and management plans that recommend priority corrective actions to restore estuarine water quality, fish populations, and other designated uses of the waters.

Section 320 authorizes EPA, on its own or at the request of a state, to convene a management conference to address water pollution problems in estuaries. This conference must identify the causes of environmental problems within the estuarine zone and develop a comprehensive conservation and management plan for the estuary that recommends corrective actions and compliance schedules for controlling point and nonpoint sources of pollution.

Pesticides Program

Administered by EPA, this program controls some forms of nonpoint pollution under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA). It authorizes EPA to control pesticides that may threaten groundwater and surface water. FIFRA provides for the registration of pesticides and enforceable label requirements, which may include maximum rates of application, restrictions on use practices, and classification of pesticides as "restricted use" pesticides, which would limit their use to certified applicators trained to handle toxic chemicals.

Watershed Restoration and Pollution Control Programs

AGENCY AND PROGRAM	PROGRAM DESCRIPTIONS AND AGENCY RESPONSIBILITIES	RESOURCES AVAILABLE AND POSSIBLE ROLES
U.S. Environmental Protection Agency (EPA)	Administers educational and regulatory programs designed to protect the environment (prevent and control pollution). Provides environmental assessments, water quality monitoring, regulations and regulatory oversight, education, planning, technical assistance, grants, and loans for pollution control. Works mainly with state, federal, regional, and local agencies on pollution control efforts	Staff, information and data, laboratories and research facilities, grants and loans for pollution control, educational materials, monitoring equipment. Offices located in 10 regional centers and Washington, DC.
EPA Water Quality	Overall water quality planning and management: • Nonpoint Source Control program oversees and approves state development of water quality assessments and implementation of management programs designed to control nonpoint source pollution; directs funds to high priority watersheds or projects. • Clean Lakes program provides funds to restore or enhance publicly owned lakes. • Water Quality Standards Program provides technical assistance in developing numeric, narrative, and biological limits (standards) to protect water quality and its use. • Coastal programs oversee a number of different programs and initiatives designed to assess coastal resources and study ways to protect coastal waters. Includes the National Estuary program, administers new CZARA	Staff for technical assistance to state and local agencies; review and approval of state programs, research, and special studies. Provides grants to states for most water quality protection activities, educational materials, and programs; funds for special studies or projects.

AGENCY AND PROGRAM	PROGRAM DESCRIPTIONS AND AGENCY RESPONSIBILITIES	RESOURCES AVAILABLE AND POSSIBLE ROLES
U.S. Environmental Protection Agency (continued)		
EPA Permits	NPDES permits for industries, cities, and confined animal feeding operations, provides enforcement for noncompliance.	Staff for technical assistance with modeling and permit drafting, site inspections, and compliance monitoring; funds for special studies or projects.
EPA Pesticides	Regulates pesticide labeling and registration, including application rates, allowable crops and pests, environmental and human health cautions, disposal procedures; licenses restricted-use pesticide applicators.	Staff to review research results, assist with strategic planning, education and training, oversee enforcement procedures of states; funds for special projects and studies.
EPA Groundwater	Administers the Sole Source Aquifer Protection Program; provides technical and programmatic assistance to state wellhead protection programs.	Staff for technical assistance; funds for special studies.
EPA Wetlands	Cooperatively administers wetlands dredge and fill permits with the Corps of Engineers, enforces actions for illegal wetlands filling; technical support for wetlands delineations; research and education about wetland values and function.	Staff to oversee and enforce activities, monitoring wetland status, health, and trends, funds for special studies, educational materials, and programs; data.
EPA Monitoring and Surveillance	Provides environmental assessment, data analysis, oversight of state monitoring programs, special studies and agency research, EPA lab and Office of Research and Development coordination.	Staff for technical assistance to states and citizens on monitoring programs and projects; special studies and data analysis upon request; water quality monitoring at select locations.
EPA Drinking Water	Regulates public drinking water supplies and suppliers; special studies on human health and risk; develops drinking water criteria and maximum contaminant levels (MCLs). Administers special program for watershed treatment to decrease pollution loads to drinking water supplies if installation of BMPs is cheaper than the water treatment method needed.	Staff for technical assistance to set drinking water standards. Special studies, oversight, and compliance monitoring of public water supplies and suppliers.
EPA National Environmental Policy Act (NEPA)	Reviews and comments on other federal agencies' environmental impact statements (EISs); prepares EISs for EPA-sponsored projects.	Staff for technical assistance to prepare NEPA documents and review pollution control techniques required as part of federal action.
EPA Office of Research and Development (ORD)	Conducts basic and applied research to support EPA's mission, including biological and physical studies on fate and transport of environmental contaminants; studies ecosystems at large.	Provides reports, data, maps, monitoring equipment, study and demonstration sites, staff for technical assistance in interpreting research results. Laboratories and research stations located throughout the country.
U.S. Department of Agriculture (USDA)	Stabilizes and supports efficient production, marketing, and distribution of food and fiber. In addition to commodity and public welfare programs, administers a number of conservation programs to assist private and federal land owners or managers in natural resource conservation and multiple-use management. Works mainly with private individuals on improving resource management.	Staff, technical assistance, information and data, educational materials, cost-share funds, engineering equipment. Field offices located in nearly every county, state, and Washington, DC

AGENCY AND PROGRAM	PROGRAM DESCRIPTIONS AND AGENCY RESPONSIBILITIES	RESOURCES AVAILABLE AND POSSIBLE ROLES
U.S. Department of Agriculture (continued)		
USDA — Multiple agency administration of the 1985 and 1990 Farm Bill programs:		
Conservation Reserve Program	Conserves and protects highly erodible or other environmentally sensitive land from production with permanent vegetative cover through 10-year easements and annual rental payments.	In most cases, responsibilities within programs are divided between various USDA departments: **SCS** — Technical assistance in planning, designing, and implementing BMPs. **ASCS** — Administrative oversight of program and cost-share funding disbursement. **CES** — Education and information about the variety of conservation and economic choices available **CSRS** — Research, data, and the results of demonstration field trials of new technologies.
Wetlands Reserve Program	Available only in pilot states to return drained wetlands to wetland status and protect existing wetlands. Uses same easement/payment method as CRP.	
Sustainable Agricultural Research and Education Program	A practical research and education and grant program to promote lower input methods of farming	
Conservation Cross Compliance (Sodbuster and Swampbuster)	A quasi-regulatory program that denies subsidy payments to farmers who plow highly erodible land or drain wetlands.	
Water Quality Incentives Program	A watershed treatment program designed to improve or protect soil and water resources in watersheds impacted or threatened by NPS pollution	
USDA Soil Conservation Service (SCS)	Technical assistance on planning site-specific design, and installation and management of soil and range conservation, animal waste, and water quality management systems, special land and water resource assessments and inventories. Cost-share funds to install BMPs on private lands available from some programs	Staff and equipment in field offices for technical assistance including engineering designs, survey work and planning for water resource protection.
USDA SCS — Small Watershed Program (PL-566)	Evaluates and treats small agricultural watersheds with multiple resources to protect. Targets resources for both technical and financial assistance and educational programs.	Staff for technical assistance to landowners and decisionmakers in the watershed; funds for demonstration projects
USDA SCS — Great Plains Conservation Program (GPCP)	Intensive conservation treatment for individual farms located within the Great Plains ecoregion through long-term agreements (3 to 10-year contracts) with farmers.	Technical assistance and cost-share funds up to 75 percent of the average cost of selected high priority conservation practices
USDA SCS — Resource Conservation & Development Program (RC&D)	Helps local governments in authorized areas plan and use natural resources and solve local problems.	Planning assistance for small communities for resource protection; financial assistance up to 25 percent of a project — not to exceed $50,000.
USDA SCS — River Basin Program	Assists state and local governments identify water and related land resource problems, evaluate alternative solutions, and develop their implementation program.	Staff for technical assistance to decisionmakers for inventory and planning activities.
USDA SCS — Natural Resource Assessment Programs: Soil Survey, Natural Resources Inventory	Various programs to map and assess the condition of natural resources (soil, water, vegetation, and wildlife) and conservation treatments.	Maps, reports, data information, statistical analysis.

AGENCY AND PROGRAM	PROGRAM DESCRIPTIONS AND AGENCY RESPONSIBILITIES	RESOURCES AVAILABLE AND POSSIBLE ROLES
U.S. Department of Agriculture (continued)		
USDA Agricultural Stabilization and Conservation Service (ASCS)	Provides administrative oversight and cost-sharing programs for approved conservation practices from ASCS and other USDA administered programs, tracks crop production and other statistics; distributes crop subsidy and deficiency payments.	Financial assistance (i.e., cost sharing); map and conservation practice information.
USDA ASCS — Agricultural Conservation Program (ACP)	Annual cost-sharing for a number of soil conserving, production improving, and water quality practices.	Funding for cost-share programs generally limited to $3,500 per farm per year.
USDA ASCS — Emergency Conservation Program (ECP)	Annual cost-sharing to replace conservation treatments (mainly structural) destroyed in areas designated as natural disaster areas.	Cost-share funds for high priority conservation practices.
USDA ASCS — Water Bank Program	Designed to improve and restore wetland areas through financial compensation for 10-year easements on private property.	Funding for easement compensation on eligible lands in participating states.
USDA ASCS — Colorado River Salinity Control Program (CRSCP)	Financial assistance on farm projects that seek to control salinity levels delivered to the basin, primarily irrigation water management.	Funds, reports, data on level of conservation treatment and demonstration sites; cost-sharing, monitoring, and education.
USDA ASCS — Forestry Incentives Program (FIP)	Cost-share to revegetate and improve timber stands on private lands.	Cost-share funds.
USDA Cooperative Extension Service (CES)	Educational programs and information to aid individuals in selecting, operating, and maintaining the most beneficial conservation treatments. Economic analysis and data for each farm or ranch, technical assistance in integrated pest management and landscape issues. Programs generally carried out in cooperation with state land-grant universities.	Staff to offer educational programs and technical assistance and personalized economic analysis; coordinates small-scale demonstrations on local farms; educational materials.
USDA Cooperative State Research Service (CSRS)	Applied research, usually at state experiment stations, on agricultural production and soil and water conservation, generally using demonstration plots. Conducts the Sustainable Agriculture Research and Education (SARE) program. Many projects in cooperation with state land grant universities.	Provides reports, data, equipment; occasionally has funds for joint or special projects outside the normal research agenda; grants for Agriculture in Concert with the Environment (ACE) program.
USDA Forest Service (FS) — National Forest System (NFS)	Manages national forests and grasslands for sustained production and multiple use. Works with individuals, industries, and other agencies.	Staff, maps, reports, equipment for construction and monitoring, educational materials; occasionally funds for special projects. Field offices located in each national forest; regional offices located in 9 areas and Washington, DC.
USDA NFS — Permit Program	Oversees timber sales and harvest contracts, grazing leases, and minerals developed on FS property; provides technical assistance to permittee in proper resource use.	Staff for technical assistance and compliance monitoring.
USDA NFS Air and Watershed Programs	Overall environmental planning and technical support for forest management decisions; special studies and watershed demonstration projects in certain areas.	Funds for special studies and watershed demonstration projects; natural resource inventories and reports, water quality or habitat monitoring; environmental analysis of resource trends and conditions.
USDA NFS — Research	Basic and applied research on range and forest lands.	Technical papers on effects of management on water quality

AGENCY AND PROGRAM	PROGRAM DESCRIPTIONS AND AGENCY RESPONSIBILITIES	RESOURCES AVAILABLE AND POSSIBLE ROLES
U.S. Department of Agriculture (continued)		
USDA NFS — State and Private Forestry —Forest Stewardship Initiative	Technical assistance and cost share to inholding or privately owned lands adjacent to national forest lands for installing BMPs.	Funds for and technical assistance to individuals
USDA Farmers Home Administration (FmHA)	Loans and loan guarantees to eligible producers for operating expenses, land purchase, and conservation measures	Funds and loans for property improvement and conservation, treatment installation, and water conservation practices. Located in counties, states, and national offices.
USDA Agricultural Research Service (ARS)	Basic and applied research on agricultural production and conservation measures, including fertilizers, pesticides, and BMP effectiveness	Reports on BMP effectiveness and environmental fate and transport data, demonstration sites; occasionally provides funds for joint sponsored projects. Research stations, located throughout each state, specialize in particular types of investigations
U.S. Department of Commerce — National Oceanic and Atmospheric Administration (NOAA)	Administers programs in cooperation with states to inventory and manage coastal resources, funds and performs basic research and assessments relating to coastal eutrophication, maintains database for agricultural pesticides and nutrient loadings	Funds to state coastal programs; staff for technical assistance, data reports, and educational materials; occasionally administers funds for special demonstration projects
NOAA — Coastal Zone Management Act Programs (CZMA)	Administers a quasi-regulatory coastal protection program, in cooperation with EPA, that sets performance-based management measures for control and prevention of nonpoint source pollution in coastal areas for all land use activities	Staff for technical assistance, funds for plan development.
U.S. Department of Defense (DOD) Army Corps of Engineers (COE)	Oversees construction and operation of large flood control and public water supply reservoirs, conducts water quality monitoring on lakes within its jurisdiction, regulates in-lake activities and shoreline development. Cooperatively administers wetlands dredge and fill permit program with EPA and Fish and Wildlife Services; can enforce permit requirements for wetland BMPs or other mitigation measures	Maps, special studies, water quality monitoring data, staff and funds for improvement of existing projects, staff to review and oversee 404 (wetlands) permits. Field offices located in various districts throughout states and Washington, DC.
U.S. Department of the Interior (DOI)	Oversees, manages, or monitors national natural resources, including land, water, and wildlife.	Staff, maps, reports, demonstration sites, educational materials, monitoring equipment. Offices located in regional centers, management areas, and Washington, DC.

R0011579

AGENCY AND PROGRAM	PROGRAM DESCRIPTIONS AND AGENCY RESPONSIBILITIES	RESOURCES AVAILABLE AND POSSIBLE ROLES
U.S. Department of the Interior (continued)		
DOI Fish and Wildlife Service	Oversees and regulates the nation's wildlife resources; manages national wildlife reserves; enforces federal game and fish laws; cooperatively administers national wetlands program with the Corps of Engineers and EPA. Cooperative projects to enhance wildlife habitat; special studies, especially fisheries investigations.	Staff to enforce Endangered Species Act and other laws on public and private land; research reports and data on habitat, populations, and management of wildlife. Funds for cooperative projects. Educational materials, teacher training, curricula, and maps.
DOI Bureau of Land Management (BLM)	Administers and manages federal lands; oversees grazing leases, mineral exploration, and extraction bids and leases on BLM lands; technical assistance to permittees on BLM land in proper resource use; oversees recreational users of BLM land.	Staff for environmental analysis and trend evaluation on BLM land, technical assistance, and oversight. Funds for special studies and cost-share for permittees for certain conservation practices (generally grazing/range management); funds for range improvement, riparian area management, and recreational area development projects Maps
DOI Bureau of Indian Affairs (BIA)	Technical assistance to tribes on tribal lands mainly for social services; some assistance for conservation work and educational programs, natural resource inventories and monitoring surface and groundwater.	Maps; natural resource inventories of Indian and tribal lands; funds for special projects; staff for technical assistance to tribes.
DOI Bureau of Reclamation	Administers, constructs, and oversees water supply facilities in western states; regulates discharges from these facilities; jointly administers the Colorado River Salinity Control Program with many agencies to set consistent salinity standards and manage public and private lands within the basin; new initiative to reclaim lands damaged by federal irrigation projects	Staff to oversee projects and manage federal property and facilities; assesses water quality around reservoirs as part of the national irrigation water quality program, maps, reports, and some data.
DOI National Park Service	Administers and manages national parks for preservation of natural resources	Staff to oversee and administer; funds for special studies and occasional cooperative projects on land adjoining park boundaries
DOI Office of Surface Mines (OSM)	Regulates the removal and reclamation of surface mined minerals, mostly coal on private lands	Staff to oversee and provide technical assistance in mining operations, reclamation efforts, and engineering studies; vegetative site inspections and monitoring resources; educational materials, data, and reports.
DOI U.S. Geological Survey (USGS)	Long-term baseline monitoring of water resources (quantity, flow, and quality), hydrologic and geologic investigations and data, special intensive short-term studies.	Maps, data, and information on hydrology and water quality status and trends; staff for technical assistance in designing a monitoring plan.
State Water Quality Agencies	Administer many programs (similar to EPA) to protect water quality in surface and groundwaters, including the NPDES permit program, water quality standards regulations, the nonpoint source program, and ambient statewide monitoring programs.	Staff for technical assistance to local governments and individuals implementing BMPs; water quality monitoring, data, and reports, funds for pollution control projects, educational materials, and programs.

AGENCY AND PROGRAM	PROGRAM DESCRIPTIONS AND AGENCY RESPONSIBILITIES	RESOURCES AVAILABLE AND POSSIBLE ROLES
State Agencies (continued)		
State Natural Resource Agencies	Administer programs for wetlands and coastal protection.	Staff for technical assistance to local governments; monitor natural resource trends, reports, and data educational materials and programs
State Departments of Agriculture	Regulate pesticide registration and use and administer marketing and rural development programs, sometimes issue permits for fertilizer or feedlots	Staff to oversee pesticide applicators and other regulatory functions.
State Forestry Commissions or Departments	Oversee activities on state forest lands, administer forest practice laws or BMP regulations.	Staff for site inspections, technical assistance, and education for private landowners and state forests; information on forest resources.
State Cooperative Extension Services	Natural resource, family health, and agricultural production education and training programs for citizens	Staff, reports, educational materials, technical assistance. Field offices located in each county or state office connected with land-grant universities
State Parks and Tourism Departments or Bureaus	Administer programs to promote tourism and the use of state parks for recreation	Maps, signs, educational materials, occasional small grants for historic preservation or local development
State Natural Heritage Commissions or Boards	Administer programs to educate people and preserve historic and cultural resources	Maps signs, educational materials
State Highway or Transportation Departments	Oversee design, construction, and maintenance of state and federal highways provide assistance to local governments on road-related issues, responsible for erosion and pollution control along highway right-of-ways and during construction and maintenance activities	Maps, signs, educational materials, maintenance equipment, and flower and grass seeds, technical assistance for local governments; sometimes provide funds for special studies or beautification projects.
State Public Lands Commissions or Boards	Oversee administration of state lands, generate revenues for state treasury.	Natural resource information and maps.
State Natural and Scenic Rivers Commissions	Oversee use and protection of state designated scenic rivers; may levy taxes and take enforcement actions to protect the river.	Staff for river protection and (sometimes) assessments; occasionally provide funds for special protection or improvement projects.
State Livestock and Poultry Boards or Commissions	Regulate health, welfare, and safety of livestock, poultry production, and products.	Staff for site inspections, technical assistance, and enforcement actions; sometimes special studies and reports.
State Water Well Boards	Regulate the drilling of new wells and the sealing of old ones.	Staff for site inspections, technical assistance, and enforcement; educational materials and training for drillers.
State Oil, Gas, and Minerals Departments or Commissions	Oversee the leasing, production, and administration of state and privately owned natural resources, responsible for spills and environmental programs related to petroleum.	Staff for oversight and inspection including site-specific environmental audits and spill prevention and clean-up.

R0011581

AGENCY AND PROGRAM	PROGRAM DESCRIPTIONS AND AGENCY RESPONSIBILITIES	RESOURCES AVAILABLE AND POSSIBLE ROLES
State Agencies (continued)		
State Plant Boards	Administer programs that evaluate mainly agricultural plants and conservation plantings.	Staff for technical assistance; special studies and reports.
State Health Departments	Administer septic tank and public drinking water regulatory programs; monitor water supplies; provide technical assistance to local governments.	Staff for technical assistance to local governments, monitoring, and educational programs; data, reports, and educational materials.
State Soil and Water Conservation Commissions	Administer cooperative programs with the USDA/SCS to conserve soil and water resources on private lands; provide technical assistance to individuals.	Staff for technical assistance to individuals; engineering or construction equipment, services, and supplies that support BMP implementation. Some states have cost-share funds for BMPs.
State Fish and Game Agencies	Regulate the harvest of fish and wildlife resources by individuals and commercial operations; responsible for state cost recovery of lost fish and wildlife affected by environmental contamination.	Staff for enforcement of state fish and game laws and for technical assistance in wildlife and fisheries management for private individuals; educational materials; natural resource inventory data.
State Water Rights Agencies	Allocate water rights (mostly in western states); regulate consumptive use of water resources.	Staff for permit writing and oversight; data and reports on water flow.
Local Planning and Zoning Boards, City Planning Commissions, County Planning Boards	Specify land use zoning and boundary determinations; general community planning; oversee program operation.	Maps, long-range plans, inventory of local resources, special reports, budget information, staff for technical assistance.
Local County Judges, Commissioners Court, or Parish Police Jury	Manage, construct, and maintain county roads and bridges; oversee and approve county budgets for all county programs. Taxing authority.	Information on county conditions, equipment for construction and maintenance, budget reports; occasional funds for special projects.
Local SWCDs	Local field office of state agency.	See State Soil and Water Conservation Commission.
Local Erosion and Sediment Control Districts	Oversee activities that could cause erosion and sedimentation.	Staff for on-site inspections, technical assistance, and sometimes enforcement actions.
Local Irrigation or Acequia Districts	Regulate local water use and maintain public or jointly owned irrigation projects; responsible for controlling pollution and erosion from projects.	Maintenance workers.
Local Flood Control, Water Management, or Subsidence Districts	Regulate water and land use and management to prevent subsidence or flooding.	Staff for on-site assessments and inspections; maps, reports, land use data; zoning information.
Local School Boards and School Administrations	Oversee public education within jurisdictional boundaries; can set local curricula requirements and priorities. Taxing and bond issuing authority.	Information on status of current educational programs; assistance in developing new initiatives.
Local Municipal Utilities Districts	Oversee construction and maintenance of public works projects for water, sewer, and occasionally energy. Taxing and bond issuing authority.	Information and special reports on water issues; funds for special projects to enhance system operation and reduce costs.

AGENCY AND PROGRAM	PROGRAM DESCRIPTIONS AND AGENCY RESPONSIBILITIES	RESOURCES AVAILABLE AND POSSIBLE ROLES
Regional River Authorities	Manage and coordinate activities within their basin for flood control, water quality protection, energy development. Taxing authority.	Data, reports, maps, water quality monitoring, staff for technical assistance to local government and other agencies or groups. Funds for special projects
Regional Planning Commissions and Councils of Government	Assist in coordinating activities of all governments within the area; provide technical assistance and information; promote special projects of benefit to all	Staff for technical assistance to local governments; occasional water quality monitoring, reports, and data about local conditions; funds for special projects.
Others — Commodity Groups	Various groups usually formed to improve marketing and lobbying capabilities for specific crops or livestock interests. Nearly every major crop has at least one such group.	Staff for data gathering and analysis, public education campaigns, technical support to growers, legislative and market analysis; funds from members for special projects
Environmental Organizations	Various groups formed to protect, conserve, or preserve the environment in general or to address a specific issue; lobby for environmental laws and programs as well as funding. Many perform volunteer services such as water quality monitoring, natural resource rehabilitation work, cost-share, or provide other funds for special projects	Staff and volunteers assist with local projects; educational materials and programs, reports and data on environmental conditions and trends; occasional funding for cooperative work
Social and Service Clubs	Formed for reasons other than resource protection, most have local projects that enhance or beautify community. Provide labor, supplies, and equipment on mutually beneficial projects as well as insight into the community	Volunteers for special projects

PROJECT

A Health Effects Study of Swimmers in Santa Monica Bay[1]

Summary

In the summer of 1995, the Santa Monica Bay Restoration Project (SMBRP) conducted the first large-scale epidemiologic study in the nation to investigate possible adverse health effects associated with swimming in ocean waters contaminated by urban runoff. The overall objective of this study was to answer the public's most frequently asked question, *"How safe is it to swim in Santa Monica Bay?"* by investigating swimmers' reports of illness and determining whether the risks of contracting these illnesses were associated with exposure to pathogens in urban runoff.

Restore And Protect
Santa Monica Bay

Funded by US EPA
and the State Water Resources
Control Board in cooperation
with the public, local agencies,
and industry.

BACKGROUND

Since the genesis of the Santa Monica Bay Restoration Project (SMBRP), a primary focus of energy has been to find the answer to a fundamental human health question: *"How safe is it to swim in Santa Monica Bay?"* Nearly fifty million tourists and local residents come to Santa Monica Bay's public beaches each year to enjoy its recreational resources, but there has been wide public perception and some scientific evidence that there may be health risks associated with swimming in beach areas contaminated by runoff.

In previous investigations conducted by the SMBRP, human pathogens were detected in summer runoff, an unexpected result since sewer and storm drain systems in Los Angeles are completely separate. Possible sources of pathogen contamination into the storm drain system include illegal sewer connections, leaking sewer lines, malfunctioning septic systems, illegal dumping from recreational vehicles, or direct human sources such as campers or transients. Other potential sources of human pathogens in near shore areas include sewage spills into storm drains, small boat waste discharges and swimmers themselves.

---

[1] "An Epidemiological Study of Possible Adverse Health Effects of Swimming in Santa Monica Bay."

The members of the SMBRP therefore decided that the definitive step necessary to answer this question of swimming-related health risks was an epidemiological study. Through this study, we would finally know if risks exist and whether they differ according to where one swims, and we would have the basis for revising recreational water quality standards and monitoring programs so that they are based on risks to human health.

STUDY OVERVIEW

During the course of the study (June to September 1995), 15,492 beachgoers who swam at three Santa Monica Bay beaches located near flowing storm drain outlets (Santa Monica Beach near Ashland Avenue, Will Rogers Beach at Santa Monica Canyon, and Surfrider Beach near Malibu Creek), were interviewed. Nine to 14 days after the beach interviews, 13,278 follow-up telephone interviews were conducted to ascertain the occurrence of symptoms--fever, chills, eye discharge, earache, ear discharge, skin rash, infected cut, nausea, vomiting, diarrhea, diarrhea with blood, stomach pain, coughing, coughing with phlegm, nasal congestion, sore throat and a group of symptoms indicative of "highly credible gastrointestinal illness" (HCGI)[2] and "significant respiratory disease" (SRD)[3].

Water samples were collected daily in ankle depth water at various distances from the drains (0, 100 yards north and south, and at 400 yards) (Figure 1) and analyzed for total and

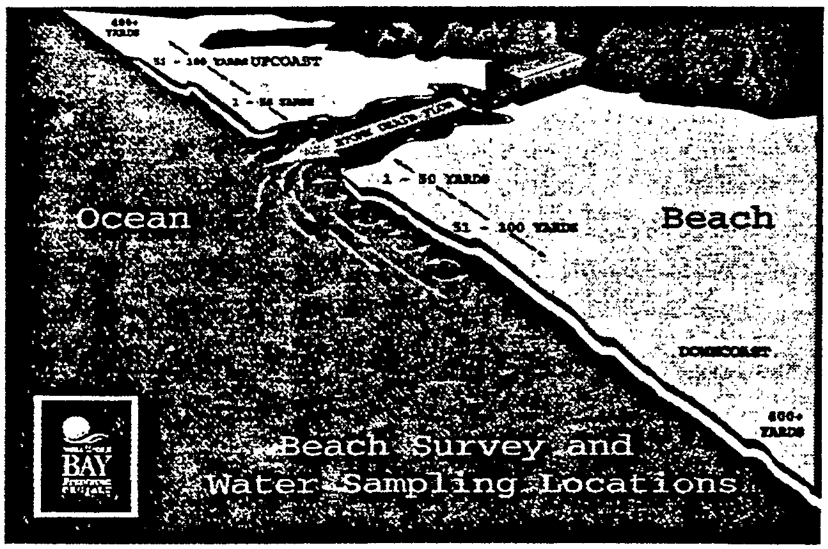

Figure 1. Beach survey and water sampling locations.

---

[2] Two definitions of HCGI were used in this study and grouped as HCGI-1 (vomiting, diarrhea and fever, stomach pain and fever) or HCGI-2 (vomiting and fever).

[3] Symptoms including fever and nasal congestion, fever and sore throat, and cough with sputum.

fecal coliforms, enterococci, and *E. coli*. In addition, water samples were collected at storm drain sites every Friday, Saturday and Sunday and analyzed for enteric viruses.

SUMMARY OF FINDINGS

The analyses conducted in this study addressed two questions: a) What are the risks of illness relative to the distance one swims from a flowing storm drain?; and b) Are the risks of illness associated with measures of water quality? The major findings resulting from these analyses are as follows:

1. **There is an increased risk of illness associated with swimming near flowing storm drain outlets in Santa Monica Bay.** Statistically significant increases in risks for a broad range of adverse health effects (fever, chills, ear discharge, vomiting, coughing with phlegm, HCGI-2[4] and SRD) were found for subjects that swam in front of storm drains (at 0 yards) in comparison to those who swam over 400 yards away[5] (Table 1). For example, there was a 57 percent greater incidence of fever for swimmers at the drain than at 400 yards away. These increases in risk appeared to be limited to the 0 yards distance, as a significant drop-off in effects were observed at other distances upcoast or downcoast from the drain (Figure 2).

Table 1. Comparative health outcomes for swimming in front of drains versus 400+ yards away.

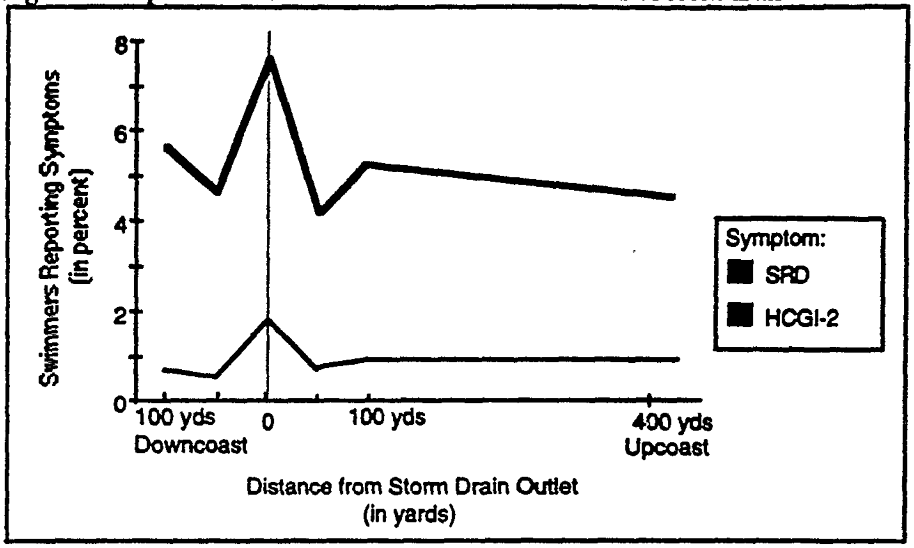
Health Outcome	Relative Risk (0 vs. 400+ Yds.)	Estimated No. of Excess Cases per 10,000 Persons
Fever	57%	259
Chills	58%	138
Ear Discharge	127%	88
Vomiting	61%	115
Coughing with phlegm	59%	175
Any of the above symptoms	44%	373
HCGI-2	111%	95
SRD	66%	303
HCGI-2 or SRD	53%	314

4 See footnote 2.

5 Indicator bacteria levels at 400 yards are low, therefore comparisons could be made between rates of illness in swimmers at this distance and at 0 yards.

The estimated number of excess cases of illness attributable to swimming at the drain reached into the 100's per 10,000 exposed subjects (greater than 1 percent) suggesting that significant numbers of beachgoers swimming near storm drain outlets are subject to increased health risks.

Figure 2. Reports of HCGI-2 and SRD relative to distance from drains.



The results did not change when adjusted for age, beach, gender, race, California versus out-of-state resident, socioeconomic status, or worry about potential health hazards at the beach. Distance results also did not change substantially when controlled for each bacterial indicator.

2. **There is an increased risk of illness associated with swimming in areas with high densities of bacterial indicators.** Researchers used "cutoff points" to determine whether there were differences in the incidence of illness for those who swam in waters with bacterial densities "greater than" versus "less than" certain cutoff levels. Symptoms were found to be associated with swimming in areas where bacterial indicator counts were "greater than" the cutoff points that are used as part of federal and state water quality standards. (Cutoffs vary by type of bacterial indicator.)

Table 2 shows the various outcomes that were found to be associated with these high densities of indicator bacteria. For *E. coli*, associations were seen for earache and nasal congestion. Only skin rash was associated with total coliforms and fecal coliforms. For enterococci, effects were noted for diarrhea with blood and HCGI-1.

Table 2. **Health outcomes associated with swimming in areas with high bacterial indicator counts.**

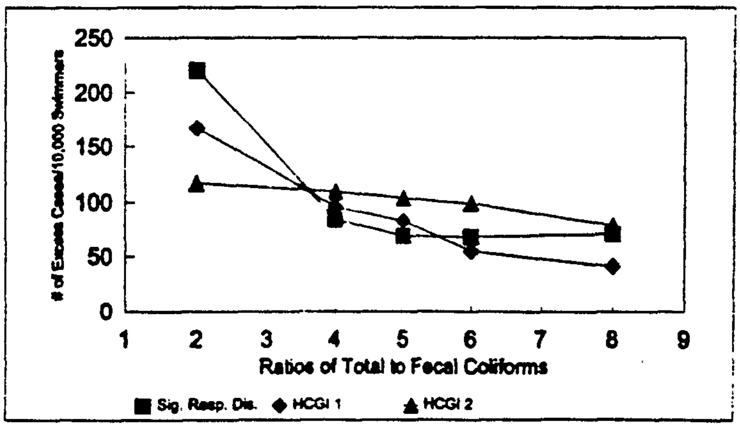
Indicator (cutoff)	Health Outcomes	Increased Risk	Excess Cases per 10,000 Persons
E. coli (> 320 cfu*)	Earache	46%	149
	Nasal Congestion	24%	211
Enterococcus (>106 cfu)	Diarrhea w/ blood	323%	27
	HCGI-1	44%	130
Total coliform (>10,000 cfu)	Skin rash	200%	165
Fecal coliform (>400 cfu)	Skin rash	88%	74

*colony forming units

3. **The total coliform to fecal coliform ratio was found to be one of the better indicators for predicting health risks.** In addition to investigating single bacterial indicators, associations between adverse health effects and the ratio of total to fecal coliforms were investigated. Significant associations were observed, with incidence of illness generally increasing as the ratio of densities of total coliforms to fecal coliforms decreased (Figure 3). When analyses were restricted to times when total coliforms exceeded 1,000 cfu, the strongest effects were generally observed when the ratio of 2:1 was used for comparison.

None of the bacterial results changed when adjusted for age, beach, gender, race, California vs. out-of-state resident, socioeconomic status or worry about potential health hazards at the beach.

Figure 3. Relationship of excess cases of illness and total-to-fecal coliform ratios.



4. **Illnesses were reported more often on days when the samples were positive for enteric viruses.** Seventeen water samples (taken in the storm drain) were positive for enteric viruses. Although based on small numbers, a comparison of subjects who were swimming within 50 yards of the drain on days when samples were tested for viruses indicates that a number of outcomes were reported more often on days when the samples were positive for viruses versus days when samples were negative. Symptoms for which increased risks were noted include: fever (53 percent increase), vomiting (89 percent increase), HCGI-1 (74 percent increase) and HCGI-2 (126 percent increase). Results remained essentially unchanged when adjusted for covariates or for each bacterial indicator. Research with gene probes is ongoing and will be presented in a future addendum to this report.

5. **High densities of bacterial indicators were measured on a significant number of survey days, particularly in front of drains.** A great deal of day-to-day variability in bacterial indicator counts was recorded, however high bacterial densities in water samples were detected most frequently directly in front of drains (at 0 yards) (see Table 4). High densities of *E. coli*, fecal coliforms, and enterococcus occurred on over 25 percent of survey days. Total coliform levels were exceeded less frequently (8.6 percent of days). Total-to-fecal coliform ratios of less than 5 occurred on 12 percent of survey days.

Table 4. Percentage of survey days when bacterial indicator cutoff levels were exceeded in Santa Monica Bay.

Bacterial Indicator (cutoffs)	**Percent of Survey Days Bacterial Cutoffs Exceeded** — Distance from Drain Outlets: 0 yards	1-100 yards upcoast	1-100 yards downcoast	400+ yards upcoast
E. coli (>320 cfu)	25.0%	3.5%	6.7%	0.6%
Total coliforms (>10,000 cfu)	8.6%	0.4%	0.9%	0.0%
Fecal coliforms (>400 cfu)	29.7%	3.0%	8.6%	0.9%
Enterococcus (>106 cfu)	28.7%	6.0%	9.6%	1.3%
Total/fecal ratio ≤5 (total coliforms>1000 cfu)	12.0%	0.5%	3.9%	0.4%

High counts were recorded more frequently downcoast (versus upcoast) from storm drain outlets due to the general pattern of water flow along the Bay's shoreline. At 400 yards away, high counts occurred on generally less than one percent of days.

5. **Characteristics of the survey population.** Persons who bathed and immersed their heads in the ocean water were potential subjects for this study. There were no restrictions based on age, sex or race. Persons who had bathed at the study beaches within seven days of the survey date (before and after) were excluded, as were subjects who bathed on multiple days. Since a primary research question was whether the risk of illness was associated with levels of particular indicator organisms in the water, it would have been impossible to link subjects' experiences with specific counts on a given day if they were in the water on numerous days.

   Fifty-five percent of the subjects surveyed were male, 45 percent female. Forty-eight percent of the subjects were children (under 12 years of age); 13-to-25 year-olds comprised 26 percent of the survey population and the remaining 26 percent were aged 26 and over. The ethnicity of the survey population was 45 percent white, 43 percent Latino, 3 percent black, 3 percent Asian, 3 percent multi-ethnic, and 2 percent "other." Children and Latino subjects tended to swim closer to the drain. Sixty-three percent of subjects swimming at the drain were children under 12. Eighty-eight percent of the surveyed subjects were residents of California.

THE EPI STUDY ACTION AGENDA

The results of this health risk investigation provide both good news and cause for concern. *The good news is that, of the Bay's 50-plus mile coastline, less than 2 miles are problematic.* However, the study has also confirmed that there is a risk of illness associated with swimming immediately adjacent to flowing storm drains. Although it is not yet known what specific pathogens cause illness, the study confirms that the bacterial indicators that are being monitored *do help* to predict risk. In addition, a new tool, the total-to-fecal coliform ratio, has been found to be a useful predictor of illness. With the scientific findings now documented through this study, we have laid the foundation to develop new policies and actions that will improve our ability to protect the public's health.

As a first step, the members of the Santa Monica Bay Restoration Project have identified a preliminary "Epi Study Action Agenda" to respond to the findings of this study and because of the need to "act now." Some of these actions have already begun, but many more steps are yet to be taken. Like the broader issue of urban runoff and storm water pollution, however, prevention and elimination of pathogen contamination in recreational waters requires a long-term, comprehensive approach. There is, however, much that can begin immediately.

Educating and advising the public about the health risks of swimming near storm drain outlets, ensuring that pathogen sources are identified and controlled, and preventing contamination of runoff into the drainage system are among the governmental actions that have been initiated. The general public also has a role to play -- taking action to prevent urban runoff pollution at home, at the work site and at play.

EDUCATE AND ADVISE THE PUBLIC

1. **Improve warnings to swimmers by posting new signs and flags near flowing storm drains.** The Los Angeles County Department of Health Services (LACDHS) will revise the Beach Regulatory Protocol to ensure that beaches are well posted and/or closed as necessary. These revisions include:

    a. Strengthen the wording on warning signs posted near flowing storm drain outlets to read as follows: "WARNING! STORM DRAIN WATER MAY CAUSE ILLNESS. NO SWIMMING." This warning will be posted in both English and Spanish.

    b. Post warning signs on both sides of all flowing storm drains in Los Angeles County and place crossed flags adjacent to the signs.

    The remaining procedures contained in the Protocol (regarding incidents such as beach closure requirements in cases of sewage spills, etc.) will continue to be implemented as appropriate.

2. **Warn swimmers to stay away from storm drain outlets.** Los Angeles County Lifeguards will attempt to warn and advise swimmers to stay away from areas directly in front of storm drain outlets, especially in ponded areas.

3. **Strengthen messages about human health risks associated with contaminated urban runoff into current storm water education campaigns based on the results of this study. Integrate new messages into the educational campaigns if necessary.**

IMPLEMENT SOURCE CONTROL MEASURES

4. **Prevent and control sources of pathogens to urban runoff.** Controlling pathogen sources is but one part of a comprehensive strategy to address the problem of urban runoff pollution. The Los Angeles County Department of Public Works (LAC-DPW) and the cities in the Santa Monica Bay watershed will therefore continue to implement urban runoff source control measures (including Best Management Practices such as catch basin stenciling, storm drain inspection, illegal discharge reporting, enforcement of "pooper-scooper" laws) and where needed, will expand or accelerate these programs.

5. **Divert dry-weather flows from problem storm drains.** The LAC-DPW and cities will continue to work with municipal wastewater agencies and the Los Angeles Regional Water Quality Control Board (LARWQCB) to complete the assessments of projects to divert dry-weather flows from problem storm drains to sewage treatment facilities. Projects that are feasible and cost-effective and for which funding is available will be implemented in a timely manner.

6. **Construct a pilot dry-weather flow treatment facility at the Pico-Kenter drain.** The cities of Los Angeles and Santa Monica have been investigating construction of a pilot ozonation facility to treat dry-weather flows from the Pico-Kenter drainage area.

7. **Investigate and correct malfunctioning septic systems.** Cities and the Los Angeles County Department of Health Services will enhance programs to investigate and correct malfunctioning septic systems, especially in the watersheds along the northern Santa Monica Bay coastline;

8. **Maximize the ability to respond to and control sewage spills.** Municipal wastewater treatment facility operators will review sewage spill reporting and response procedures and develop/modify procedures where necessary to block, capture and re-direct spills to storm drains back into the sewer system.

IDENTIFY AND PREVENT PATHOGEN SOURCES

9. **Identify and eliminate illicit connections and illicit discharges to the storm drain system.** .The municipal storm water/urban runoff pollution control permit issued by Los Angeles Regional Water Quality Control Board (LARWQCB) requires

implementation of programs to identify and eliminate illicit connections and discharges to the storm drain system. To accelerate the implementation of these programs, the LAC-DPW will develop a model program which includes standardized storm drain inspection procedures, illicit connection and discharge identification and elimination procedures, and enforcement procedures to terminate illicit connections and discharges.

10. **Assess the impacts of street and sidewalk washing and develop methods to eliminate or minimize impacts.** The City of Los Angeles will, in the next year, investigate the impact of street and sidewalk washing on pathogen loadings to storm drain systems and will develop appropriate Best Management Practices to minimize impacts on water quality.

11. **Develop standardized procedures for locating sources of pathogens.** The LAC-DPW will lead efforts, with the assistance of SMBRP, to develop a standardized sanitary survey protocol (procedures) for locating sources of pathogens and based in the results of this study, develop criteria for initiation of a sanitary survey.

INCORPORATE FINDINGS INTO STANDARDS AND MONITORING PROGRAMS

12. **Provide periodic reports to the public on beach water quality.** Shoreline bacterial monitoring programs are currently conducted by the City of Los Angeles, the County Sanitation Districts of Los Angeles County and the Los Angeles County Department of Health Services. These programs currently report individual bacterial indicator counts. It is recommended that the total-to-fecal coliform ratio also be added and incorporated into the regional water quality data base maintained by the LARWQCB. Both the individual indicator counts and total/fecal ratio should be used as the basis for development of periodic reports to the public on beach water quality prepared by the LARWQCB, SMBRP, Heal the Bay or other organizations.

13. **Review and revise recreational water quality standards or criteria.** Recreational use of coastal waters occurs near urbanized regions throughout California and the U.S. Current standards/criteria for bacterial indicators are not based on epidemiological studies of swimmers in marine waters contaminated by urban runoff. Given the results of this study, it is recommended that the U.S. Environmental Protection Agency, the California State Department of Health Services and the State Water

Resources Control Board review existing recreational water quality standards/criteria for marine waters and revise them as appropriate.

14. **Review water quality data trends in Santa Monica Bay.** The SMBRP will spearhead a team to review existing water quality data utilizing analytical methodologies identified through this study, so that additional results can be incorporated into modifications of the beach warning protocol and water quality monitoring and reporting activities.

15. **Support additional research projects that help answer additional questions about potential health risks.** Examples of such studies may include an assessment of health risks to persons who frequently swim in the Bay (e.g. surfers and lifeguards) or research efforts necessary to improve our ability to more quickly detect human pathogens in urban runoff.

FINANCE SOURCE CONTROL MEASURES

16. **Seek financing at local, state and federal levels for implementation of source control measures.** The members of the SMBRP will investigate financing mechanisms to support implementation of local efforts to control storm water and urban runoff pollution.

ACTIONS THE PUBLIC CAN TAKE

In addition to governmental action, the general public can take steps to help reduce urban runoff pollution. Urban runoff pollution includes bacteria, trash and chemicals which are washed into the storm drain system from streets, neighborhoods, business locations, parking lots, construction sites, etc. This type of pollution is a problem because, unlike the sewer system, which includes treatment plants, the storm drain system carries water and whatever else is put into it--without treatment--to our streams and the ocean. Urban runoff pollution can be minimized by following these suggestions:

1. **Practice "good housekeeping " in and around the home.**
    - Clean up after your pet. Dispose of wastes in trash cans.
    - Make sure that septic tanks are properly maintained.
    - Properly dispose of disposable diapers.
    - Use a broom rather than a hose to clean up garden clippings. Deposit leaves and grass clippings in a trash can or start a compost pile.

- Take leftover household hazardous materials to a Countywide Household Hazardous Waste collection event or other local collection program.
- Take used motor oil and antifreeze to a participating gas station or other recycling center.
- Have your car inspected and maintained regularly to reduce leakage of oil, antifreeze and other fluids.
- Recycle reuseable materials.

2. **Practice "good housekeeping" at your worksite and where you play.**
   - Clean up spills of materials such as vehicle fluids, paints and solvents properly.
   - Control runoff and prevent erosion at construction sites.
   - Cover and maintain dumpsters.
   - Properly dispose of kitchen wastes. Wash down floor mats in areas that drain to the sewer system.
   - Compost or haul away manure from horses or other livestock.
   - Use pumpout and dump stations to dispose of sewage from boats and recreational vehicles.

3. **Promote pollution prevention and awareness in your community.**
   - Participate in programs such as storm drain stenciling and Coastal Cleanup Day.
   - Support your municipality by reporting any dumping of inappropriate materials into storm drains (such as oil and antifreeze) to 1-800-303-0003.

STUDY PARTICIPANTS

The SMBRP assembled a unique team to carry out the various elements of this study. Dr. Robert Haile, USC School of Medicine, Department of Preventive Medicine, was the Principal Investigator. Dr. Haile led the research team that conducted the beach and follow-up telephone interviews and conducted the health risk analyses utilizing water quality and survey data. The City of Los Angeles Environmental Monitoring Division (LA-EMD) analyzed daily water samples for total coliform, fecal coliform and enterococcus. Heal the Bay volunteers collected the daily bacterial indicator samples and their Executive Director, Dr. Mark Gold served as a principal study advisor. The County Sanitation District of Orange County (CSDOC) collected and analyzed water samples for enteric viruses. The University of Southern California, Department of Biology conducted enteric virus analysis utilizing polymerase chain reaction (PCR)/gene probe technique. The Santa Monica Bay Restoration Project and Foundation served as principal project organizer and was responsible for project management, coordination of financing and contracts, and for providing technical and policy oversight.

FUNDING FOR THIS STUDY

Many public and private entities provided the financial and human resources for this study. The Santa Monica Bay Restoration Project and Foundation thanks the following organizations for their support and commitment to this important scientific undertaking: the State Water Resources Control Board, City of Los Angeles, Beach Cities Health District, City of Santa Monica, Los Angeles County Department of Public Works, Los Angeles Regional Water Quality Control Board, Chevron Companies, Las Virgenes Municipal Water District, Milken Families Foundation, Heal the Bay, and the U.S. Environmental Protection Agency.

ABOUT THE SANTA MONICA BAY RESTORATION PROJECT AND FOUNDATION

The Santa Monica Bay Restoration Project (SMBRP) is a coalition of government, environmentalists, scientists, industry and the public charged with finding solutions to the Bay's problems. The SMBRP, established in 1988 as part of the Clean Water Act National Estuary Program, completed a comprehensive "Bay Restoration Plan" in 1994 that outlines a wide range of actions necessary to restore and protect the Bay. Implementing this health effects study was one of the Plan's highest priorities.

The Santa Monica Bay Restoration Foundation is a non-profit, 501(c)(3) community foundation of the SMBRP. The Foundation is an independent fundraising vehicle created to attract research, planning and implementation funds for activities, such as this epidemiological study, that lead to the restoration and enhancement of Santa Monica Bay.

Water quality of first flush runoff from 20 industrial sites

D. E. Line, J. Wu, J. A. Arnold, G. D. Jennings, A. R. Rubin

ABSTRACT: A sampling program was conducted to assess the quality of first flush storm water runoff from 10 industrial groups typical of many businesses located in North Carolina. Analysis of samples collected during the first 30 min of runoff (first flush) indicated that zinc and copper were the most common of the eight metals measured in runoff from the 20 industrial sites monitored. Ten volatile organic, semivolatile organic, or pesticide compounds were found at eight different sites, with the most common being methylene chloride (three sites). Conventional pollutants such as nutrients and solids were measured at varying levels at every site, but were generally the highest where a significant amount of biological waste or exposed soil was present. *Water Environ. Res.*, **69**, 305 (1997).

KEYWORDS: metals, monitoring, runoff, stormwater, water quality

The quality of storm water runoff is a major concern in the United States. In the National Water Quality Inventory, 1990 Report to Congress, states estimated that ~30% of identified cases of water quality impairment are attributable to storm water discharges (U.S. EPA, 1992). This assessment has prompted an effort, initiated by the U.S. EPA through the National Pollutant Discharge Elimination System (NPDES) storm water permitting program, to characterize storm water discharges and develop pollution prevention plans and best management practices to control these discharges. While a considerable amount of monitoring data exists for runoff from urban areas (U.S. EPA, 1983b; Marsalek and Schroter, 1984; Bannerman *et al.*, 1993; Marsh, 1993; Thomas and Greene, 1993) similar to those subject to NPDES storm water permits, a very limited amount of data has been published on runoff from individual industrial sites (Amick, 1994; Smith *et al.*, 1995). The Nationwide Urban Runoff Program (NURP) included monitoring data from selected industrial areas; however, these areas included a combination of several facilities, streets, and other source areas.

As part of the NPDES permit program, each state that has obtained authority must issue permits for storm water discharges from certain individual industrial facilities and municipalities. Many of the permits require the industrial facility to monitor storm water discharges for certain pollutants. However, the wide range of industries involved and a lack of information about the types and concentrations of storm water pollutants that characteristically come from an industrial group or sector make it very difficult to identify pollutants that should be monitored.

Faced with issuing thousands of storm water discharge permits to industrial facilities in the next few years, the states and U.S. EPA need more information on storm water contaminants from industrial sites. Results of this study will provide some of the background data needed in issuing permits for industrial storm water discharges. These data may also serve as a comparison with sampling results submitted by industries as part of their storm water permit requirements.

Procedure

Ten industrial groups representing common industries in North Carolina were chosen (Table 1). After obtaining permission from responsible parties, two businesses, from each of the 10 groups except chemical repackagers, were selected for inclusion in the study. Only one chemical repackager was included because businesses engaged in just repackaging were relatively rare; therefore, a scrap and recycler (SR III) was substituted. Selection criteria included willingness to participate, representativeness of the plant/site for the industrial group, availability of suitable sampling locations, and hydrology of the site. While the two sites in each industrial group are similar in their activities, replication was not a criterion.

After selection, each site was visited and characterized. All data in Table 1 are based on a site plan or survey, when available, but were often obtained from observation, communication with plant operators, and, in several cases, estimations. The business size (column 3) is a cursory estimate of how the business or plant compares in production with other North Carolina businesses in the same industrial group. Data on drainage area, percent of impervious area, slope, and exposed material all pertain only to the area draining to the sampling station. The exposed material indicates the presence of a significant amount of exposed production or waste materials in the sampled drainage area.

An automatic sampler and a runoff-depth sensing device were installed at a storm water outfall or conveyance channel on each site. When sites had more than one outfall, the sampling station was located such that activities most representative of the business occurred within the sampled drainage area. Sampling locations were always upstream of storm water controls, if any were present. The sampler was programmed to collect a single grab sample within 5 min of being actuated by a flow meter or flow actuator. This actuation occurred as soon as the runoff water at the sampling point was deep enough to sample (~25 mm), which usually occurred within the first 15 min of runoff. The first flush grab sample is one of the sampling requirements for storm water permit applications. When possible, a manual grab sample was collected in place of, or in addition to, the automatic samples; however, because of the unpredictability of runoff, FM I and PM I were the only sites sampled manually.

Only first flush runoff samples collected from storm events that met the U.S. EPA NPDES storm water permit sampling criteria of rainfall accumulation >2.54 mm after a 72-hr dry period were analyzed. When feasible, events with an accumulation of precipitation within 50% of the mid-Atlantic rain zone's

average depth (16.3 mm) and a duration of between 5.1 and 15.2 hr were sampled (U.S. EPA, 1992). These accumulation and duration guidelines were set by U.S. EPA to help ensure that storms representative of the region were sampled. Because of the time constraints of this study, some storms that did not meet the guidelines were sampled.

Eleven sites had rain gauges installed at the sampling station while for the other sites rainfall was recorded by a nearby rain gauge. The rainfall amounts in Table 2 are for the entire precipitation event. Rainfall accumulation at all sites exceeded the 2.54 mm minimum (U.S. EPA, 1992), and rainfall at 12 sites fell within the 50% optimum (8.1–24.4 mm) for the mid-Atlantic rain zone. Storm duration was not considered an important criteria because only first flush samples were collected.

A 11.32-L (3-gal) first flush runoff sample was collected from every site and iced as soon after collection as possible. Because some sites were inaccessible after business hours, some samples remained in the sampler for several hours before being iced; however, because most of the sampling was conducted during the winter months, samples were often cooled by the surrounding air until being removed from the sampler. Samples were then transported to an U.S. EPA-certified laboratory on ice and preserved and analyzed using standard, U.S. EPA-approved procedures for storm water analysis (40 CFR. Part 136; U.S. EPA, 1983a; *Standard Methods*, 1989). Samples were analyzed for many of the conventional pollutants and all but two (p-chloro-M-cresol and 1,2-diphenylhydrazine) of the 112 toxic pollutants listed in the NPDES storm water sampling guidance document (U.S. EPA, 1992). The two compounds were omitted because as a cresol, the p-chloro-M-cresol is often included in the total phenol analysis and the laboratory did not analyze for 1,2-diphenylhydrazine.

The contract laboratory maintained a rigorous quality control program during the project making and analyzing duplicate, standard, and spiked samples for ≥10% of the field samples. To investigate the possibility of cross-contamination between sites, distilled water was obtained and pumped through the sampler into a set of 12 clean sample jars. These sampler blanks were then prepared and delivered to the lab for analysis. Analysis of the blanks did not include pesticides and PCBs as these compounds were rarely detected during sampling. The first blank contained detectable concentrations of only total phosphorus (0.06 mg/L) and dissolved solids (13 mg/L), which resulted from a small amount of floating organic matter that washed off the sampler intake strainer. The intake strainer was rinsed before installation at the next site. The second blank, obtained from another sampler after completing SR I, contained no detectable levels of any compound in the list of analytes. These blanks indicated that cross-contamination between sites and contamination due to handling and transportation were negligible.

Results and Discussion

As stated above, all sampling stations were located upstream of storm water controls; therefore, the results reflect the quality of runoff directly from the pollutant sources. Several sites, including SR I, LF II, and SR II, had wet detention ponds constructed on the site downstream of the sampling point, which probably reduced first flush pollutant concentrations in runoff leaving the site. This observation is included to emphasize that most of the businesses in this study are concerned about the quality of runoff and have taken steps such as removing unnecessary debris, revegetating denuded areas, replacing the cover on stacks of treated wood, and cleaning spilled chemicals to reduce pollutant export. However, these improvements are not reflected in the data presented because the worst-looking drainage areas were sampled.

The results are discussed with the realization that this was a characterization study primarily focused on identifying the

presence of pollutants and approximate concentrations in first flush runoff. For this reason and because discharge measurements were not performed at many sites, the interpretation of the results was limited.

Toxic pollutants. Concentrations of toxic pollutants (U.S. EPA, 1992) measured in first flush runoff samples from each of the 20 study sites are shown in Table 2. Of the metals shown, zinc and copper were the most prevalent, being found at every site, and arsenic was the least prevalent. Concentrations of zinc were greater than all other metals for every industrial group except wood preservers. Samples were also analyzed for antimony, beryllium, selenium, silver, and thallium, none of which was measured in any of the samples. Method detection limits (MDLs) for the metals varied from 0.2 ppb for mercury to 50 ppb for antimony.

Zinc and copper were also found to be prevalent in storm water runoff from textile and food sector facilities nationwide. Amick (1994) analyzed storm water monitoring permit data for >110 facilities in the above two sectors and found that 38 and 31% of the runoff samples submitted by textile facilities contained zinc and copper in concentrations greater than the detection limit. For food sector facilities, 48% had detectable levels of zinc. Chromium was also prevalent being detected in 22% of the textile sector's samples reported by Amick (1994) and 75% of the sites included in this study.

To lend additional perspective to the copper, lead, and zinc data, the median event mean concentrations (EMC) for sites in the Nationwide Urban Runoff Program (NURP) were 34, 144, and 160 ppb for copper, lead, and zinc, respectively (U.S. EPA, 1983b). Thus, the first flush runoff from 9, 3, and 15 of the sites in this study contained higher concentrations of copper, lead, and zinc than NURP sites (Table 2). While first flush samples usually have higher concentrations of contaminants than EMCs, the NURP data provide a benchmark for simple comparison purposes.

Generally, higher levels of metals were found at sites that had exposed metal stored on site, except for wood preservers, which had exposed wood treated with compounds containing the metals arsenic, copper, and chromium. However, runoff from the junkyards (JY I & JY II), even though they probably had the most exposed metal on-site, did not contain the highest levels of metals indicating, that total amount of exposed material is not the only factor important in determining concentrations of metals in runoff. Other factors, such as rust, amount of cut metal surfaces, and hydrologic transport efficiency, can also effect concentrations of metals in runoff.

R0011599

While no standards exist for first flush runoff from industrial sites, comparisons with receiving water standards or action levels provide some basis for assessing the quality of runoff. State standards and action levels for all freshwater in North Carolina are shown at the bottom of Table 2. All 20 samples collected had concentrations of zinc greater than the state action level of 50 ppb while for nickel, only one sample was greater than the state standard of 88 ppb. Because the method detection limit for mercury was much greater than the state standard, determining the exact number of samples with concentrations exceeding the standard was impossible; however, first flush samples from at least four sites were >16 times the standard. Concentrations of As and Cr were high (> mean+standard deviation) compared with other industrial groups and the state standards for both of the wood preserver sites indicating a relatively high potential for contamination of surface waters. The data show that metals are present in the storm water runoff of industrial sites. How easily the metals are transported off-site and to receiving waters will determine the potential threat to designated uses.

Relatively few volatile and semivolatile organics or pesticides and PCBs (column labeled "Other") were found at concentrations greater than the MDLs which ranged from 5 to 50 ppb for all compounds, except acetone, acrolein, acrylonitrile, and 2-butanone, which had an MDL of 100 ppb. None of these compounds was measured at either of the metal fabricators, paint manufacturers, or wood preservers. Methylene chloride was the most frequently detected (>5 ppb) compound, found at three sites, with a maximum concentration of only 51 ppb. Acetone was detected in the first flush sample from nine sites, but was at concentrations below the MDL (<100 ppb) in seven of the nine runoff samples. Detection of acetone was indicated by the method of analysis but was at a concentration less than the MDL; therefore, the concentration could not be reported with any certainty and thus, was not included in Table 2.

Conventional water quality parameters.

Table 3 lists concentrations of 10 conventional water quality parameters measured in the first flush samples from the 20 study sites. These parameters are divided into aggregate organics (biochemical oxygen demand, BOD_5; chemical oxygen demand, COD; and oil and grease), nutrients (ammonia nitrogen, NH_3; nitrate plus nitrite nitrogen, NO_3+NO_2; total Kjeldahl nitrogen, TKN; total phosphorus, TP; and dissolved phosphorus), and solids (dissolved and suspended, TSS).

Comparing concentrations of aggregate organics, runoff from scrap and recycling, landfill, metal fabricating, and vehicle maintenance sites contained the highest concentrations, while runoff from textile manufacturing, chemical repackaging, and wood preserving sites had the lowest. Runoff from eight sites exceeded the NURP median EMC for COD of 65 mg/L (Table 3). While most runoff samples contained <5 mg/L (detection limit) of oil and grease, runoff from sites VM II, SR I, and SR III exceeded the storm water effluent limit of 15.0 mg/L for oil and grease (Amick, 1994).

Runoff from several sites with relatively high (> mean + standard deviation) COD levels (LF II and SR III) also had elevated concentrations of NH_3, TKN, and BOD_5 indicating that a significant portion of the COD may have originated from readily biodegradable compounds. Conversely, reduced metals, oil and grease, and/or certain pesticides and halogenated compounds probably contributed more to the elevated COD levels of runoff from sites with relatively low BOD_5 and NH_3 such as SR I, SR II, and MF II.

Although no one site or industrial group had the greatest concentrations of all nutrients, overall, runoff from SR III and LF II contained the highest concentrations of nitrogen forms and WP II the highest concentrations of phosphorus forms. Both SR III and LF II had waste food and other consumer products on-site, which probably contributed to elevated nitrogen levels, whereas all other sites had primarily inorganic industrial products and associated wastes. The relatively high level of phosphorus at WP II may be attributed to factors other than industrial activity, such as soil erosion or possibly animal waste deposited near the sampler. Factors other than business activity can affect many of the conventional parameters. This is especially the case for the elevated levels of TKN and NO_3+NO_2 at MF II which do not have an apparent source.

The solids concentrations in runoff from scrap and recycling, wood preserving, and junkyard sites were generally greater than other industrial groups, while runoff from textile manufacturing and vehicle maintenance sites had the lowest levels of solids. The sites in the three industrial groups with the highest solids concentrations each had a significant amount of exposed, unstabilized soil in the sampled drainage area. The groups with the lowest concentrations of solids had very little pervious area (Table 1) or, in the case of VM I, had all the pervious area stabilized with grass.

Comparing the 20 study sites to the NURP data, 8, 5, 10, 13, and 13 study sites exceeded median EMC for COD, NO_3+NO_2, TKN, TP, and TSS, respectively (Table 3). Only one site (TM II) had runoff with concentrations of pollutants lower than all five corresponding NURP EMCs. Using the NURP EMC as a benchmark, these data indicate that most industries evaluated in this study should focus on reducing TP and TSS, which can probably be accomplished by improved erosion control. Sites with consumer wastes such as SR III and LF II probably need to focus more on reducing organic nitrogen forms and oxygen demanding substances.

The NC Division of Environmental Management (DEM) has reported a set of "problem concentrations" that are designed to indicate nutrient levels which could cause problems in streams or rivers that enter impoundments or estuaries (NC DEM, 1983). Comparing those concentrations to the sample analysis data in Table 3, shows that 11, 15, 18, and 20 samples contain concentrations of NH_3, NO_3+NO_2, TKN, and TP greater than the corresponding problem concentration. Comparisons with problem concentrations must be made with the realization that the first flush probably contains the highest concentrations of pollutants in runoff from the entire storm and that the total volume of runoff and peak runoff rates from these sites are relatively small compared to the discharge of nearly all tributaries.

Sampling method effects on results.

The hydrology of the site and the sampling method can affect monitoring results, especially first flush pollutant concentrations. For example, because the sampling location at LF I was ≥360 m down slope of the largest active area of the landfill and the time-of-travel to the sampling point was probably >30 min, the sample was probably collected before most pollutants arrived. However, at nearly all the other sites, the runoff peaked within the first 30 min of runoff, indicating that the time-of-travel was <30 min. Most of the sampled drainage areas were

Table 3—Concentrations (mg/L) of conventional water quality parameters in first flush runoff samples.

relatively flat and small in area and were monitored during light- to moderate-intensity rainfall to be as consistent as possible.

The use of automatic samplers makes collecting samples in wide channels during low flow difficult because runoff is often not deep enough to submerge the sampler intake. Conversely, when runoff is much deeper than the sampler intake, floating pollutants such as oil and grease may be collected in less than representative amounts and pollutants that move along or closer to the channel may be collected in greater than representative amounts. These difficulties were also encountered during manual sampling, especially when collecting samples in ditches and natural channels. Additionally, other variability such as vaporization of volatile organics from the open sampler containers before the sample is put into sealed containers was possible. These conditions were minimized by temporarily altering the sampled channel, programming the sampler to begin at the minimum depth, and capping the sampler jars as soon as possible.

Summary

A first flush runoff (<30 min) sample was collected from each of 20 industrial sites located in North Carolina. Sample analysis results showed that the metals zinc and copper were the most common toxic contaminants being found in the runoff from all sites at concentrations ranging from 60 to 2 689 and 5 to 780 ppb, respectively. In contrast, the metals antimony, beryllium, selenium, silver, and thallium were not detected in any of the 20 samples. Volatile and semivolatile organics and pesticides were found in the runoff from eight sites with methylene chloride the most frequently detected compound. Conventional pollutants such as nutrients and solids were found in runoff from every site, many at concentrations greater than the corresponding median EMC measured from the NURP sites (U.S. EPA, 1983b).

Because only one sample was collected per site, generalizations drawn for the data should be limited; however, several observations seem appropriate. First, industrial groups with a lot of exposed metal on site (JY, SR, and MF) tended to have higher concentrations of the metals Cu, Pb, and Zn than all other groups except wood preservers. First flush runoff from wood preservers had high concentrations of As, Cr, and Cu probably due to the use of these metals in the preserving process. Finally, sites with consumer products stored or processed on site (LF II and SR III) tend to have higher BOD_5, COD, and nitrogen concentrations in runoff.

AVERAGE LOADING ANALYSIS FOR CITIES IN THE SAN PEDRO BAY TRIBUTARY AREA

August 12, 1999

R0011603

Introduction

As requested by the Regional Water Quality Control Board (RWQCB), we performed an analysis of pollutant loading from San Pedro Bay tributary areas for 4 constituents. The tributary watersheds in this study include the Los Angeles River watershed management area (WMA), the San Gabriel River WMA, and the Dominguez Channel/L.A. Harbor WMA. We made a loading comparison among the cities in Los Angeles County that lie in these tributaries.

It is our understanding that the RWQCB may use the analysis as a tool to allocate the share of the cost of a possible San Pedro Bay receiving water study. The cost would be proportioned according to the total loading contributed by each city. Two scenarios were examined, one in which the U.S. Forest Service area was included and one in which it was excluded.

Analysis

The pollutant loading was determined using the GIS Pollutant Loading Model developed by the Los Angeles County Department of Public Works (LACDPW). The model utilizes precipitation recorded throughout the county and imperviousness values assigned to land use categories to calculate a runoff flow volume. An event mean concentration (EMC) is obtained through the LACDPW water quality sampling program which collects stormwater runoff samples from eight different land use monitoring stations. The product of the runoff volume and the EMC produces an estimated pollutant loading.

As requested by the RWWCB, the analysis examined loading from four constituents: total suspended solids, total phosphorus, chémical oxygen demand (COD), and dissolved copper. The 1997-1998 seasonal EMC's of these constituents with an average annual rainfall amount were used to determine the total loading from each city and the U.S. Forest Service area. The list of cities was derived from the membership lists of each WMA. For the City and County of L.A., only those areas geographically within the WMA boundaries were included. Also note that because Rolling Hills and Rolling Hills Estates are geographically in the Dominguez Channel/L.A. Harbor WMA, they were included in the analysis, even though they administratively belong to the Ballona Creek WMA. Areas in Orange and Ventura Counties, although tributary, were not included.

The total pollutant loading was calculated by summing the loading from the individual constituents. The cities were then ranked according to the percentage of total load. The attached pages include a map of the study area, tables of the loadings for each jurisdiction along with their rank, a rainfall isohyet for the average annual rainfall, and a table of the 1997-1998 seasonal EMC's of the four constituents used for analysis.

Results

There are 72 individual jurisdictions involved in this analysis, including the U.S. Forest Service and unincorporated Los Angeles County. Based on this study, the greatest percentage of the total loading is generated by the City of Los Angeles (26.5% with U.S. Forest Service, 29.5% without) followed by the U.S. Forest Service (10.3%), where included, or unincorporated areas of Los Angeles County (9.33% with U.S. Forest Service, 10.4% without). The balance of the jurisdictions contribute less than 4% each.

INTRODUCTION

Urban stormwater runoff is now regarded as one of the largest sources of pollution to the coastal waters of the United States. In Southern California, point source control and advanced sewage treatment have greatly reduced the emissions of contaminants from sewage treatment plant and industrial discharges into the ocean. As a consequence, mass emissions from stormwater runoff now constitute a much larger portion of the constituent inputs to receiving waters and may represent the dominant source of some contaminants such as lead and zinc.

Stormwater runoff is widely believed to be one of the largest sources of contaminants to coastal waters.

While stormwater runoff can produce impacts in both freshwater and seawater environments, effects on the ocean are of greatest concern in urban Southern California. Our coastal waters provide many beneficial uses, including recreation, aesthetic enjoyment, fishing, marine habitat, fish reproduction, industrial water supply, and navigation. Ocean-dependent activities contribute approximately $9 billion annually to the economies of coastal communities in Southern California.

Substantial resources are spent monitoring the chemical constituents in stormwater runoff, yet little is known about the effects of these inputs once they enter the ocean. Of greatest concern to the public are whether impairments are occurring to the beneficial uses that relate to human health (safety of swimming and seafood consumption) or ecosystem health (presence of a natural balance of species). Stormwater discharge has the potential to impair these beneficial uses through: 1) contamination of recreational waters or seafood with disease-causing microbes, 2) aesthetic degradation from trash and reduced water clarity, and 3) ecosystem degradation from contaminants or other stormwater constituents.

Current water quality monitoring programs do not assess the effects of stormwater runoff on the environment.

Understanding the effects of stormwater on beneficial uses is essential. Information about the extent and type of adverse impacts is useful to guide and refine management actions to improve water quality. The monitoring programs of various agencies collect information that is useful for assessing some beneficial use impairments, primarily those related to human health. For example, public health and sanitation agencies regularly conduct shoreline microbiological monitoring near storm drain discharges, which indicates impacts to swimming and shellfish consumption. However, very little information is available to assess the impacts of urban stormwater on ecosystem health. Studies of impacts to freshwater systems (particularly in the west) are rare; impacts to the coastal ocean have never been assessed.

This report summarizes a three-year study funded by the Los Angeles County Department of Public Works, Southern California Coastal Water Research Project (SCCWRP), and University of Southern California (USC) Sea Grant Program.

This study is one of the first to assess stormwater impacts on the marine ecosystem.

This study examined plume characteristics, water column and seafloor biology.

The purpose of the study was to assess the impacts of urban stormwater runoff to the receiving waters of Santa Monica Bay. The goal of this study was to examine impacts that were relevant to ecosystem health, rather than impacts related to human health or recreation issues. This effort was conducted by an interdisciplinary team of scientists from SCCWRP, the University of Southern California, and the University of California at Santa Barbara.

The Santa Monica Bay Receiving Waters Study incorporated four design elements. The first element used physical and optical oceanographic instruments to characterize the size, composition, and mixing of stormwater plumes, providing information on the impacts to beneficial uses that are associated with water clarity. The second element used toxicity tests to assess the biological effects of runoff on water column biota and to identify the responsible toxicants. The third element examined seafloor biota and chemistry in order to assess the long-term effects of storm-discharged particles with their associated contaminants.

Comparisons between Ballona and Malibu Creeks evaluated effects of different watershed types.

The fourth element of the study design was a comparison of stormwater impacts from different watershed types. Land use patterns and development within a watershed are thought to influence the composition and quantity of stormwater runoff. The influence of watershed type was investigated by comparing stormwater impacts in the receiving water offshore of the highly urbanized Ballona Creek watershed with impacts in the receiving water offshore of the less-urbanized Malibu Creek watershed (Figure 1).

Sampling and analysis were conducted over three wet seasons (1995/96 to 1997/98). This document provides a summary of the study and focuses on major concepts and important findings. For the detailed results and raw data, we encourage readers to consult the Annual Progress Reports, available through USC Sea Grant.

STORMWATER PLUME CHARACTERIZATION

The impact of stormwater on the coastal ocean is determined by the composition of the stormwater and the dynamics (mixing, transport, and persistence) of the stormwater plume once it enters the coastal ocean. These dynamics influence the location, duration, and magnitude of impacts from stormwater.

The low salinity and high turbidity of stormwater provide markers that allow plumes to be mapped in the ocean.

The research team mapped the three-dimensional distribution of the stormwater plumes resulting from several winter storm events during 1996-1998. Mapping was performed using a towyo system, which carried sensors to measure temperature, salinity, light transmission (turbidity), chlorophyll fluorescence (plant biomass), and ambient visible light. The towyo was towed through the water in a vertical zigzag pattern that enabled us to map the horizontal and vertical distributions of the measured parameters. In addition, surface water was pumped to similar sensors on the boat so that the distribution of these parameters at the water's surface could be mapped. Maps were constructed for two regions of Santa Monica Bay, the receiving waters offshore of Ballona Creek and those offshore of Malibu Creek.

The characteristics of stormwater discharged into Santa Monica Bay from the two watersheds were similar in several respects. The most obvious and important physical characteristic was that the stormwater, being primarily composed of freshwater, had very little salinity. This low salinity enabled us to trace the stormwater plume in the ocean and differentiate it from the ambient seawater, which was not directly influenced by stormwater discharge. The stormwater also contained high concentrations of suspended particulate material, derived from various sources such as land erosion, street dust, aerial deposition, and litter. Suspended particulate material increased the turbidity of water by scattering and absorbing light. The turbidity and salinity together allowed the differentiation of seawater influenced by stormwater discharge from seawater containing freshwater from direct rainfall input.

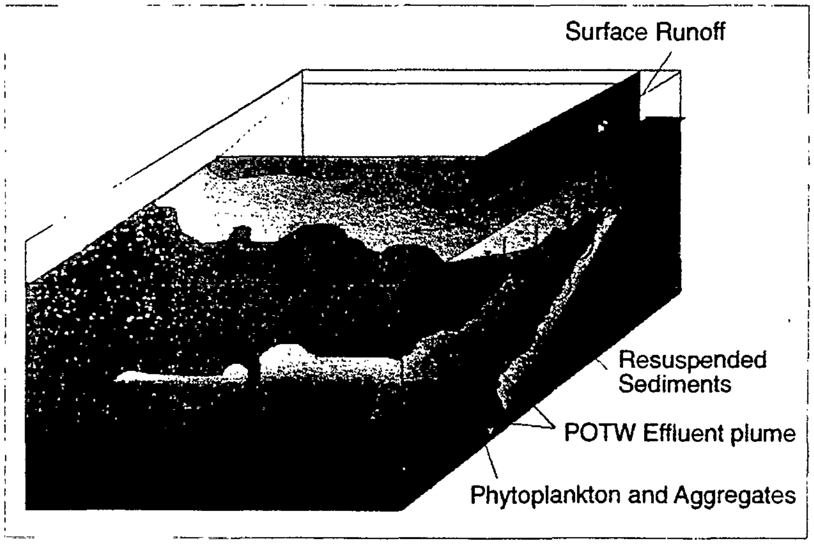

FIGURE 2

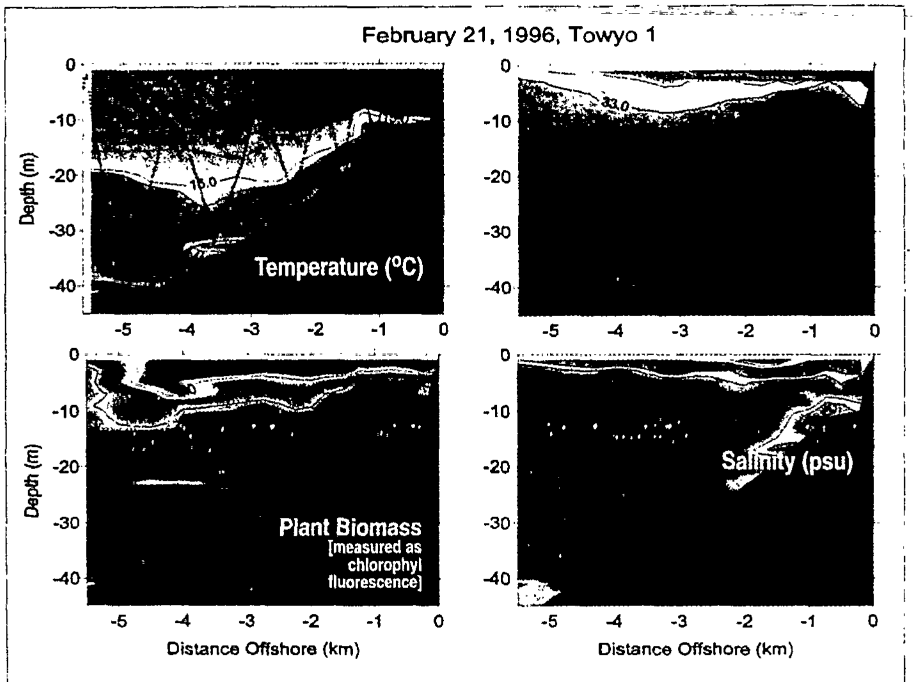
Schematic of coastal ocean with several sources of suspended particulate matter. Sources include surface runoff, Publicly Owned Treatment Works (POTW) discharge, bottom resuspension, and naturally occurring phytoplankton and detiritus.

R0011619

The stormwater plume was most concentrated in the surface layer.

Understanding the dispersion and fate of stormwater plumes is a complex task. The distribution of dissolved components such as nutrients and small particles is dependent upon the amount of rainfall, the coastal currents, and the winds, which can drive currents and cause vertical mixing (Figure 2). Large stormwater particles often have a different fate; they settle out of the low salinity plume, become incorporated into bottom sediments, and may be redistributed later by wave resuspension and transport. As the plume disperses, the components of stormwater mix with other sources of suspended particles, nutrients, and freshwater in the receiving water. These sources include bottom resuspension, phytoplankton growth, and wastewater discharge.

FIGURE 3



Vertical cross-shelf sections of the Ballona Creek discharge plume following a storm event in February, 1996. The maps shown were generated using a towyo system, which carried sensors for temperature, salinity, turbidity (beam attenuation), and plant biomass (chlorophyll fluorescence). The zigzag pattern on the temperature section indicates the path of the towyo. The stormwater plume is indicated by water with a salinity less than 33.0 practical salinity units (psu).

Stormwater plumes usually formed relatively thin layers at the surface of the ocean that are 2-10 m deep (Figure 3). The depth of penetration increased with time as winds mixed the upper layer vertically. The horizontal scales of the plumes studied in Santa Monica Bay were variable, with plumes extending from 1 to 6 miles cross-shelf (offshore) for storms of 1- to 2-year frequencies (0.8 to 4 in. of rainfall). During the February 19-21, 1996 storm (4 in. of rainfall), the plume spread approximately 4 miles offshore of Ballona Creek (Figure 4).

The speed and direction of coastal currents determine the cross-shelf scale of the plume. The Coriolis force (an apparent force that acts on oceans and lakes) also has an influence on the distribution of stormwater plumes. This force is due to the rotation of the earth and its motion through space, resulting in a tendency for currents to turn toward the right in the Northern Hemisphere. If the plume is carried to the north when it enters the ocean, it will be more likely to remain near the coast due to the influence of the Coriolis force.

The distribution of stormwater plumes along the coast depended upon the tidal variations in the currents, the presence of additional runoff sources, and the amount of runoff. Longshore distances of up to 6 miles were measured for plumes within Santa Monica Bay.

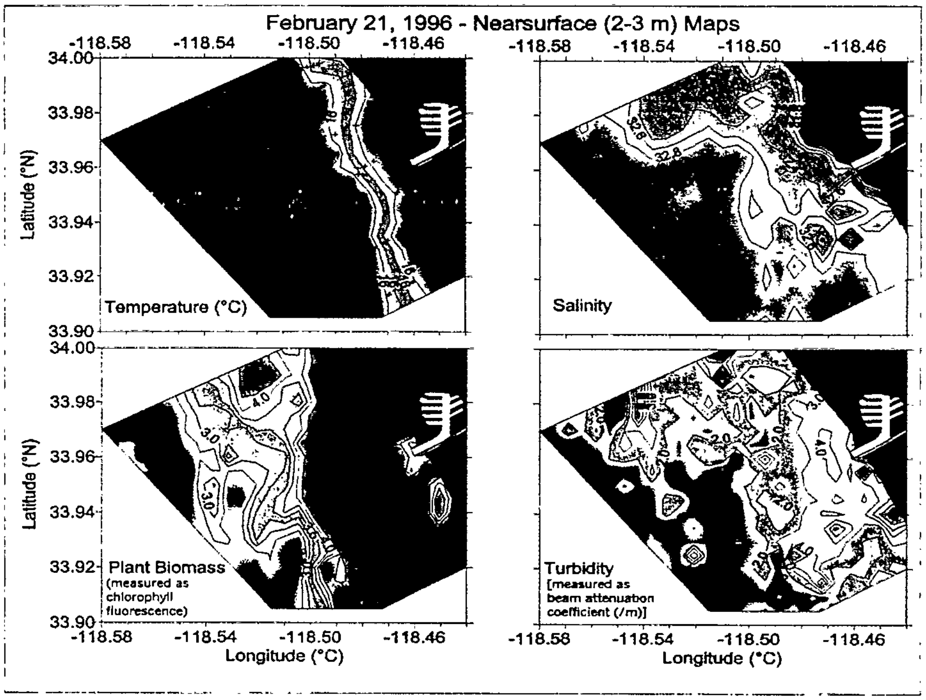
Spatial gradients in the dissolved and particulate components of the plume occurred as it was diluted through mixing with the receiving water. Although larger stormwater particles tended to settle out from the plume rapidly, smaller, lighter particles remained in suspension near the surface (Figures 3 and 4), where they can reduce the amount of light available for photosynthesis by marine plants. Measures of primary production were not part of this study, so adverse effects on phytoplankton in Santa Monica Bay resulting from turbid stormwater plumes were not determined.

Stormwater plumes reduced surface water clarity and persisted for several days after a storm.

The duration of stormwater plumes depends upon the rate of plume dispersion and particle sinking. Stormwater plumes were observed to persist in Santa Monica Bay for at least three days, even for the smallest storm sampled (0.8 in. rainfall). The maximum duration of stormwater plumes could not be assessed in this study because measurements did not extend more than three days after a storm.

High concentrations of the plant pigment chlorophyll were present in the surface layer during some storm events, indicating the presence of increased phytoplankton populations. Phytoplankton growth may have been stimulated by stormwater discharge due to the addition of nutrients to the surface layer, where light is readily available. Dense patches of phytoplankton were observed off of Malibu Creek on the boundary of stormwater plumes 1-2 days after rain events. Off of Ballona Creek, we observed increased phytoplankton in the plume even while a large proportion of suspended particulate material was still present in the surface water. The ecological effects of these changes in phytoplankton density were not determined in this study.

FIGURE 4



Near surface map of the February, 1996 stormwater plume from a 2-year storm off of Ballona Creek. The plume (surface water with a salinity less than 33.0 psu) extended approximately 4 miles offshore.

R0011621

WATER COLUMN BIOLOGY

The initial and most concentrated exposure to stormwater occurs in the upper few meters of the water column. A diversity of organisms occupies this habitat, ranging from mobile fish and mammals to drifting microscopic plants and animals (plankton). Plankton have a relatively high potential to be affected by stormwater toxicants because they have a limited ability to avoid the plume and are often more sensitive to contaminants than larger animals. Changes in the abundance and type of plankton present can have important consequences for the marine ecosystem. This group of organisms constitutes the base of the food chain for most marine life, so changes in plankton numbers may affect populations of other species. The larvae of many fish and other animals such as sea urchins, clams, and shrimp occur in the plankton, providing the potential for diminished reproductive success if their survival is reduced by water column toxicity.

Water column effects were measured using toxicity tests.

Toxicity tests were used to determine whether stormwater plumes contained harmful concentrations of dissolved constituents. Surface water samples were collected offshore of the two study sites in conjunction with measurements of the plume characteristics so that the data could be related to the concentration of the stormwater discharge plume. Samples of stormwater collected from Ballona Creek were also measured for comparison. The toxicity tests used sensitive stages of marine species that occur in Southern California. Most samples were measured using the sea urchin fertilization test, in which the effect of the sample on the ability of sea urchin sperm to fertilize eggs is measured. Sea urchin sperm are highly sensitive to some types of dissolved metals. The fertilization test is appropriate for stormwater monitoring because it is rapid (40 min exposure) and uses an organism which spends a portion of its life cycle in the water column of Santa Monica Bay. All tests were adjusted to the appropriate salinity prior to exposure so only the effect of chemical constituents were evaluated.

Virtually every sample of Ballona Creek stormwater tested was toxic.

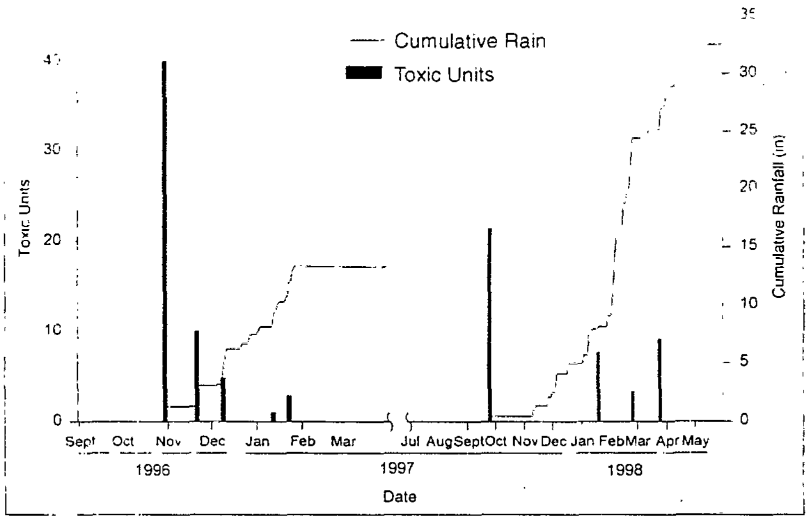
Undiluted samples of urban stormwater collected from drainage channels (before discharge into the ocean) usually contained toxic concentrations of constituents. Toxicity was detected in virtually every sample obtained from Ballona Creek and this toxicity was often present even after the sample was diluted 10-fold in the laboratory. The results indicated that even though a large portion of the constituents present in stormwater may be bound to particles, the dissolved concentrations of some materials are high enough to cause toxicity. Prior research by SCCWRP and others has detected toxicity in stormwater from other watersheds in Los Angeles, Orange, and San Diego Counties.

The first storms of the year produced the most toxic stormwater.

The results showed that time of year was an important variable influencing stormwater toxicity (Figure 5). Samples of Ballona Creek stormwater, obtained from the first storm of the season, were between two and ten times more toxic than samples from later storms. These data indicated that the first storms of the year provide the most concentrated inputs of toxicants to the environment.

Toxicity was frequently detected in surface water within the stormwater plume offshore of Ballona Creek, indicating that the initial dilution of stormwater discharge from this watershed was not sufficient to reduce the concentrations of stormwater toxicants below levels that are harmful to marine organisms. The magnitude of toxicity was greatest in the portion of the plume nearest the mouth of Ballona Creek (Figure 6), where the highest concentrations of stormwater were present. Within the plumes studied, toxicity was usually present whenever stormwater concentrations above 10% were present. The duration of toxicity in surface waters was not specifically addressed in this study, but can be expected to be determined by the rate of plume dispersion. In this study, toxicity was detected in surface water near the mouth of Ballona Creek two days after a storm event.

FIGURE 5

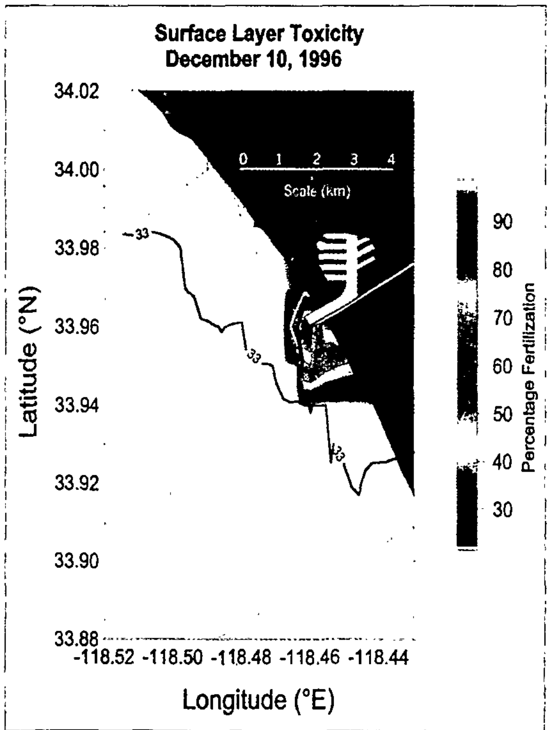


Seasonal changes in the toxicity of Ballona Creek stormwater over two storm seasons. Toxicity was measured using the sea urchin fertilization test. The greatest toxicity was observed in stormwater obtained from the first storm of each year.

Toxic portions of the stormwater plume were variable in size, extending from 1/4 to 2 miles offshore of Ballona Creek.

The spatial extent of surface water toxicity varied between storms, and was influenced by the amount of storm flow, the degree of toxicity of the stormwater, and the amount of mixing that occurred upon discharge. The greatest offshore extent of toxicity was measured following a storm on February 21, 1996, a two-year event, when toxicity was detected 2 miles offshore of Ballona Creek. For other storms, the toxic portion of the plume extended ¼-1 mile offshore. The distribution of toxicity along the shoreline was not determined in this study. The boundaries of stormwater plumes can be described using a number of parameters (i.e., salinity, turbidity, and toxicity) each with different thresholds of detection. Because a relatively high concentration of stormwater is

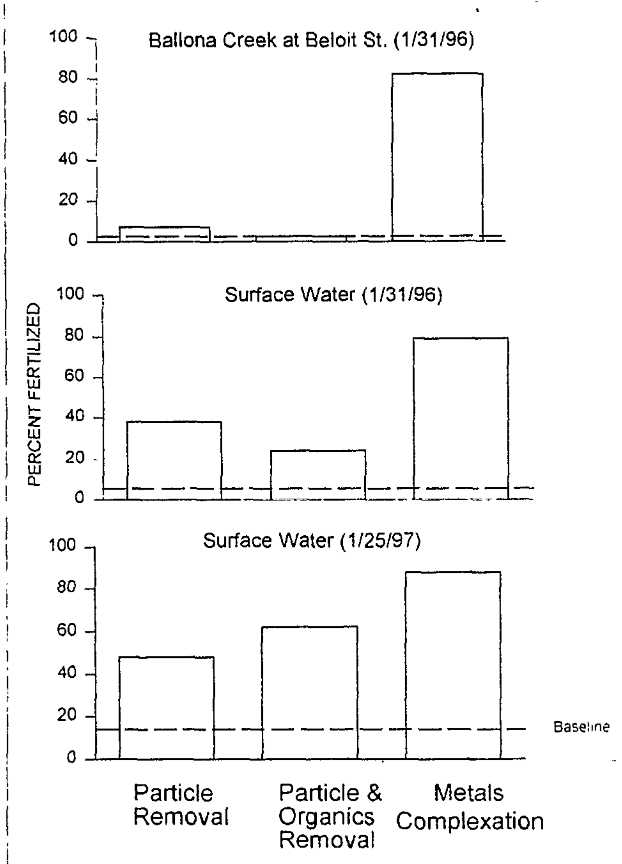
FIGURE 6



Map of surface layer toxicity (effect on sea urchin fertilization) from Ballona Creek stormwater discharge following a 2-year storm in December, 1996 (3.1 in. rainfall). Expected toxicity was calculated from measurements of salinity (indicates concentration of stormwater) and the concentration dose-response curve for the effects of stormwater on sea urchin fertilization. The greatest toxicity (lower fertilization percentage) was present closest to the point of discharge. The area of toxicity was smaller than the physical extent of the plume, as indicated by the solid line showing a salinity of 33 psu. This figure illustrates the relative size of the toxic portion of the plume for a single storm, but does not represent the largest plume offshore for other storms.

Surface water toxicity caused by unidentified sources was frequently encountered during dry weather.

FIGURE 7



Effect of toxicity identification evaluation treatments on the toxicity of Ballona Creek stormwater and two samples of surface water collected within the Ballona Creek discharge plume. Complexation of metals by addition of EDTA usually eliminated toxicity, as shown by the large increase in sea urchin fertilization above the untreated (baseline) value. Other treatments, removal of particles by filtration and removal of organic compounds, were of limited effectiveness. Similar results were found for other samples of stormwater and surface water.

needed to produce toxicity, the area of potential biological impact within a plume will be smaller than the region defined by physical characteristics such as salinity (Figure 6).

An unexpected result of this study was the detection of toxicity in receiving waters that appeared to be due to sources other than urban runoff. An average of 53% of the surface water samples collected offshore of Ballona and Malibu Creeks during periods of dry weather were found to be toxic. The location of the toxic samples was variable and there was no relationship between toxicity and the amount of freshwater in the samples, indicating that dry weather urban runoff was not the cause. Additional sources of receiving water toxicity were also indicated during the wet weather sampling, as some water samples were more toxic than could be accounted for by the amount of stormwater present.

The dry weather toxicity results suggest that factors other than stormwater discharge have a major influence on surface water quality in Santa Monica Bay. While the cause of dry weather toxicity was not determined, its frequent detection indicates that impaired surface water quality in Santa Monica Bay extends beyond the spatial and seasonal boundaries associated with stormwater discharge. Potential sources of dry weather toxicity include the deposition of contaminants from the atmosphere, biological events such as red tides, and inputs from boating activities.

Dissolved metals in stormwater were identified as important contributors to impaired water quality in Ballona Creek stormwater plumes. This conclusion was the result of experiments that combined chemical treatments designed to remove specific types of constituents in water samples with sea urchin toxicity tests, a process known as Toxicity Identification Evaluation (TIE). The toxicity of Ballona Creek stormwater and receiving water samples was usually eliminated when treatments were applied that neutralized toxic trace metals by complexation (Figure 7). Chemical analysis confirmed that dissolved concentrations of zinc, and occasionally copper, were at toxic levels in undiluted stormwater. The dissolved concentrations of other metals were below toxic levels for the sea urchin test. Measurements of receiving water also detected elevated concentrations of zinc (but not copper) in the stormwater plume offshore of Ballona Creek.

Chemical analysis were unable to attribute all of the toxicity measured to zinc and copper, indicating that additional constituents may contribute to the toxicity of stormwater discharged into Santa Monica Bay. The measured concentrations of zinc and copper in Ballona Creek stormwater were estimated to account for only 5-44% of the observed toxicity. Zinc concentrations in the toxic portion of the discharge plume were usually below levels shown to cause toxicity in the laboratory. The unaccounted-for toxicity may be due to synergistic interactions between toxic metals, variability in the chemical analysis, or the influence of other toxic chemicals, such as pesticides. Additional research is needed before these alternatives can be evaluated. TIE studies have not been completed for other stormwater discharges into the Bay, so we do not know if the pattern demonstrated for Ballona Creek is representative of other sites.

Zinc was the most important toxic constituent identified in stormwater. Copper and other unidentified constituents may also be responsible for some of the toxicity measured.

SEAFLOOR BIOLOGY

Much of the natural diversity and many of the commercially important species in the ocean occur on the seafloor. Clams and shrimp live in this environment, as well as worms and starfish, all of which serve as food for fish. This is also the location where stormwater particles, and associated contaminants, eventually settle. Unlike the water column, where a stormwater plume eventually mixes and disperses, the sediments on the seafloor can accumulate runoff inputs over an entire storm, over several storms, or over several seasons. These inputs can alter the seafloor biology by either changing the habitat, such as altering sediment grain size, or by the build-up of pollutants. The potential for impacts to seafloor organisms is great because they are not mobile and are therefore subjected to the accumulated stormwater inputs for long periods of time. Typically, these seafloor organisms are relatively sensitive and changes to the number or types of organisms may result in changes to fish populations.

The deposition of stormwater particles influences the physical and chemical characteristics of the seafloor.

We estimated impacts of stormwater runoff discharges on the seafloor by collecting samples from the ocean bottom between one and two weeks following large storm events, after the stormwater plumes had dispersed and particles had time to settle, and then again during dry weather. Seafloor samples were collected directly offshore of Ballona and Malibu Creeks at 75 ft. depth in the heart of the stormwater plumes, along intervals upcoast and downcoast representing gradients of plume impact, and then outside the area of the plume. The top 2 cm (< 1 inch) of these seafloor samples, which represented the most recent seafloor accumulations, were collected for contaminant analysis and toxicity testing. Sediment samples were analyzed for contaminants including trace metals, chlorinated hydrocarbons (DDTs and PCBs), and petroleum hydrocarbons (PAHs). The toxicity tests included survival of crustaceans (an amphipod) and sea urchins, fertilization success and development of sea urchin embryos, and bioaccumulation of contaminants from seafloor mud in adult sea urchins. A second sediment sample was collected, sieved through a fine mesh screen, and the organisms were enumerated to determine the abundance and diversity of the native seafloor fauna.

An increase in sediment constituents was present on the seafloor offshore Ballona Creek.

TABLE 1

		Sediment Concentration

Silver	µg /dry g	**0.95**	0.31
Zinc	µg /dry g	54	56
Total DDTs	ng/dry g	**25.6**	15.5
Total PCBs	ng/dry g	**21.5**	3.0
Total PAHs	ng/dry g	**240.6**	56.2

Average concentrations of sediment constituents offshore (75 ft. depth) of creek mouths in Santa Monica Bay following storm events between 1995 and 1997. Boxed numbers indicate significantly higher concentrations. Sediment offshore of the less urbanized watershed (Malibu Creek) had higher levels of naturally occurring constituents such as aluminum and iron. Higher concentrations of anthropogenic constituents such as lead and PAHs were present offshore of the more urbanized watershed (Ballona Creek).

Alterations to the seafloor habitat and sediment constituent concentrations had occurred offshore of the Ballona Creek watershed (Table 1). The sediments offshore of Malibu Creek generally had higher concentrations of naturally abundant constituents including fine-grained particles, organic carbon, and trace metals such as chromium. In contrast, the sediments offshore of Ballona Creek generally had higher concentrations of urban contaminants including common stormwater constituents such as lead and zinc, as well as other rarely detected constituents in routine stormwater monitoring programs, such as DDTs, PCBs, and PAHs. Moreover, sediments offshore of Ballona Creek showed evidence of stormwater impacts over a large area. Concentrations of copper, lead, zinc, DDTs, PCBs, and PAHs were highest directly offshore of the creek mouth and then decreased in both the upcoast and downcoast directions at distances up to 3 miles away (Figure 8). The increased sediment contamination was also observed more than 1 mile offshore, where water depths reached over 100 feet.

Biological communities offshore of Ballona Creek were similar to those offshore of Malibu Creek (Table 2). Both areas had comparable abundance and similar species composition. Seventeen of the 19 most commonly found taxa offshore of Ballona Creek were present offshore of Malibu Creek, and both watersheds had a low abundance of so-called "pollution indicator" organisms. Both areas had healthy benthic communities, as measured by the Benthic Response Index, which is a tool for assessing the relative importance of pollution indicator species at a site. Species richness and diversity were statistically higher near Malibu Creek than Ballona Creek.

Biological communities offshore of Ballona and Malibu Creeks were also similar to background reference conditions established in previous studies of Southern California (Table 2). The mean abundance, mean number of taxa per sample, and mean diversity at the creek sites were comparable to reference sites located in waters of similar depth, but distant from river and creek mouths. The present study was limited to the area offshore of the Ballona Creek jetty; previous studies by other scientists have shown impacts to benthic communities and the presence of pollution indicator organisms inside of the jetty (adjacent to Marina del Rey).

The seafloor biology results were consistent with the results from sediment toxicity tests. Seafloor sediments offshore of Ballona Creek did not kill amphipods or impair the fertilization success or normal embryo development of sea urchins. However, seafloor sediments were found to be a potential source of contaminants that bioaccumulate in seafloor organisms such as adult sea urchins. Concentrations of lead, DDTs, and PCBs were three to ten times higher in sea urchins exposed to sediments collected offshore of Ballona Creek than in sea urchins living on sediments from our reference location. While the effect of this bioaccumulation on the sea urchin is not known, it does represent a mechanism by which sediment- associated pollutants can enter the food chain and biomagnify within fish.

The fate of most stormwater constituents is unknown.

One significant finding of this study was that the fate of most stormwater constituents discharged to Santa Monica Bay is unknown. Although we documented the accumulation of contaminants on the seafloor offshore of Ballona Creek, these amounts were not permanent and represent only a fraction of the total mass emissions discharged. Further, reductions in constituent concentrations were observed at some locations that may have resulted from the resuspension and transport of sediments by waves and currents. Until the location where this material eventually settles is known, we cannot be certain that we have examined the seafloor areas having the greatest influence from stormwater or dry weather discharges. An additional concern is that constituents from other sources may have similar transport and fate mechanisms, producing enhanced impacts from the cumulative effects of multiple sources.

TABLE 2

	Ballona (n=8)	Malibu (n=7)	Reference (n=29)
Abundance (No. organisms/ 0.1 m²)	238 (±51)	316 (±55)	276 (±61)

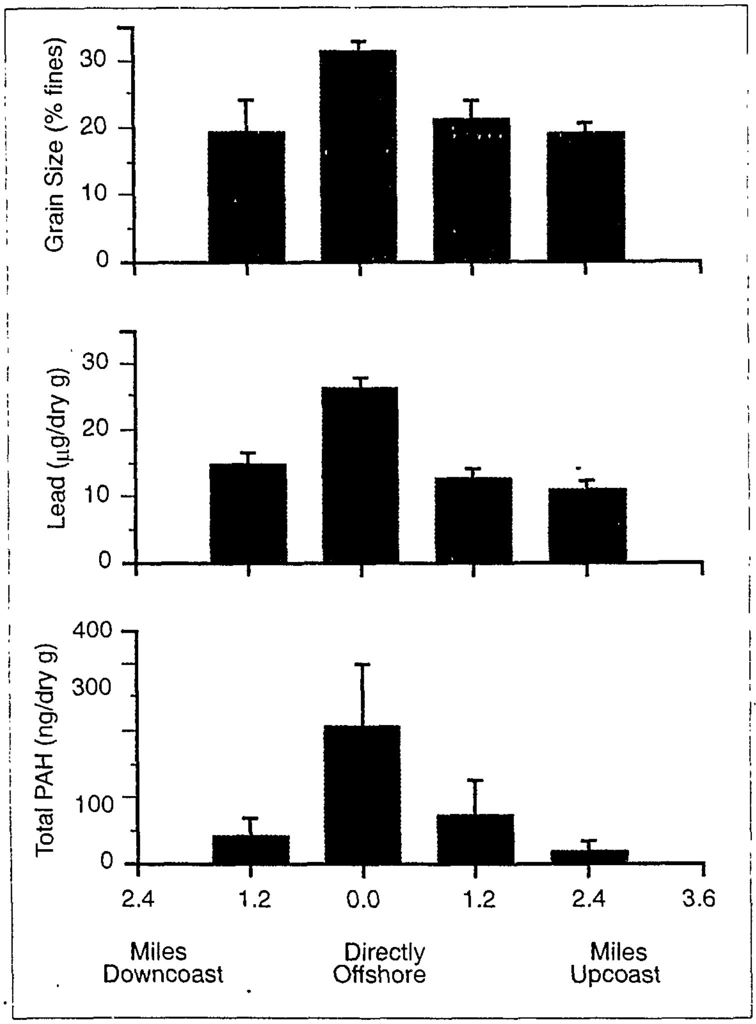
Biological community parameters offshore of a highly urbanized watershed (Ballona Creek), a less urbanized watershed (Malibu Creek), and other reference areas in near-coastal waters of Southern California at similar depths (30 to 75 feet). Values are the mean (±95% confidence limits).

FIGURE 8



Grain size and contaminant concentrations in surface sediments across the gradient of stormwater influence offshore of Ballona Creek. Sampling stations were located 1.5 miles offshore (75 ft. depth) and at various distances upcoast or downcoast of the creek. Each value represents the mean (±95% confidence interval) of eight samples, each collected after a storm event. The influence of stormwater particle deposition is shown by the elevated values directly offshore of Ballona Creek.

EFFECTS OF WATERSHED TYPE

The comparison of receiving water impacts from different watersheds is a powerful tool to distinguish between natural and man-made effects. Although the Ballona Creek and Malibu Creek watersheds are similar in size and discharge into the same body of water (Santa Monica Bay), they differ in their degree of urbanization (Figure 1). The measurement of similar parameters in each receiving water area provides the information needed to distinguish between natural processes and impairment due to man-made factors. This approach also identifies which monitoring methods are most useful for detecting man-made impacts.

Different impacts to Santa Monica Bay were produced by an urbanized and an unurbanized watershed.

The characteristics and impacts of stormwater from the Ballona Creek and Malibu Creek watersheds were found to differ in a number of respects (Table 3). The impacts observed were the result of the interaction of three key factors: land use, flow characteristics, and receiving water conditions. Receiving water impacts were less near Malibu Creek and were related to the discharge of less toxic stormwater and lower peak flows.

Ballona Creek watershed is highly urbanized. Stormwater entering the concrete channel is rapidly transported to the ocean, with little opportunity for dilution.

Malibu Creek drains a mostly undeveloped watershed. Stormwater flow and particle inputs into the ocean are moderated by the presence of a natural creekbed and coastal lagoon.

R0011628

TABLE 3

	Ballona Creek	Malibu Creek
Watershed Characteristics	The largest watershed draining to Santa Monica Bay, 83% of its 130 square miles is developed. The principal land use is residential.	Similar in size to Ballona Creek (110 square miles), 88% of this watershed is undeveloped.
Flow Characteristics	The largely impermeable surface area (41% overall) and concrete channel drainage system results in rapid changes in flow following rainfall. Peak flows are relatively high and of shorter duration compared to other areas.	More permeable surface area (96% overall) absorbs early season rainfall and increases lag time between rainfall and peak flow. Discharges have relatively lower peak flows but duration can be days longer than concrete channelized systems. Discharge into Malibu Lagoon may reduce flows and particle loads to ocean.
Plume Characteristics	The stormwater plume in both areas consisted of a thin buoyant layer of low salinity water floating at the surface. The dissolved and particulate components of stormwater were most concentrated in the upper 2 m of the water column. Plumes extended up to 6 miles offshore and were widely distributed along the shore.	
	Higher flows and less mixing produced well-defined plumes that contained higher concentrations of stormwater near Ballona Creek.	Lower flows, more mixing, and discharges from adjacent canyons resulted in more complex and ill-defined plume boundaries near Malibu Creek.
Debris	Floating debris was often concentrated near the margins of the plume and contained many items of man-made origin, such as plastic.	Floating debris was dominated by organic materials of natural origin, such as twigs and charred wood.
Water Clarity	Less mixing of stormwater usually produced larger areas of reduced water clarity.	Stormwater inputs were often more turbid, but lower flows and greater dilution near the mouth resulted in better clarity.
Stormwater Toxicity	Samples from the creek were always toxic to sea urchins. Concentrations higher than 10% stormwater usually produced adverse effects in laboratory tests.	Samples were less toxic than Ballona Creek stormwater and occasionally nontoxic. High concentrations (>25%) usually needed to produce toxicity.

Characteristics of a highly urbanized watershed (Ballona Creek) and a less urbanized watershed (Malibu Creek) adjacent to Santa Monica Bay, California.

R0011629

TABLE 3 Continued

	Ballona Creek	Malibu Creek
Receiving Water Toxicity	Surface water in most concentrated portion of plume was often toxic to sea urchins. Toxicity was detected in receiving waters up to 2 miles from discharge.	Toxicity in water column was rarely present and was not related to plume concentration.
Cause of Toxicity	Zinc is responsible for a portion of the stormwater toxicity. The influence of pesticides and other organics is uncertain.	Metals are implicated but have not been confirmed as important toxicants.
Seafloor Habitat	Sediments were higher in urban stormwater associated contaminants, such as lead and zinc.	Higher concentrations of constituents were derived from natural sources, such as fine sediments and organic carbon.
Sediment Toxicity	Changes in sediment toxicity were minor and not related to stormwater discharges.	
Seafloor Biological Communities	Biological communities were similar among Malibu Creek, Ballona Creek, and background reference sites.	

R0011630

RECOMMENDATIONS FOR FUTURE STUDIES

The Santa Monica Bay Receiving Waters Study produced the first integrated assessment of impacts from stormwater discharges into the Bay. The presence of well-developed plumes containing toxic materials demonstrates the need for continued studies of the impacts from urban stormwater runoff in Santa Monica Bay and elsewhere. Additional information regarding the sources, characteristics, and extent of the receiving water impacts should be determined in order to refine management actions.

A high priority should be placed upon locating sources of toxicity and contamination within the Ballona Creek watershed. Identification of the land uses or regions of the watershed that contribute most to the impacts will enable management actions to be targeted where they will have the greatest beneficial impact. Source identification studies should include sampling of systems tributary to Ballona Creek for measurement of toxicity and chemical constituents.

Additional receiving water studies are recommended for Santa Monica Bay to provide a more complete understanding of the nature and magnitude of stormwater impacts. Future studies should include constituents of concern that were not emphasized in this study, such as bacteria, nutrients, pesticides, and trash. These constituents should be incorporated into studies of plume persistence, cause of toxicity, and constituent fate.

Information on the duration, size, and cause of adverse impacts is needed to identify appropriate stormwater management actions.

Plume persistence information is needed to estimate the duration of exposure of: 1) swimmers to bacteria and 2) marine life to stormwater toxicants and nutrients. Improved information on plume persistence can be obtained by the use of moored sensors in the discharge area in combination with data from remote sensing instruments (e.g., satellites). A goal of these studies should be to develop plume dilution and/or tracking models of plume duration and magnitude. This information is valuable because different management responses may be appropriate for stormwater discharges that produce short- versus long-lived impacts.

Toxicity testing using multiple marine species is also needed to provide a more complete assessment of the causes of toxicity in stormwater discharged into Santa Monica Bay. Identification of zinc and copper as contaminants of concern was based primarily on studies with a single species (sea urchin). Because different species vary in their sensitivity to contaminants, tests with multiple species are needed to determine if other contaminants are present at toxic concentrations. Tests with crustaceans (e.g., shrimp) are especially recommended as they are likely to be sensitive to pesticides such as diazinon and chlorpyrifos, which have been found to be important factors in the toxicity of stormwater from other watersheds. These tests should include toxicity identification procedures so that potential constituents of

A suite of species should be used to identify toxicants in stormwater.

concern (e.g., metals and pesticides) can be confirmed and others can be discounted. Toxicant identification is needed to prioritize chemical-specific management actions.

The fate of stormwater particles must be determined in order to assess seafloor impacts.

Chemical and oceanographic studies are needed to determine the fate of stormwater particles discharged into Santa Monica Bay. Although some of the particles in Santa Monica Bay stormwater plumes may be deposited near the mouth of an urban watershed, they do not necessarily persist there for long periods of time. Since the spatial extent of particle dispersal in Santa Monica Bay was not determined, there may be areas of significant accumulation that were not investigated. Studies of currents, sediment resuspension, and sediment transport, coupled with chemical source identification methods, should be conducted to determine whether stormwater discharge is a significant source of adverse sediment contamination within Santa Monica Bay. This information is needed to identify areas of the seafloor with the greatest potential for biological impacts from stormwater discharge.

Additional receiving water systems should be studied to identify impairments from other watersheds.

The impacts of stormwater runoff on other receiving water systems should also be studied. This is because differences in watershed size and land use patterns will likely result in different levels of risk to the receiving water beneficial uses. For example, changes in land use may contribute different toxicants, and changes in watershed size will influence the magnitude of the toxicant input. The nature of the receiving water environment is also important. Semi-enclosed water bodies, such as most bays and harbors, do not have the mixing and dilution capacity of the open coastal environment studied in Santa Monica Bay. The potential for impairment will be greater in these areas because organisms will have an increased exposure to the stormwater plume and more stormwater particles will settle nearby and influence sediment quality. Until the effects of variations in watershed or receiving water characteristics can be accurately predicted, additional integrated studies will be necessary to assess impacts to receiving waters in other areas.

Introduction

Twenty-one sites, including tributary drains and the main creek bed, were sampled for bedload sediment quality along Ballona Creek. The sediment sampling stations were designed to trace the upstream sources of contaminants of concern associated with sediment deposition at the mouth of Ballona Creek and the entrance to Marina del Rey Harbor. Deposited sediments were sampled from sediment accumulation areas representative of a variety of storm drain inputs into Ballona Creek. This report is a summary and evaluation of the chemistry results of the Ballona Creek sediment sampling program.

Sediment samples were collected from the channel bottom of 17 drainages at their mouths, immediately upstream of their confluence with Ballona Creek. In addition, sediments were sampled from the main channel of Ballona Creek at 4 locations. Samples were collected towards the end of the annual low-flow period, on October 5 and 6, 1999 (Table 1). This list varies from that presented in the Sampling and Analysis Plan (CH2M HILL 1999) in that Overland North and the Jefferson area drains were not sampled due to a lack of sediment accumulation. In addition, two new drains were added, from the Holly Hills drains entering below Dauphin Ave. and from the main drains entering under Higuera Street. Sampling locations are shown on the map in the Sampling and Analysis Plan and summarized in Table 1.

Methods

Field Sampling Methods

Deposited sediments were collected from drainage channel mouths and the main channel of Ballona Creek from areas visually determined to be sediment accumulation areas. The sediment was scooped from the channel bottoms with stainless steel hand trowels. Three separate equal-volume samples were collected within an approximate 1-meter radius and mixed thoroughly by hand in a stainless steel bowl. The resulting composite sample was packed with no head space into chemically clean glass jars. Samples were chilled in the field, held chilled, and transported to the laboratory within two days of collection.

Sampling equipment was chemically decontaminated between sites. A single decontamination rinsate sample (water sample) was collected for each day of sediment sampling.

Sediment Quality Constituents of Concern

The sediments were analyzed for those constituents listed in the Sampling and Analysis Plan and shown in the Results Section, below. Major contaminant groups investigated included metals, PAHs, organochlorine compounds, and pesticides. Grain size analysis and total organic carbon analysis was performed on all samples. All samples were collected in chemically clean glass jars, kept in the dark, and refrigerated prior to analysis.

Normalization of Results

The raw, wet chemistry results expressed in concentration units per weight of wet sediment would not offer a particularly effective means of comparison among sites. In contrast, several types of standardizations were created to provide insights into the differences in contamination among sites. The techniques used were:

- Dry weight normalization; all results were presented as concentration units per dry weight (DW) of sediment.

R0011636

- TOC normalization; all results were presented as dry weight concentrations per weight of total organic carbon (TOC) in the sample.
- Silt/clay normalization; all results were presented as dry weight concentrations per proportion of silt and clay in the sample.

Sediment chemistry results are presented in the Appendix for all samples and analytes on a wet and dry weight basis. Sediment chemistry results are presented using the three normalization techniques in Tables 2 - 5 for all sampling locations. Sediment toxicity guidelines, presented as Effect Range Low (ERL) values, are shown in the first column of Table 2 as a basis of comparison to known toxic levels of individual contaminants as assessed on a dry weight basis. Tables 3 - 5 shows the ordering of sites by level of contamination in sediment based on selected Table 2 results. Table 6 shows the average ranks for each site by analyte class.

Results

Comparisons Among Sites

The results are presented in several different ways as a means of elucidating differences among sites and to correct for biases in sediment chemistry associated with sediment deposition characteristics. Comparative toxicity information is available for sediment as assessed on a dry weight basis. Thus, dry weight results in Table 2 are presented in comparison to toxicity guidelines. The two additional normalization techniques (TOC and silt/clay) are useful in ranking sites by relative levels of contamination. In general, toxic constituents in sediments tend to be associated with fine particles and with organic compounds and the normalized results shown in Tables 3 and 4 provide a method of standardizing for variability in silt/clay and organic fractions in the samples. Depositing sediment is highly variable with respect to grain size and associated organic content that is associated with the physical process of site-specific deposition rather than sources of contaminants. Thus the normalized values, although not directly comparable to toxicity guidelines, were useful in ranking sites on the basis of the chemistry of the fine, organic fraction of the sediment.

The samples ranged from less than 1% silt plus clay fraction (Ballona Creek at Pickford) to 66% silt/clay (Inglewood Blvd.)(Table 2). Total organic carbon content ranged from 442 mg/kg (Ballona Creek at Pickford) to 17% of total sediment dry weight (Marvin Ave. drain). In general, many of the drains had only fine deposited sediment dominated by living and dead algal mats while the main Ballona Creek channel had relatively much more sand and gravel in the sediment. Locations with noticeable oil in the discharge were Ballona Creek below Pickford, Marvin Ave. (with tar included, as well), Ballona Creek below Fairfax, and Dauphin Ave (particularly heavy oil flow). In addition, the flow from Overland Ave. drain (north side, drain 9404) had no accumulated sediment to sample and appeared to be chronically toxic; no algae or plants occupied the area within the drainage flow or for several hundred feet downstream in Ballona Creek.

Only 4 of the 21 sites were without any chemical concentrations exceeding toxicity guidelines (ERLs); Dauphin Ave., Westwood St., Ballona Creek at Sawtelle, and Centinela Channel. The other sites most often exceeded ERLs for copper, lead, nickel, zinc, and anthracene. Four sites exceeded ERLs for total PAHs or total DDT compounds. With the exception of dieldrin, most pesticides and all PCBs were undetected in the samples (Table 2).

Site Rankings

The sites can be ranked on the basis of dry weight chemistry as presented in Table 2 and shown in rank order for selected constituents of concern. Table 3 shows that Pickford, Centinela Ave., Marvin, and Inglewood most consistently rank as the most contaminated sites with respect to metals and PAHs. The two areas of the main Ballona Channel ranked as most contaminated and exceeding ERLs were sites just downstream of Madison and Fairfax. Other main creek sites appeared relatively clean, probably as a result of dilution of the toxic fraction by gravel and sand.

Rankings based on silt/clay normalized results revealed that Ince Blvd. and Ballona Creek locations at Pickford and Sawtelle could be added to the list of more contaminated sites (Table 4). Marvin, Inglewood, Pickford, and Centinela Ave. remained in the ranks of more contaminated drains in this analysis.

When viewed as TOC normalized values, Ballona Creek sites at Pickford and Fairfax and Higuera, Centinela Ave., Sepulveda Blvd., and Ince drains appeared most contaminated (Table 5). These TOC-based rankings are particularly important in the case of organic contaminants (PAHs).

The summary of average ranks based on the dry weight values as shown in Tables 2 and 3 is shown in Table 6 for major groups of contaminants. For combined metals the 5 most contaminated sites (in order of most contaminated to least) were Pickford, Centinela Ave., Inglewood, and Marvin/Overland (tie). For combined PAHs, the 6 most contaminated sites (same ordering) were Centinela Ave., Inglewood, Madison, St. Nicholas, and Higuera/Sepulveda Blvd (tie). Centinela Ave and Pickford drains consistently rank as containing the most contaminated sediments for either metals or PAHs. The main Ballona Creek sites, Sepulveda Channel, and Centinela Channel consistently rank as among the cleanest sites.

Conclusions

The deposited sediment in the Ballona Creek drains, as sampled toward the end of the seasonal dry period in 1999, represented baseflow conditions incorporating an unknown degree of contaminant accumulation since the last stormwater flows. To the extent that the samples analyzed in this report represent an averaging of upstream sediment quality, results can be compared for relative sediment toxicity and overall levels of contamination. Presumably, the sediments analyzed here were washed out and replaced with stormflow bedload as part of the first rainfall flows in the fall of 1999. It is assumed that the relative contamination associated with suspended sediment in stormflows can be generally related to the sediment quality results as presented in this report.

As shown in Tables 3– 6, many drains into Ballona Creek possess sediments with potentially toxic concentrations of contaminants. The most upstream locations (Pickford and Ballona Creek below Pickford) rank among the most contaminated locations. Many of the drains along the length of Ballona Creek also contribute contaminated sediment. The rankings and comparisons to ERL values shown above point out those most contaminated sites. It is notable that the bedload sediment in the major tributary drains of Sepulveda and Centinela Channels are among the least contaminated samples. Upstream control measures focused on those most contaminated drainages would be likely to improve the quality of Ballona Creek bedload and suspended sediment, including sediment deposited at the mouth of Marina del Rey.

DECEMBER 1999

Introduction

Twenty-one sites, including tributary drains and the main creek bed, were sampled for bedload sediment quality along Ballona Creek. The sediment sampling stations were designed to trace the upstream sources of contaminants of concern associated with sediment deposition at the mouth of Ballona Creek and the entrance to Marina del Rey Harbor. Deposited sediments were sampled from sediment accumulation areas representative of a variety of storm drain inputs into Ballona Creek. This report is a summary and evaluation of the chemistry results of the Ballona Creek sediment sampling program.

Sediment samples were collected from the channel bottom of 17 drainages at their mouths, immediately upstream of their confluence with Ballona Creek. In addition, sediments were sampled from the main channel of Ballona Creek at 4 locations. Samples were collected towards the end of the annual low-flow period, on October 5 and 6, 1999 (Table 1). This list varies from that presented in the Sampling and Analysis Plan (CH2M HILL 1999) in that Overland North and the Jefferson area drains were not sampled due to a lack of sediment accumulation. In addition, two new drains were added, from the Holly Hills drains entering below Dauphin Ave. and from the main drains entering under Higuera Street. Sampling locations are shown on the map in the Sampling and Analysis Plan and summarized in Table 1.

TABLE 1
Sampling Locations for Deposited Sediment Quality Sampling in the Ballona Creek Drainage.

Mouth of Drain Location	Approximate miles upstream from mouth of Ballona Creek	L.A. County Drain Number
Centinela Channel	2.6	NA
Centinela Avenue	3.2	51
Inglewood Boulevard	3.5	503
Sepulveda Channel	3.8	NA
Ballona Creek at Sawtelle Boulevard	4.3	All upstream drains
Sepulveda Boulevard	4.5	NA
Westwood/Kingston	4.6	RDD 208
Saint Nicholas Avenue	4.7	2901
Overland (south side)	5.0	RDD 208
Ballona Creek below Madison	5.7	All upstream drains
Madison Avenue	5.7	Benedict Canyon Channel
Ince Boulevard	6.0	Ince Boulevard Drain
Higuera	6.5	NA
National Boulevard	7.0	84
S. La Cienega Boulevard	7.5	9408

Sampling Locations for Deposited Sediment Quality Sampling in the Ballona Creek Drainage.

Mouth of Drain Location	Approximate miles upstream from mouth of Ballona Creek	L.A. County Drain Number
Dauphin Ave.	7.6	9408/Holly Hills Drain
Ballona Creek below Fairfax	8.0	All upstream drains
Fairfax	8.0	Holly Hills Drain
Marvin Avenue	8.5	494
Pickford Street	9.0	648
Ballona Creek at Pickford	9.0	All upstream drains

NA = Not applicable or not available.

Methods

Field Sampling Methods

Deposited sediments were collected from drainage channel mouths and the main channel of Ballona Creek from areas visually determined to be sediment accumulation areas. The sediment was scooped from the channel bottoms with stainless steel hand trowels. Three separate equal-volume samples were collected within an approximate 1-meter radius and mixed thoroughly by hand in a stainless steel bowl. The resulting composite sample was packed with no head space into chemically clean glass jars. Samples were chilled in the field, held chilled, and transported to the laboratory within two days of collection.

Sampling equipment was chemically decontaminated between sites. A single decontamination rinsate sample (water sample) was collected for each day of sediment sampling.

Sediment Quality Constituents of Concern

The sediments were analyzed for those constituents listed in the Sampling and Analysis Plan and shown in the Results Section, below. Major contaminant groups investigated included metals, PAHs, organochlorine compounds, and pesticides. Grain size analysis and total organic carbon analysis was performed on all samples. All samples were collected in chemically clean glass jars, kept in the dark, and refrigerated prior to analysis.

Normalization of Results

The raw, wet chemistry results expressed in concentration units per weight of wet sediment would not offer a particularly effective means of comparison among sites. In contrast, several types of standardizations were created to provide insights into the differences in contamination among sites. The techniques used were:

- Dry weight normalization; all results were presented as concentration units per dry weight (DW) of sediment.

- TOC normalization; all results were presented as dry weight concentrations per weight of total organic carbon (TOC) in the sample.
- Silt/clay normalization; all results were presented as dry weight concentrations per proportion of silt and clay in the sample.

Sediment chemistry results are presented in the Appendix for all samples and analytes on a wet and dry weight basis. Sediment chemistry results are presented using the three normalization techniques in Tables 2 - 5 for all sampling locations. Sediment toxicity guidelines, presented as Effect Range Low (ERL) values, are shown in the first column of Table 2 as a basis of comparison to known toxic levels of individual contaminants as assessed on a dry weight basis. Tables 3 - 5 shows the ordering of sites by level of contamination in sediment based on selected Table 2 results. Table 6 shows the average ranks for each site by analyte class.

Results

Comparisons Among Sites

The results are presented in several different ways as a means of elucidating differences among sites and to correct for biases in sediment chemistry associated with sediment deposition characteristics. Comparative toxicity information is available for sediment as assessed on a dry weight basis. Thus, dry weight results in Table 2 are presented in comparison to toxicity guidelines. The two additional normalization techniques (TOC and silt/clay) are useful in ranking sites by relative levels of contamination. In general, toxic constituents in sediments tend to be associated with fine particles and with organic compounds and the normalized results shown in Tables 3 and 4 provide a method of standardizing for variability in silt/clay and organic fractions in the samples. Depositing sediment is highly variable with respect to grain size and associated organic content that is associated with the physical process of site-specific deposition rather than sources of contaminants. Thus the normalized values, although not directly comparable to toxicity guidelines, were useful in ranking sites on the basis of the chemistry of the fine, organic fraction of the sediment.

The samples ranged from less than 1% silt plus clay fraction (Ballona Creek at Pickford) to 66% silt/clay (Inglewood Blvd.)(Table 2). Total organic carbon content ranged from 442 mg/kg (Ballona Creek at Pickford) to 17% of total sediment dry weight (Marvin Ave. drain). In general, many of the drains had only fine deposited sediment dominated by living and dead algal mats while the main Ballona Creek channel had relatively much more sand and gravel in the sediment. Locations with noticeable oil in the discharge were Ballona Creek below Pickford, Marvin Ave. (with tar included, as well), Ballona Creek below Fairfax, and Dauphin Ave (particularly heavy oil flow). In addition, the flow from Overland Ave. drain (north side, drain 9404) had no accumulated sediment to sample and appeared to be chronically toxic; no algae or plants occupied the area within the drainage flow or for several hundred feet downstream in Ballona Creek.

Only 4 of the 21 sites were without any chemical concentrations exceeding toxicity guidelines (ERLs); Dauphin Ave., Westwood St., Ballona Creek at Sawtelle, and Centinela Channel. The other sites most often exceeded ERLs for copper, lead, nickel, zinc, and anthracene. Four sites exceeded ERLs for total PAHs or total DDT compounds. With the exception of dieldrin, most pesticides and all PCBs were undetected in the samples (Table 2).

Site Rankings

The sites can be ranked on the basis of dry weight chemistry as presented in Table 2 and shown in rank order for selected constituents of concern. Table 3 shows that Pickford, Centinela Ave., Marvin, and Inglewood most consistently rank as the most contaminated sites with respect to metals and PAHs. The two areas of the main Ballona Channel ranked as most contaminated and exceeding ERLs were sites just downstream of Madison and Fairfax. Other main creek sites appeared relatively clean, probably as a result of dilution of the toxic fraction by gravel and sand.

Rankings based on silt/clay normalized results revealed that Ince Blvd. and Ballona Creek locations at Pickford and Sawtelle could be added to the list of more contaminated sites (Table 4). Marvin, Inglewood, Pickford, and Centinela Ave. remained in the ranks of more contaminated drains in this analysis.

When viewed as TOC normalized values, Ballona Creek sites at Pickford and Fairfax and Higuera, Centinela Ave., Sepulveda Blvd., and Ince drains appeared most contaminated (Table 5). These TOC-based rankings are particularly important in the case of organic contaminants (PAHs).

The summary of average ranks based on the dry weight values as shown in Tables 2 and 3 is shown in Table 6 for major groups of contaminants. For combined metals the 5 most contaminated sites (in order of most contaminated to least) were Pickford, Centinela Ave., Inglewood, and Marvin/Overland (tie). For combined PAHs, the 6 most contaminated sites (same ordering) were Centinela Ave., Inglewood, Madison, St. Nicholas, and Higuera/Sepulveda Blvd (tie). Centinela Ave and Pickford drains consistently rank as containing the most contaminated sediments for either metals or PAHs. The main Ballona Creek sites, Sepulveda Channel, and Centinela Channel consistently rank as among the cleanest sites.

Conclusions

The deposited sediment in the Ballona Creek drains, as sampled toward the end of the seasonal dry period in 1999, represented baseflow conditions incorporating an unknown degree of contaminant accumulation since the last stormwater flows. To the extent that the samples analyzed in this report represent an averaging of upstream sediment quality, results can be compared for relative sediment toxicity and overall levels of contamination. Presumably, the sediments analyzed here were washed out and replaced with stormflow bedload as part of the first rainfall flows in the fall of 1999. It is assumed that the relative contamination associated with suspended sediment in stormflows can be generally related to the sediment quality results as presented in this report.

As shown in Tables 3 - 6, many drains into Ballona Creek possess sediments with potentially toxic concentrations of contaminants. The most upstream locations (Pickford and Ballona Creek below Pickford) rank among the most contaminated locations. Many of the drains along the length of Ballona Creek also contribute contaminated sediment. The rankings and comparisons to ERL values shown above point out those most contaminated sites. It is notable that the bedload sediment in the major tributary drains of Sepulveda and Centinela Channels are among the least contaminated samples. Upstream control measures focused on those most contaminated drainages would be likely to improve the quality of Ballona Creek bedload and suspended sediment, including sediment deposited at the mouth of Marina del Rey.

SUMMARY

This report examines the health risks of swimming (and water-contact recreation more generally) at the beaches in Los Angeles County and the policies and programs in place to reduce these risks. Health risks are of concern first because of the negative effects on the swimmers who contract illnesses. They are also of concern because the perception or reality that beach waters are not safe for swimming has negative effects on the economies of beach communities and perhaps even on the economy of the county as a whole. Finally, health risks are of concern because they limit an important recreational opportunity and reduce the well-being of the citizens of L.A. County.

Based on the findings of our investigation, we believe there are important areas where policies and programs to clean up beach waters can be improved. Therefore, we make recommendations to the Los Angeles County Board of Supervisors, various departments in the County and in the cities within the County, that address:

- the process for monitoring water quality at the beaches, assessing swimming risks, and communicating these risks to the public.
- efforts to improve the water quality during dry weather at seven problem beaches.
- policies and procedures for improving the quality of rivers, creeks and storm drains that flow into the ocean.

The objectives of our recommendations are to reduce the health risks of swimming at beaches in L.A. County and to ensure that the programs in place to reduce risks are sensible in terms of cost. Our recommendations also aim to establish programs that accurately communicate the health risks of swimming at L.A. beaches to the citizens of the County. Many of our recommendations are addressed to government entities other than the Board of Supervisors or County departments. However, in the interests of the residents of L.A. County, the Board of Supervisors should take an aggressive leadership role to ensure that all these recommendations are carried out.

In the remainder of this summary, we present our key findings and recommendations on (1) water quality at Los Angeles County beaches; (2) health risks of swimming at the beach; (3) improving the public understanding of beach water quality; (4) improving water quality at seven problem beaches in L.A. County; and (5) improving the water quality in the rivers, creeks, and storm drains that flow into the ocean. We conclude with a table listing the government agencies responsible for key recommendations.

WATER QUALITY AT LOS ANGELES COUNTY BEACHES DURING DRY AND WET WEATHER

Most of the beaches in L.A. County meet health standards during dry weather. Heal the Bay, an environmental group based in Santa Monica, grades beaches based on water quality data provided by city and county agencies. Over the last five years, slightly over two-thirds of the beaches monitored received annual grades of A or better during dry weather. Roughly speaking, an A grade means that water quality meets health standards in more than 90 percent of the samples taken during the year. Even during dry weather, however, there are a number of beaches in the County with persistent pollution problems. The water at Cabrillo Beach, considered the dirtiest in the County, exceeded health standards in more than two-thirds of dry-weather samples over the last year.

Water quality is poor at almost all L.A. County beaches during wet weather--defined as periods during and for the three days following rain. It rains more than 0.01 inches an average of 36 days per year in Los Angeles. Over the last 5 years, less than 20 percent of beaches on average received grades of A or better during wet weather.

HEALTH RISKS OF SWIMMING AT THE BEACH

Studies have shown higher rates of fever, chills, ear discharge, vomiting, phlegm, highly credible gastroenteritis, and significant respiratory disease among those swimming in beach waters that do not meet health standards. The increases in illness rates are not large, however, rising to roughly 4 percent in people swimming in water with elevated pollutant levels from 2 percent in those swimming in clean water.

Severity of these illnesses has not been well studied, either in L.A. County or marine water elsewhere, but there have not been reports of life threatening illness associated with swimming in the County, despite the large number of beachgoers. There has also been little study of long-term health effects of repeated exposure to elevated pollution levels in beach waters. But again, the lack of reports of chronic effects suggests that such risks are not substantial.

Even though demonstrated health effects of swimming in L.A. County beach water do not appear substantial, uncertainties remain both about health effects and how well current water-quality monitoring techniques protect the public. We thus recommend additional research on health risks and on the most effective way to detect water quality problems (see Section 3.1).

IMPROVING THE PUBLIC UNDERSTANDING OF BEACH WATER QUALITY

We are concerned that the public has an inaccurate and overly negative impression of beach water quality. Beach attendance fell by 32 percent between 1983 and 1997. This decline could have been due to many factors, but increasing concern about water quality may have played a role. Ongoing research on perceptions about L.A. County beaches suggests that people think that some beaches are dirtier than others but are confused about which ones have the worst water quality. We also suspect that the public has very little understanding of the types of illnesses that are associated with swimming in polluted water.

We make two recommendations aimed at improving the public's understanding of water quality at County beaches. (The recommendation numbers correspond to section numbers in the full report.)

Recommendations

3.2-A **The L.A. County Department of Health Services should develop a grading system for beaches similar to that used at L.A. County restaurants and post these grades at sampling locations and in other highly visible locations at the beaches.**

3.2-B **The L.A. County Department of Health Services should initiate a public information campaign to accurately communicate to L.A. County residents the health risks of swimming at L.A. County beaches. The message should be that:**

- **Beaches in L.A. County are among the best monitored in the nation.**
- **Swimming is safe during dry weather at the vast majority of beaches, although a few problem areas remain.**
- **Water quality standards are typically exceeded during rainstorms and beachgoers should not swim during or in the three days following significant rain (i.e. greater than 0.1 inch).**

The campaign should also provide accurate information on the types of illnesses and the chances of contracting them from swimming at beaches that violate health standards.

IMPROVING WATER QUALITY AT SEVEN PROBLEM BEACHES IN L.A. COUNTY

We examined the specific problems at seven beaches: Surfrider, Topanga Canyon, Santa Monica Canyon, Santa Monica Pier, Pico-Kenter, Mother's Beach in Marina del Rey, and Cabrillo Beach (See Figure 4.1 for a map of their locations). The beaches were chosen based on their consistently poor water quality. With only a few exceptions, these beaches are the only beaches in the County with consistent dry-weather problems.

Our investigation of these seven beaches uncovered two major issues. The first is what should be done about the septic systems in Malibu. The second is how to handle conflicting uses at some beaches.

Septic Systems in Malibu

Most of the stakeholders we interviewed outside the City of Malibu think that septic systems are a major source of pollution in the Malibu Lagoon and Surfrider Beach and think that a sewer system should be installed. Most in Malibu think that there is not clear evidence that septic tanks are a problem and vigorously resist sewers. We see the need for independent, objective information on the scope of the problem and, given the power of vested interests, believe that Malibu cannot be left to resolve this issue on its own. We thus recommend that the Regional Board take the lead to resolve this issue.

Recommendations

4.1-A **Commercial and multi-family residential septic system owners in Malibu should obtain waste discharge permits from the Regional Board and comply with the terms of those permits.**

This type of permit is required of anyone discharging waste that could affect the quality of water resources in the State of California. Septic system owners in Malibu should not be exempted from this requirement. The groundwater monitoring information collected under the terms of these permits is needed to resolve the issue of whether or not septic systems are a problem.

4.1-B Groundwater levels in residential areas with a high water table, especially residential properties near the Malibu lagoon, should be monitored.

The City of Malibu has found it difficult to access private residential properties for monitoring.

Competing Uses

The second major issue we found is the existence of competing uses at three of the seven problem beaches investigated. The minimal success of the City of Santa Monica's substantial efforts to improve water quality south of Santa Monica Pier raises the concern that a heavily-visited pier and an adjacent swimming area are not compatible uses. Similarly, swimming may not be an appropriate use at Mother's Beach, a beach that has limited water circulation, is populated by birds, and that is located adjacent to a marina. Cabrillo has limited circulation, is located adjacent to a wildlife refuge, and is heavily populated with birds. The competing uses at Cabrillo Beach are swimming and bird habitat.

Society's resources are scarce, and there is no point in spending money to try to meet health standards for swimming when the efforts will be frustrated by other uses. At each of these three beaches, we thus recommend that the responsible authorities (the City of Santa Monica for the Santa Monica Pier, the County of Los Angeles for Mother's Beach, and the City of Los Angeles for Cabrillo Beach) regularly reassess their water quality goals for these beaches. It may not make sense to spend large amounts of money to meet the swimming standards at these beaches.

Recommendations

4.4-E, 4.6-C, 4.7-C The responsible authorities at Santa Monica Pier, Mother's Beach, and Cabrillo Beach should continue with some of the modest programs that are in place or planned to improve water quality. However, before moving on to very expensive solutions they should reconsider the water quality goals for these beaches.

Given the relatively modest health risks of swimming at these beaches, we do not believe that they should be closed if water quality does not improve. Rather we make the following recommendations:

Recommendations

4.4-D, 4.6-B, 4.7-B Until water quality improves, the responsible authorities should permanently post signs at Santa Monica Pier, Mother's Beach and Cabrillo Beach that warn beachgoers of consistently poor water quality and briefly describe the health risks associated with swimming in polluted waters.

IMPROVING THE QUALITY OF URBAN RUNOFF

The water in the rivers, creeks, and storm drains that flow into the ocean carries pollution that causes a large majority of beaches to exceed health standards during wet weather and that causes violations at some beaches during dry weather. The Regional Board has ambitious plans to improve the water quality of these watercourses in L.A. County. However, we are concerned that the institutions, programs, and resources in place may not be up to the job. We make recommendations for improving the system in seven different areas (numbered according to where they appear in the full report):

- 5.1 - Setting goals for the uses of rivers, creeks, estuaries, and beach waters.
- 5.2 - Identifying pollution sources.
- 5.4 - Enhancing incentives to improve water quality.
- 5.5 - Matching authority with responsibility.
- 5.6 - Policies for diverting urban runoff into the sewer system.
- 5.7 - Monitoring and enforcement.
- 5.8 - Funding for water quality programs.

Here we discuss the four most important.

Setting Goals for the Uses of Rivers, Creeks, Estuaries, and Beach Waters

The Regional Board has designated beneficial uses for specific water bodies in L.A. County. These designated beneficial uses drive the water quality goals for these water bodies and thus the cleanup costs. There is a great deal of controversy over these beneficial uses. Several important stakeholders feel that some of the designated beneficial uses are inappropriate and that the process through which beneficial uses were designated (mainly in the 1970s) was inadequate. Their lack of support stops many of them from fully supporting and contributing to efforts to improve the quality of urban runoff and may lead to lawsuits that can further slow the process.

Our examination of the beneficial uses in L.A. County also suggests that there are conflicts among the beneficial uses that have been designated for some water bodies. Examples include the three beaches discussed above. The inconsistencies between some beneficial uses and the lack of support for others lead us to the following recommendation.

Recommendation

5.1 A meaningful process to prioritize the beneficial uses for the water bodies in L.A. County should be created. Near-term water quality programs should attempt to achieve the high-priority beneficial uses. Programs required to achieve lower priority beneficial uses should be deferred.

Matching Authority with Responsibility

There are several important sources of pollution in urban runoff that neither the Regional Board nor the cities, County, and businesses it regulates have the power to reduce at the source. For example, automobile and truck brake pads are thought to be a significant source of the copper that winds up in urban runoff, but neither the Board nor the regulated entities can require that brake pads contain less copper. Current institutional boundaries also restrict the types of remediation strategies that can be considered. Natural attenuation of some pollutants in stream beds and wetlands may make a lot of sense and create multiple benefits, but the Regional Board and regulated entities often do not have the authority to restore stream channels that are encased in concrete to more natural states or to build or restore wetlands.

The lack of authority over important sources of pollution or the ability to implement certain treatment strategies means that certain types of solutions are not even considered, and even if considered, are quickly taken off the table. As a consequence, cities and others may be forced into expensive end-of-the-pipe treatment when other approaches are more sensible. This is not a desirable outcome. We as a society should not let institutional boundaries get in the way of the best solutions.

Recommendation

5.5 The County should lead an effort to identify what additional powers are needed by the Regional Board, the cities, and the County pertaining to water quality control, determine who should have these powers, and then obtain them.

Monitoring and Enforcement

No matter how good they may look on paper, efforts to clean up the rivers, creeks, and ocean in L.A. County are only effective to the extent that the responsible organizations translate the words into action. To make sure that our pollution control system is more than a paper tiger, additional resources need to be spent on auditing the activities that actually reduce pollution. In addition, our investigation found overlap and lack of coordination between enforcement efforts of the Regional Board and the county and the cities in the County. We also found that current requirements in most jurisdictions to prosecute violations of urban runoff ordinances as criminal violations hinders the enforcement process. These findings led us to the following recommendations.

Recommendations

5.7-A Programmatic audits of city and County storm water programs should be conducted. These audits should verify whether programs outlined in the permits are being implemented and assess their adequacy and effectiveness.

5.7-B The cities and County should coordinate and consolidate as appropriate their inspection programs of industrial and construction sites, with the Regional Board. This program should increasingly focus on the adequacy of the storm water management plans and the extent to which they are being implemented.

5.7-C More generally, the cities and County should clarify the division of enforcement responsibilities between them and the Regional Board. Enforcement should be delegated to the cities and County, whenever possible.

5.7-D The County of Los Angeles Department of Public Works should investigate the advantages and disadvantages of ticketing authority for runoff violations. Based on a review of experiences in the City of Los Angeles and other jurisdictions that have the ability to issue tickets for infractions, the Department should make a recommendation to the Board of Supervisors on whether the County code should be amended to allow such ticketing.

Funding for Water-Quality Programs

To be effective, there must have adequate resources to carry out the permitting, monitoring, and enforcement responsibilities. Recommending additional funding for a public agency is often not popular, but we believe that the benefits from potential improvements in programs and enforcement are likely to outweigh the costs.

Recommendation

5.8 The Board of Supervisors should lead an effort to increase funding for the Regional Board.

Potential funding sources include increased permit fees from the municipalities and businesses in L.A. County and the State General Fund. The Supervisors should appeal to the governor and the State Water Resources Control Board directly as well as enlist the support of the L.A. delegation to the State legislature.

AGENCIES RESPONSIBLE FOR KEY RECOMMENDATIONS

Table S.1 summarizes the most important recommendations by the government entity responsible for implementation.

Table S.1
Agencies Responsible for Key Recommendations

Number	Recommendation to:
Los Angeles County	
3.2-A	Department of Health Services should develop a grading system for beaches.
3.2-B	Department of Health Services should initiate a public information campaign to communicate health risks of swimming.
4.6-B,C	Department of Beaches and Harbors should continue modest programs to improve water quality at Mother's Beach, but reconsider water quality goals before moving on to expensive solutions. Permanently post Mother's Beach until water quality improves.
5.7-D	Department of Public Works should investigate advantages and disadvantages of ticketing authority for runoff violations.
5.8	Board of Supervisors should lead an effort to increase funding for the Regional Board.
City of Los Angeles	
4.7-B,C	Continue with modest programs to improve water quality at Cabrillo Beach, but reconsider water quality goals before moving on to expensive solutions. Permanently post Cabrillo Beach until water quality improves.

City of Santa Monica

4.4-D,E Continue with modest programs to improve water quality at Santa Monica Pier, but reconsider water quality goals before moving on to expensive solutions. Permanently post Santa Monica Pier until water quality improves.

Regional Water Quality Control Board –

As a State agency, the Board is beyond the purview of the Grand Jury; however, it is an integral part of waste water control in Los Angeles County, and may want to consider the following:

4.1-A Issue waste discharge permits for commercial and multi-family residential septic systems in Malibu.

4.1-B Require monitoring of groundwater levels in residential areas in Malibu.

5.1 Create a meaningful process to prioritize beneficial uses and defer programs required to achieve lower priority uses.

5.3 Focus more on setting limits on contaminants than on requiring implementation of prescribed programs.

5.5 Lead efforts to identify what additional powers are needed by the Regional Board, the cities, and the County and to obtain them.

5.7-A Conduct programmatic audit of city and County storm-water programs.

5.7-B Coordinate and consolidate inspection programs with the County and cities; increasingly focus inspections on adequacy of storm-water management plans.

5.7-C Clarify division of enforcement responsibilities between Regional Board, cities, and County.

SECTION 1. INTRODUCTION

This report examines the health risks of swimming (and water-contact recreation more generally) at the beaches in Los Angeles County and examines the policies and programs in place to reduce these risks. Health risks are of concern first because of the negative effects on the swimmers who contract illnesses. They are also of concern because the perception or reality that beach waters are not safe for swimming has negative effects on the economies of beach communities and perhaps even on the economy of the county as a whole. And finally, health risks are of concern because they limit an important recreational opportunity and reduce the well-being of the citizens of L.A. County.

Improving water quality at L.A. beaches is part of a larger effort to clean up the rivers, creeks, groundwater basins, and ocean in the region. Substantial resources have been spent on this effort, and significantly greater amounts would be required by some additional programs under consideration. The scope of this effort has been likened to the long-running campaign to clean up the region's air. We in the county need to make sure that the resources spent on this effort are spent wisely, both because society's resources are limited and because there are many benefits to be gained by cleaning up the county's beaches and waters.

1.1 SCOPE OF THIS REPORT

We examine the policies and procedures in place for monitoring water quality at beaches in L.A. County and assessing the health risks of swimming. We also assess programs to communicate these risks to the public. We examine the sources of and efforts to reduce pollution at seven of the beaches in the county with the worst pollution problems. As will be discussed below, one of the major sources of beach water pollution is polluted discharge from the rivers, creeks and storm drains that flow into the ocean. We thus also examine policies and programs to improve the quality of waters that discharge to the ocean.

We investigate efforts to improve water quality both during dry weather and during wet weather. Water quality and health risks are of primary concern during the dry, summer months when beach attendance is highest. However, even though beach attendance is lower during wet weather, there are still some who swim at the beach (e.g., surfers). Water quality during wet weather may also affect overall perceptions about the attractiveness of the beaches and their use during dry weather. Investigation of policies to improve water quality during wet weather is also important because of the large amount of resources that will potentially be required by the programs currently under consideration.

We use the information gathered in our investigation to make recommendations on:

- The process for monitoring water quality at beaches, assessing swimming risks, and communicating these risks to the public;
- Efforts to improve water quality during dry weather at seven problem beaches;
- Policies and procedures for improving the quality of rivers, creeks and storm drains flowing to the beach.

The objectives of our recommendations are to reduce the health risks of swimming at beaches in L.A. County and to ensure that the programs in place to reduce risks are sensible in terms of cost. Our recommendations also aim to put in place programs to accurately communicate the health risks of swimming at the beaches to the citizens of the county.

1.2 EVALUATION APPROACH

Our evaluation and recommendations are based on a review of relevant literature and interviews with 26 experts on water quality programs and policies in L.A. County. The experts interviewed spanned the many agencies and organizations involved in water quality issues in L.A. County. Appendix A lists the organizational affiliations of those interviewed.

Most of the interviews were conducted in person, although a few were done over the telephone. Interviews typically lasted two to three hours and were usually done at the interviewee's place of employment. The interviews were conducted between October and December 1999. To encourage candor, interviews were conducted on a confidential basis. Thus, we do not identify the people interviewed nor attribute statements to them in this report. A semi-structured interview format was used. Questions were prepared in advance, but both the interviewers and interviewees were free to pursue topics not on the list.

1.3 ORGANIZATION OF THE REPORT

Section 2 sets the stage for our review of beach water pollution issues. It provides background on water quality at the beaches in L.A. County, the health risks of swimming, and the potential sources of pollution. It also provides an overview of the roles and responsibilities of the agencies and organizations involved in beach water quality issues. Sections 3, 4, and 5 each examine a different set of issues surrounding beach water quality. For each issue area, we first define the issue and why it is important. We then present the findings of our investigation of the issue and conclude with recommendations to improve policies in the issue area. Section 3 examines the policies and procedures in place to assess the risks of swimming at the beaches in L.A. County and the procedures for communicating these risks to the public. Section 4 assesses efforts to reduce pollution at seven of the most polluted beaches in the county and makes suggestions for improvements. Section 5 evaluates and makes recommendations about efforts to improve the water quality of the rivers, creeks and storm drains that flow into the ocean. A review of the literature on the health risks of swimming in marine water is contained in Appendix B.

SECTION 2. BACKGROUND

Most beaches in L.A. County are considered safe for swimming and other forms of water recreation when the weather is dry. Unfortunately, there are several beaches with persistent pollution problems even when the weather is dry, and almost all beaches have high pollution levels when it rains. In this section we characterize the water quality at L.A. County beaches and review the health risks of swimming. We also provide brief overviews of the potential sources of pollution and of the agencies and organizations involved in beach water quality issues.

2.1 WATER QUALITY AT LOS ANGELES COUNTY BEACHES

The California Department of Health Services has established water quality standards for swimming at public beaches. The standards are based on three indicator bacteria: total coliform, a group of bacteria that can originate from soil, plants, and human and animal waste; fecal coliform, a group of bacteria found in the intestinal tracts of humans, mammals, and birds; and Enterococcus, a bacterium that is part of the normal flora found in human and animal waste. These bacteria do not necessarily cause illness in humans themselves, but are thought to be good indicators of the presence of human pathogens (see Section 3.1 for a discussion of their effectiveness as indicators). The single-sample water quality standards for bacteria established by state are:

- 10,000 or fewer total coliforms per 100 ml.
- 400 or fewer fecal coliforms per 100 ml.
- 104 or fewer enterococci per 100 ml.
- 1,000 total coliforms per 100 ml, if the ratio of fecal to total coliforms exceeds 0.1.

Heal the Bay, an environmental group based in Santa Monica, provides readily accessible information on beach water quality. It develops annual grades for 61 beaches throughout the county based on weekly or daily water quality monitoring data provided by the Los Angeles County Department of Health Services (DHS), the City of Los Angeles, and the County Sanitation Districts of Los Angeles County.[1] Grades run from A+ through F. A grade of A or better means that (1) Enterococcus exceeded 104 per 100 ml in less than 10 percent of samples taken during the year, (2) total coliform exceeded 10,000 per 100 ml in less than 1 percent of samples, and (3) the ratio of fecal to total coliform exceeded 0.1 (when total coliform were greater than 1,000 per 100 ml) in less than 5 percent of samples. The beaches monitored by the City and County of Los Angeles are not randomly selected along the coast and, if anything, are more likely to be in areas with the greatest pollution problems. Factors including beach attendance, distance from storm drains or sewage outfalls, and the existence of known pollution problems were used to select the beaches monitored. (See the Heal the Bay website for the locations of the 61 beaches in L.A. County for which it issues grades.)

Most of the beaches in L.A. County meet health standards during dry weather. Over the last five years, slightly over two-thirds of the 61 beaches monitored received grades of A or better during dry weather. In contrast, water quality is poor during wet weather which is defined as

[1] More detailed information regarding California's sampling requirements can be found in Title 17 of the California Code of Regulations, Group 10, Sanitation, Healthfulness, and Safety of Ocean Water-Contact Sports Areas.

periods during and for the three days following rain. Over the last five years, less than 20 percent of beaches on average received grades of A or better during wet weather.

Even during dry weather there are a number of beaches throughout the county with persistent pollution problems. Figure 2.1 shows the percent of sampling days during which three water-quality thresholds were exceeded during the 1998-1999 monitoring year at seven problem beaches (a map with the location of these beaches is included in Section 4). At least one of the bacterial indicators was exceeded in more than 10 percent of the dry-weather samples at each of the beaches, and the Enterococcus standard was exceeded over two-thirds of the time at Cabrillo Beach.

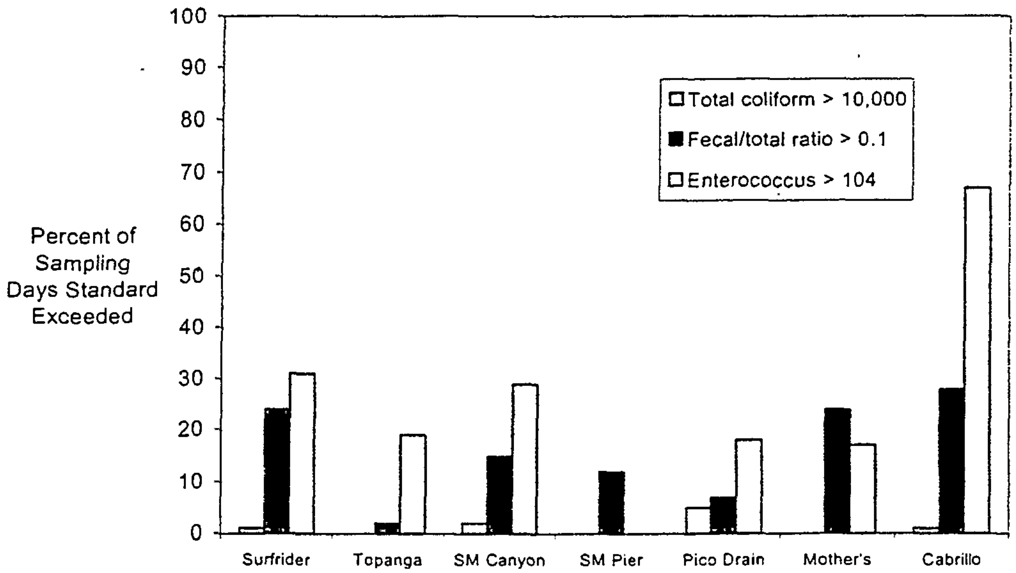

Figure 2.1—Percent Sampling Days That Water Quality Standards Were Exceeded At Seven Problem Beaches During Dry Weather in 1998-1999

The State Water Resources Control Board has established water quality requirements for discharges to the ocean for a number of contaminants other then bacteria. Many of the requirements are aimed at protecting human health and include restrictions on heavy metals and organic chemicals. Public health officials have paid the most attention to bacteria levels, however, in part because their main concerns historically have been about the spread of infectious diseases in waters contaminated with human sewage. Monitoring data on bacteria are much more extensive for bacteria than other contaminants, and we focus our characterization of beach water quality in L.A. County on them. We discuss the health risks imposed by contaminants other than bacteria below.

2.2 EXTENT OF HEALTH RISKS OF SWIMMING AT THE BEACH

A large number of people are exposed to the waters at L.A. County beaches every year (see Figure 2.2 for annual beach attendance). The most extensive study of the health risks of swimming in the beach waters of L.A. County was released by the Santa Monica Bay Restoration Project (SMBRP) in 1996. The study compared the incidence of illness among people who swam at various distances from three flowing storm drains and correlated illness rates with bacteria levels. It found that illness was higher among people who swam right in front of storm drains (where the pollution levels are the highest) than among people who swam 400 yards away. They also found that illness rates were correlated with bacteria levels in the water. This study provided the first scientifically-documented evidence that swimming at L.A. County beaches increases illness rates when bacteria levels are high.

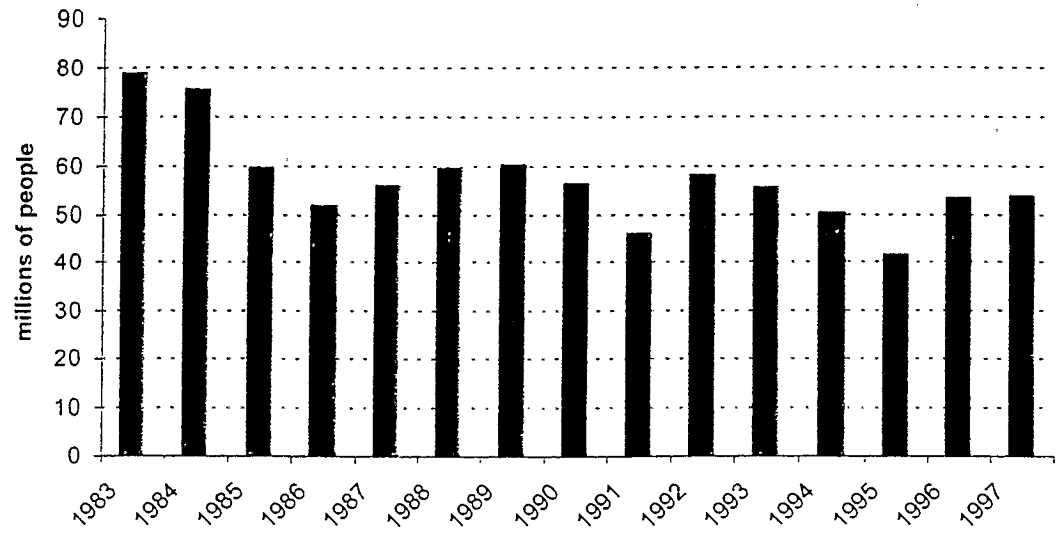

Figure 2.2—Annual Attendance at Beaches in Los Angeles County, 1983-1997
Source: Compiled by Linwood Pendelton and Miwa Tamanaha, Department of Economics, USC, based on data provided by Los Angeles County Lifeguards.

The SMBRP study found higher rates of fever, chills, ear discharge, vomiting, phlegm, highly credible gastroenteritis, and significant respiratory disease among those swimming in front of storm drains than those swimming 400 yards away.[2] Even though the differences were statistically significant, the increase in illness rates was not large. Illness rates were generally one to two percentage points higher among those who swam in front of the drain than those who swam 400 yards away. Rates for the individual illnesses named above ranged from one to five percent for those farthest from the drain versus two to seven percent for those swimming in front of the drain.

[2] Highly credible gastroenteritis is defined in the SMBRP study as (1) vomiting, (2) diarrhea and fever, or (3) stomach pain and fever. Significant respiratory disease is defined as a complex of symptoms that include (1) fever and nasal congestion, (2) fever and sore throat, and (3) cough with sputum.

The SMBRP also found higher rates for some illnesses when bacteria levels exceeded the standards listed above than when bacterial levels met the standards. Again, the increases were not large, ranging from one to two percentage points from the same low baseline levels.

The SMBRP study is part of a larger literature on the health effects of swimming in beach waters. Our review of this literature (see Appendix B) reveals that a great deal of uncertainty about the health effects of swimming remains. But given what is known, we make the following observations. First, the acute illnesses (those coming on quickly and lasting a short time) associated with swimming in beach waters contaminated at the levels found in L.A. County do not appear very severe (see list of illnesses found by SMBRP study above). We did not hear of or find studies reporting life threatening or other serious illnesses from swimming at L.A. County beaches. Given the large number of beachgoers, one would expect some such reports if serious illnesses were occurring.

Second, most of the studies on risks of swimming in marine waters focus on acute illnesses. The SMBRP study focused on illnesses coming within one or two weeks of swimming. It also restricted its attention to one-time exposure to water, and did not examine the effects of repeated exposure. This opens up the possibility that there may be chronic effects of repeated exposure to the heavy metals and organic chemicals sometimes found in ocean water. However the lack of reports again suggests that these risks are not substantial.

Finally, while there is evidence that exposure to human sewage causes illnesses, there is little information on whether exposure to water contaminated with the feces of other animals (such as birds) causes problems. Most studies that have found increased illness rates have supposed human fecal contamination. The storm drains in the SMBRP study were found to contain human viruses (indicating the presence of human sewage). It is unknown whether there are similar health effects at other beaches where the source of contamination in not human sewage but, say, bird feces.

2.3 CAUSES OF BEACH WATER POLLUTION

This section provides an overview of the many potential sources of bacteria and other pollutants that sometimes contaminate the beaches in L.A. County. As we will see in subsequent sections, there is a great deal of controversy over which of these sources are most important.

Point Sources

Twenty years ago, discharges from municipal sewage treatment plants and industrial facilities were the largest sources of water pollution in the beaches and ocean off L.A. County. Much progress has been made since then in reducing pollutants from these so-called point sources, although occasional problems crop up. Now that emissions from these point sources have been reduced greatly, pollutant loads from diffuse, non-point sources have become the focus of attention.

Non-Point Sources

Urban runoff. Urban runoff refers to the water that collects on hard, impermeable surfaces, such as streets and rooftops and flow into the county's storm drain system. Runoff is caused by rain and dry-weather sources such as over-irrigating landscaping. As runoff flows through urban areas it picks up pollutants and becomes contaminated with high levels of bacteria, metals and chemicals. Pet waste (including cats, dogs, and horses) and the homeless are potential sources of bacteria, as are restaurants that wash floor mats covered with food into the gutter. Oil and grease from trucks and cars, copper from brake pads, and the components of tail-pipe exhaust that have settled to the ground can be picked up by rain and other flows. Sediment may erode from construction sites, and fertilizers and other nutrients can be carried from residential yards, parks and commercial landscaping. Section 5.2 discusses the sources of pollution in urban runoff in greater detail.

Sewage spills and leaks. Blockages in sewers or very high flow levels can cause sewage to rise up through manhole covers and then flow into the storm drain system and out to the ocean.[3] Some also believe that leaks in the sewer pipes allow sewage to migrate underground into the storm drain system.

Illegal connections and discharges to the storm drain system. Sewage lines can be mistakenly hooked up to the storm drain system or pollutants can be illegally discharged to the storm drain system. Discharges of recreational vehicle sewage tanks or used engine oil into the storm drain system are examples of illegal discharges.

Septic systems. Septic systems that are not properly functioning may be the source of bacteria and high nutrient levels in groundwater, rivers, creeks, and the ocean.

Direct sources of beach pollution. Excrement from birds and other wildlife at beaches can cause high bacteria levels. Litter can create a medium for the growth of bacteria and can attract birds and other wildlife that leave droppings. High nutrient levels near storm drain outfalls can attract aquatic wildlife, which can also attract birds. Bathers may also use the ocean as a toilet (sometimes referred to as bather loading).

Natural sources. Runoff from undeveloped land can also contain substantial levels of bacteria (from the wildlife that live there), nutrients, and other contaminants.

2.4 OVERVIEW OF THE MAJOR AGENCIES AND ORGANIZATIONS INVOLVED IN WATER QUALITY ISSUES

A complex web of agencies and organizations is involved in water quality issues in L.A. County. Brief descriptions of the most important local agencies and organizations follow.

The California Regional Water Quality Control Board, Los Angeles Region (Regional Board). The Regional Board develops and implements water quality control plans that specify beneficial uses for the water bodies (which include the oceans, rivers, creeks, lakes, and groundwater) in the Los Angeles region, the water quality objectives that must be achieved to protect the beneficial uses, and describe implementation programs to protect all waters in the

[3] The sewer and storm drain systems are separate in L.A. County. Sewers flow to sewage treatment plants that then discharge treated effluent to the ocean (or in some cases to rivers). The storm drain system discharges to the ocean without treatment. Rainwater is not supposed to enter the sewer system, and sewage is not supposed to enter the storm drain system.

Region. The Regional Board is the regulator for water quality issues in the region with broad powers to achieve its goals.

The Regional Board is governed by nine board members who are appointed by the governor and confirmed by the State Senate. Members serve part-time for staggered four-year terms and represent the following interest groups: water quality (two members); irrigated agriculture; industrial water use; public; county government; municipal government; recreation, fish and wildlife; and water supply. Currently, one of the water quality positions and the industrial water use position are vacant. As of October 1999, the Regional Board staff included 112 positions – 92 technical, 5 administrative support, and 14 clerical. The technical staff consists primarily of engineers, geologists and biologists.

The primary mechanism used by the Regional board to regulate water quality is the National Pollutant Discharge Elimination System (NPDES) permit. NPDES permits are issued to both point and non-point dischargers. Point discharges, such as the City of Los Angeles Hyperion wastewater treatment plan, are issued NPDES permits that set effluent standards and require monitoring. Non-point dischargers, such as the County of Los Angeles, are issued municipal storm water NPDES permits that require the permittee to implement various programs designed to improve water quality.

Los Angeles County and the Cities in Los Angeles County. The Regional Board regulates local government agencies in Los Angeles County in a number of different ways. The sewage treatment plants of the City of Los Angeles and the County Sanitation Districts of L.A. County are regulated by point-source permits. Both these agencies are required under the terms of their permits to monitor water quality at many different locations in San Pedro and Santa Monica Bays.

The county and the cities in Los Angeles County are responsible for the urban runoff that originates in their jurisdictions and are subject to Regional Board regulations on storm water quality. Responsibility for urban runoff usually falls in public works departments, which, in the case of the County and the City of Los Angeles, also have responsibility for parts of the sewer system.

Independent of Regional Board requirements, the Los Angeles County Department of Health Services collects water quality data, sets health standards for swimming in beach waters and issues beach closures and warnings when pollution levels are high.

There are four cities in L.A. County whose jurisdiction abut the coast: Los Angeles, Long Beach, Malibu, and Santa Monica. These four, in addition to L.A. County which also controls areas that abut the coast, have particular interest in and enhanced roles in beach pollution issues.

Businesses. Businesses are required to have permits from the Regional Board to discharge "process water" (water from manufacturing or other business activity) into the waters of L.A. County. Certain types of industrial facilities and construction sites must also have storm water permits. Several business groups are involved in the policy debate over water quality in Southern California. Examples include the Southern California Coalition for Pollution Prevention.and the Western States Petroleum Association.

Environmental Groups. A number of environmental groups are active in water quality issues in the region. Located in Santa Monica, Heal the Bay has been a strong advocate of efforts to clean up Santa Monica Bay. The Natural Resources Defense Council and Santa Monica Baykeeper have also been very involved in the policy debates and have initiated, and won, several lawsuits against the Regional Board, the county, cities, and businesses to implement clean water programs.

Joint Powers Research and Planning Organizations. The Santa Monica Bay Restoration Project was formed in 1988 under the National Estuary Program and charged with assessing the Bay's problems, developing solutions and putting them into action. It is funded by the state and federal governments and views itself as a partnership of governments, environmentalists, scientists, industry, and the general public. The Southern California Coastal Water Research Program is a joint powers agency focused on conducting research and gathering information necessary to protect the Southern California marine environment. Its commission includes representatives of city, county, state and federal agencies with authority over and responsibility for coastal waters.

University Researchers. There are several researchers at UCLA and USC who have worked on water quality issues and been involved in the policy debate to varying degrees.

SECTION 3. IMPROVING WATER QUALITY MONITORING AND RISK COMMUNICATION

In this section we first evaluate and make recommendations about policies and procedures in place to assess the risks of swimming at the beaches in L.A. County. We then turn to the policies and procedures for communicating these risks to the public.

3.1 BEACH MONITORING AND RISK ASSESSMENT

Issue

As discussed in Section 2, the levels of three different types of bacteria are used to indicate the health risks of swimming at L.A. County Beaches. These bacteria are not necessarily harmful to humans in themselves but are presumed to indicate the presence of pathogens that are harmful to humans. How effectively do the current bacterial tests indicate human health risks? How might monitoring procedures be improved?

Findings

Water quality standards for swimming at the beach are based on the levels of three indicator bacteria (total coliform, fecal coliform, and Enterococcus) because it is too difficult, time-consuming, and expensive to test for the huge array of potential pathogens themselves. Although numerous studies have shown various degrees of correlation between these bacterial indicators and illnesses such as gastroenteritis, use of such indicators immediately raises the question of how closely associated the indicators are with the actual health risks of swimming. (See Appendix B for a review of studies that address the correlation between indicator bacteria and illness.)

High bacteria levels may overstate health risks to humans in some cases. As discussed in Section 2.2, the health effects of fecal contamination from non-human sources are unknown. The bacteria tests used to monitor beach water do not distinguish between bacteria from different types of animals. Thus, high bacteria levels may be due to birds, for example, but not cause increased illness in humans.

The bacterial indicators may also miss some important human pathogens. There is a great deal of uncertainty in the scientific community over how well the indicators predict the presence of human viruses and illness due to viruses. Several studies have shown that certain types of viruses are not well correlated with bacterial indicators, and what is more, no studies show that bacterial indicators are well correlated with particular viruses. This raises the possibility that harmful viruses may be in the water even when bacterial levels are low.

Of course, the possibility that viruses may be present when bacterial indicators are low does not mean that viruses are actually a problem. For example, viruses may not be present or the viruses that are present may be dead. More information is needed to determine whether the bacterial indicators fail to capture an important human health risk.

Also, the bacterial indicators may not be well correlated with heavy metals and organic compounds that could possibly result in chronic illness. As discussed in Section 2.2, there is currently no evidence of such effects, but more information is needed to make sure the risks are small and to better understand how bacterial indicators are correlated with any risks should they exist.

The lag between taking a water sample and the availability of test results raises some public health concerns. At present, testing for the bacterial indicators takes about 24 hours. The turnaround time from water sampling to reporting a violation to health officials and notifying the public is about 30 hours. The process in L.A. County is smooth and as timely as possible given existing monitoring technology. However, it means that the public cannot be assured at any given moment that the water at a given beach meets health standards. Public health officials and researchers are interested in finding testing methods that would drastically reduce the turnaround time for results. Some promising methods are being tried in other parts of the country and the world, but their usefulness in Southern California waters is yet to be determined.

Water quality monitoring along the beaches is done by three different agencies: the County Department of Health Services (DHS), the County Sanitation Districts of L.A. County, and the City of Los Angeles. The latter two agencies are required to do monitoring as part of their permits to discharge from waste sewage treatment plants into the Bay. Different laboratory procedures for measuring bacteria levels are used by these agencies, and results from the different procedures are not well correlated in wet weather (in dry weather the correlation is strong). Several of the experts we interviewed thought it important to understand the discrepancies between the two procedures and to understand which procedure, or combination of procedures, gives the most accurate count of bacterial levels.

Uncertainties in how well the current bacterial tests measure the risks of swimming at L.A. County beaches lead us to the following recommendations.

Recommendation

3.1 **The Board of Supervisors should direct the L.A. County Department of Health Services to assemble a panel of experts to evaluate the efficacy of current procedures for assessing the health risks of swimming at L.A. County beaches. The panel should include representatives of the L.A. County Department of Health Services, the City of Los Angeles, the Regional Board, the Southern California Coastal Water Research Project, the Santa Monica Bay Restoration Project, and experts within the academic and environmental communities.**

The panel should be charged to assess and recommend research to better understand the effectiveness of current bacterial tests and to ultimately suggest, as appropriate, changes in tests and testing procedures. In particular, the panel should examine:

- **The extent to which viruses pose a threat to swimmers.**
- **The extent to which bacterial indicators can be used to indicate the presence or absence of viruses.**

- The threat of non-human bacteria, viruses and other organisms to humans.
- The long-term health risks of regular swimming or surfing at L.A. County beaches and the relationship of near term-indicators to chronic diseases, if any.
- The availability of tests that more rapidly indicate the presence of pathogens in beach waters.
- Inconsistencies between the different bacterial measurement procedures currently used.

The panel should leverage ongoing work by the Santa Monica Bay Restoration Project on several of these topics.

3.2 RISK COMMUNICATION

Issue

The citizens of L.A. County and the region more broadly will be best served if they can make informed decisions about whether or not to swim at the beach. To make informed decisions, they need to have an accurate picture of the water quality and health risks of beach waters. They need to know if the water is contaminated and where it is contaminated. If water quality is indeed good, they need to know it is good.

How effective are current programs and policies for communicating the health risks of swimming at L.A. County beaches to the public? How might risk communication be improved?

Findings

Currently there are two main sources of information on water quality at the beaches. As discussed in Section 2.1, Heal the Bay issues grades that are posted on its web site as well as at some surf shops. Grades are updated weekly, are up-to-date, and are based on samples taken during the most recent four-week period. A history of weekly grades, in some cases going back over a year, is available for each beach. The Heal the Bay web site and grading system is a useful resource, but does not reach people who do not have internet access or who do not frequent the participating surf shops. Some of the public may also distrust or discount Heal the Bay grades because they are not government sanctioned.

The DHS is the second main source of information available to the public. DHS alerts the public of beach warnings and closures through warning signs posted at affected beaches, news releases to the media, and a telephone information hotline (800.525.5662). DHS posts warnings when bacterial levels exceed state health standards and closes beaches if there is a sewage spill that is known to have reached beach waters. The DHS is a useful and important source of information, but its public notification protocols have some shortcomings. First, the presence, or absence, of warnings may not provide an accurate picture of current water quality. People will have swum at a beach for one or two days (or longer if the beach is sampled weekly) before a test sample comes back from the lab showing that the bacterial levels are high. And, by the time the sample comes back, water quality may have improved. Second, the information hotline has not been adequately publicized so that it is well known by all potential beach-goers. Third, it is not clear how much attention people pay to posted warning signs, or really understand what they mean.

We are concerned that the public has an inaccurate and overly negative impression of beach water quality. Beach attendance fell by 32 percent between 1983 and 1997 (see Figure 2.2). This decline could have been due to many factors, including increasing traffic congestion, more limited or expensive parking, or growing concern about skin cancer, but increasing concern about water quality may have also played a role. The Los Angeles Times ran a series of articles on beach and ocean pollution last November that focused on beaches where there are pollution problems. Missing from the article was the message that the water quality at most beaches in L.A. County is good the vast majority of the time. One of the experts we interviewed who is doing work on public perceptions of water quality in Southern California said that his research shows that people generally think that water quality is poor and getting worse. (No studies have shown that water quality is in fact getting worse in recent years.) People think that some beaches are dirtier than others, but most are confused about which ones have the worst water quality. For example, most think the water in Malibu is clean, even though some beaches in Malibu (e.g., Surfrider) have poor water quality.

We also suspect that the public has very little understanding of the types of illnesses that are associated with the high bacterial levels found at some beaches (refer to Section 2.2 and Appendix B). Before our inquiry began, we at the Grand Jury had little idea of what types of illnesses are associated with swimming at the most polluted beaches in L.A. County. The public likely does not know that demonstrated risks are not life-threatening diseases, but rather an increase in earaches, runny noses, and gastrointestinal problems from a background rate of 2 percent when swimming in clean water to 4 percent.

We make two recommendations aimed at improving the public's understanding of water quality at County beaches. The first attempts to create a more accurate, visible method for communicating water quality conditions at individual beaches. The second is aimed at better informing the public about water quality at L.A. County beaches more generally.

Recommendations

3.2-A The L.A. County Department of Health Services should develop a grading system for beaches similar to that used at L.A. County restaurants and post these grades at sampling locations and in other highly visible locations at the beaches.

The current Heal the Bay grading system provides a good model for the new program. The new grading system would be most effective if groups such as Heal the Bay participate in developing it and endorse it.

Because of uncontrollable delays in the testing process, the best such grades can do is measure the likelihood, or probability, that the water is clean. Accordingly, the grades should be based on average water quality over the past several months to one year, although a second grade based on the most recent weekly sample might also be posted.

Grades should be posted at locations where sampling occurred (e.g., near storm drain outlets) and beach entrance points as well as on a county web site and telephone information line (the current County environmental phone line might be expanded to include the beach grades). The grading system and the type of health risks associated with each grade should also be posted and clearly explained.

3.2-B The L.A. County Department of Health Services should initiate a public information campaign to accurately communicate to L.A. County residents the health risks of swimming at L.A. County Beaches. The message should be that:

- **Beaches in L.A. County are among the best monitored in the nation.**
- **Swimming is safe during dry weather at the vast majority of beaches, although a few problem areas remain.**
- **Water quality standards are typically exceeded during rainstorms and beachgoers should not swim during or in the three days following significant rain (i.e. greater than 0.1 inch).**

The campaign should also provide accurate information on the types of illnesses and the chances of contracting them from swimming at beaches that violate health standards.

An effective way to engage the public in water quality issues might be to develop and publicize an overall measure of beach water quality. A weekly report on the percent of beaches meeting water quality standards is one possible method.

The media should be used to convey the message as appropriate, and the information should be available in written form and on a county web site. The campaign will be most effective if it is developed in partnership with and endorsed by local environmental groups.

SECTION 4. RECOMMENDATIONS FOR IMPROVING WATER QUALITY DURING DRY WEATHER AT SEVEN PROBLEM BEACHES

In addition to looking at regional issues related to water quality in Los Angeles County, we examined the specific problems at seven beaches: Surfrider, Topanga Canyon, Santa Monica Canyon, Santa Monica Pier, Pico-Kenter, Mother's Beach in Marina del Rey, and Cabrillo Beach. (see Figure 4.1) The beaches were chosen based on their consistently poor water quality, according to the Heal the Bay grading system.

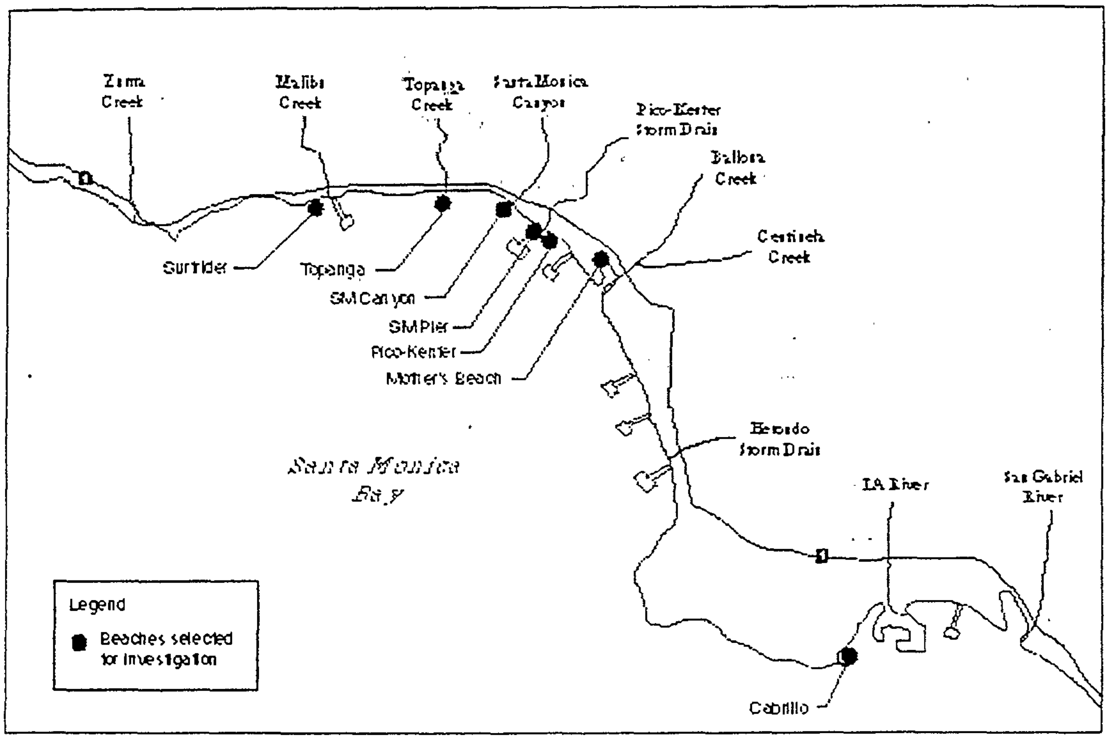

Figure 4.1 Location of the Seven Problem Beaches Chosen for Individual Examination

With only a few exceptions, these seven beaches are the only beaches in the county with consistent dry-weather problems. The exceptions include other beaches that face similar problems as the ones selected, but which have generally better water quality. For example, the beach in front of the Ashland Avenue storm drain in Santa Monica has had water quality problems similar to, but not as extensive as, those experienced at the beach in front of Pico-Kenter.

Some of the beaches have unique problems, such as low tidal circulation, and some have problems similar to beaches throughout the county, such as receiving urban runoff. In this section we focus on the specific problems at these beaches and examine local solutions. Solutions to the regional urban runoff problem are discussed in the following section. This approach allows us to get away from generalities and better understand the real-world problems and potential solutions. Studying individual beaches provides the opportunity to see which pollution-reduction strategies have worked, and which have not.

The issue addressed in this section is what progress has been made in making these beaches safer for swimming and what further should be done. We focus on bacterial indicators only in this section. We do not consider metals or toxic substances or other materials that might be harmful to the ecosystem, but not acutely harmful to humans. *Clean water* in this context thus means low levels of bacterial indicators. In this section, we also focus only on attempts to improve water quality during *dry* weather. In addition to being much more difficult to address, wet weather causes problems at most beaches in the county, not just the seven studied here. Wet weather problems are primarily caused by contaminated urban runoff, which we consider in Section 5.

4.1 SURFRIDER

Findings

Surfrider is a popular surfing beach located in front of Malibu Lagoon in the City of Malibu. Malibu Lagoon is an estuary at the bottom of Malibu Creek, the second largest watershed draining to Santa Monica Bay, after Ballona Creek. The watershed drained by Malibu Creek is 110 square miles, 88 percent of which is undeveloped.

Malibu Lagoon is usually separated from Surfrider Beach during dry weather by a sand berm. However, when water levels in the lagoon rise, either due to increased flows from Malibu Creek or other sources, the berm can breach. When the lagoon is closed, the water quality at Surfrider is very good. But when the lagoon is breached, the water quality at Surfrider quickly degrades as polluted lagoon water spills out into the ocean. As shown in Table 4.1, the water quality grades at Surfrider have been consistently Ds and Fs over the last 6 years.

There are numerous potential sources of pollution to Malibu Creek and lagoon. Wildlife, including birds, and urban runoff, including runoff from areas inhabited by horses, are two important sources. The most contentious potential sources of pollution to the lagoon are the city's commercial and residential septic systems.

In the late 1980s, before Malibu was incorporated, the County of Los Angeles decided that the area should be connected to a regional sewer because of septic system failures observed during county surveys. Locals disagreed and fought to keep the regional sewer out of Malibu. The residents finally won when they incorporated in 1991 and gained control over their wastewater systems. A consent decree between the City of Malibu and the County Board of Supervisors was signed in 1993. This document required that the County "stop work towards constructing a regional sewer system and to relinquish jurisdiction of wastewater disposal and management to the City of Malibu" (Los Angeles County Department of Public Works, 1993). The consent decree required that Malibu assume responsibility for the city's wastewater disposal practices. Thus the city took over the problem and the county stepped out of the picture.

Table 4.1
Heal the Bay Annual Grades
for Seven L.A. County Problem Beaches

Beach	Weather	1994	1995	1996	1997	1998	1999
Surfrider – breach location	Dry	D	F	F	F	D	F
	Wet	F	F	F	F	F	F

Source: Heal the Bay's Ninth Annual Beach Report Card, May 26, 1999, Tables 6 and 6a.
* Data not available

Since the City took over responsibility for the management of septic systems, a number of studies and reports have been prepared which address, in various ways, the pollution in the lagoon, possible causes of pollution, and the possible contamination from septic systems. Most of the stakeholders we interviewed outside the City of Malibu think that the studies have not provided convincing evidence that septic systems are not a source of pollution in the lagoon. Most in Malibu think that the studies have provided no solid evidence that septic systems are a problem.

In June of 1998, the Regional Water Quality Control Board (Regional Board) ordered the City of Malibu to develop a plan to assess whether the septic systems were contributing to contamination of the groundwater and/or lagoon. After a year of extended deadlines, lack of agreement on strategy, and issued and subsequently rescinded fines, the city and the Regional Board agreed upon a comprehensive monitoring investigation that was begun in the latter part of 1999. Although the results of this study have not yet been released, some stakeholders in the county are already skeptical about the reliability of the results.

The concern stems from the way the monitoring locations were chosen, especially those in front of the Malibu Colony. The city monitored at eleven locations, at every sixth lot along the coast (resulting in monitoring locations separated by distances of 300 to 800 feet). Because the city was not able to access public property in front of the Colony, the monitoring was conducted along the beach at the mean high tide line, on public property. Distances from the monitoring locations to homes ranged from 40 feet to 200 feet.

Critics of the study think that the monitoring locations should have been placed closer to individual leach fields, thus providing a better indication of whether individual septic systems are contaminating groundwater. Not having access to the study or the results, we cannot assess whether or not the monitoring locations were appropriate. This disagreement, however, illustrates the ongoing battle surrounding the septic system issue in Malibu, and the difficulty of coming to a consensus about what should be done. The dispute also touches on another relevant item: the city cannot monitor in many important locations because it cannot gain access to private property.

Groundwater levels are a critical issue in Malibu. A report prepared in 1999 indicated that when the groundwater level in the Malibu lagoon area is at least two feet below the bottom of a septic tank's leach field, pathogen transport to the Creek or lagoon is unlikely. However, when the groundwater rises closer to the leach field, pathogen transport is possible, though it is not known how far the pathogens can travel. One study found that groundwater levels in the Cross Creek Plaza commercial area, located adjacent to the lagoon, were 1.5 to 4 feet below the bottom of the leach fields, suggesting there may be problems in portions of this area. Groundwater levels in most residential areas of the City are not known; it is known, however, that the groundwater level in the Malibu Colony area is very shallow during periods of extended lagoon closure.

The Regional Board is responsible for regulating septic systems (Single family residences are specifically excluded from Regional Board septic system regulations). Owners of commercial and multi-family residences are required to apply for coverage under either an individual permit or the Regional Board's general Waste Discharge Requirement (WDR) for Domestic Wastewater Treatment Systems. Single family residences are excluded from the general WDRs. However, according to the Basin Plan, "the Regional Board retains jurisdiction over ... any situation where septic systems are creating or have the potential to create a water quality problem."

In 1999, the Regional Board began sending letters to commercial and multi-family residential septic system owners in Malibu requiring them to file for coverage under either an individual permit or a general WDR for septic systems. Coverage under both an individual permit and a general WDR would require complying with numerous requirements relating to proper maintenance and operation of the septic system, including groundwater monitoring requirements.

A confounding element in the Malibu lagoon pollution problem is the Tapia wastewater treatment plant. Tapia discharges tertiary-treated water to Malibu Creek. A 1999 UCLA study found Giardia and Cryptosporidium in Tapia effluent, but not at levels which are considered hazardous. More importantly, Tapia's effluent affects the water level of the lagoon, causing it to breach more frequently than under natural conditions. Last year the Regional Water Quality Control Board prohibited Tapia from discharging to the Creek during the summer. Without the Tapia effluent (and without rain) the lagoon did not breach this summer, and the water quality at Surfrider was good. The City of Malibu has been very active in pursuing strategies to reduce pollution in the lagoon that do not involve eliminating septic systems or monitoring existing septic systems. In addition, when failing septic systems are brought to its attention, the city takes action to ensure that the problems are remedied. A handful of the city's proposed solutions to the pollution problem include the following:

- Pumping water from Malibu Creek to a constructed wetlands to provide dry-weather flows with biological treatment.
- Construction of a spillway to control lagoon water levels in dry weather.

- Installation of disinfection equipment at storm drains discharging into the lagoon.
- Requiring that new developments and remodels have advanced treatment septic systems and maintenance contracts.

The septic system issue is enmeshed in politics. The Regional Board has been accused of backing down from issuing fines to Malibu in the face of strong political and financial support for the city. The predominant response the Regional Board has received to letters requesting application for WDRs has been letters from attorneys asking for extensions, although some commercial dischargers have been cooperating and are supportive of the Regional Board's efforts. The mixed response to the Regional Board's action foreshadows the fight that lies ahead if the Board pursues requiring these permits. A by-product of the struggle between the county and Malibu is the deterioration of the relationship between the city and county. Because Malibu does not have its own health department, the County Department of Health Services (DHS) is responsible for protecting the health of the citizens of Malibu. Therefore, residents reporting septic system failures in Malibu might call either the DHS or an agency within the city. Currently, the city notifies the county when it responds to a septic system complaint, but the city does not hear about problems attended to by the county.

Given the contentious nature of the septic system problem in Malibu and given that the city is pursuing several strategies to curtail pollution from other sources, the following recommendations focus only on reducing contamination from septic systems.

Recommendations

4.1-A Commercial and multi-family residential septic system owners in Malibu should obtain waste discharge permits from the Regional Board and comply with the terms of those permits.

This type of permit is required of anyone discharging waste that could affect the quality of water resources in the State of California. Septic systems operators in Malibu should not be exempted from this requirement. The monitoring information is needed to resolve the issue of whether or not septic systems are a problem.

4.1-B Groundwater levels in residential areas with a high water table, especially residential properties near the Malibu lagoon, should be monitored.

Everyone agrees that in order for septic systems to function properly, there needs to be adequate distance between the bottom of the leach field and the water table. Therefore, establishing the height of the water table is the first step in determining whether or not there may be septic system problems. Because of the difficulty the City of Malibu has gaining access to residential properties, the Regional Board should be requested to take the lead in this effort.

Although single family residences are generally exempted from Regional Board regulation, the unique situation in Malibu deserves a unique response. If problems are found with single-family septic systems, the Regional Board should be asked to re-examine this exemption. Los Angeles County should assist this effort. The County could provide technical and laboratory assistance to the Regional Board such as help with groundwater sampling and laboratory analysis of water samples.

4.1-C The Los Angeles County Department of Health Services should inform the City of Malibu when it responds to a septic system complaint.

In addition to allowing Malibu to keep better track of septic system problems within the city, such notification would facilitate coordination and communication between the two agencies.

4.2 TOPANGA CANYON BEACH

Findings

Topanga Beach is at the foot of Topanga Creek, which drains a watershed covering approximately 18 square miles. The Topanga watershed consists of predominantly undeveloped lands, much of which is held by state and federal park agencies as part of the Santa Monica Mountains National Recreation Area.

Water quality at the Topanga Canyon Beach is generally mediocre in dry weather and poor in wet weather, earning Fs in wet weather for the last six years in a row. Recent annual dry weather grades have been mixed, ranging A to F in the past six years (See Table 4.1).

Possible sources of pollutants within the Topanga watershed include wildlife, horses, urban runoff and septic systems. However, a lack of baseline data prevents further speculation about the extent of the contributions of each.

The water quality at Topanga Beach and sources of contamination have not received much scrutiny from environmental groups and government agencies. A group called the Topanga Watershed Committee (TWC) is taking the lead at addressing the problem. The TWC is an all-volunteer, community-based, coordinated resource management and planning group, established through a grant from the California Department of Conservation. Participants in the TWC include community members, landowners, government agencies, environmental groups, and other interested parties.

One of the goals of the TWC is to improve water quality in Topanga Canyon. To achieve that goal, TWC has developed the following actions designed to identify the degree and extent of the water quality problem:

- Monitor sites, identify existing regulations and possible solutions.
- Assess septic system function and impacts.
- Assess livestock waste/corral impacts
- Assess homeless encampment impacts
- Assess graywater disposal impacts
- Determine water quality in drinking water wells.
- Assess impacts due to use of fertilizers, pesticides, herbicides, etc.
- Assess source standards.

Another group with a role in the Topanga watershed is the Santa Monica Mountains Resource Conservation District (RCD), which oversees natural resource conservation within the Santa Monica Mountains, and is closely linked with the TWC. The RCD received a grant from the State Water Resources Control Board to fund a two-year study designed to examine the relationship between water quality and land use in the Topanga watershed. Working with the TWC, the RCD began work on the study in July 1999. The study involves water quality sampling at various locations along the creek in order to establish baseline water quality data. Results of the study will be used by the TWC and RCD to identify strategies for pollution reduction in the creek and at the beach. For example, data collected during the study could help identify where along the stream pollutants are introduced. This information would be used to narrow down the possible sources of pollutants to the water body.

Recommendation

4.2 **The County Board of Supervisors should ensure that the county continues to participate in and have an active voice in the Topanga Watershed Committee. The Board of Supervisors should require that representatives of appropriate departments (e.g., Department of Beaches and Harbors, Department of Health Services, Department of Public Works) regularly attend TWC meetings and facilitate TWC's goal of improving water quality in the canyon. The county should continue to make available to the TWC the skills, expertise and experience of its staff to provide, as appropriate and as requested by the TWC, technical assistance, advice and guidance.**

4.3 SANTA MONICA CANYON

Findings

The Los Angeles County-owned storm drain at Santa Monica Canyon discharges at Will Rogers Beach in the City of Los Angeles. The watershed contributing to this storm drain includes primarily residential and open space land uses. Roughly half of the watershed is open space owned by the state. The annual dry weather grades at Santa Monica Canyon for the last six years have been poor (see Table 4.1).

The City of Los Angeles, County and Heal the Bay conducted a study to determine the sources of pollution in the Santa Monica Canyon storm drain. The study identified no primary source. Instead, the study pointed to many different sources, including horses and septic systems. Other potential sources include wildlife and pet droppings. A study conducted in 1991 found live viruses in Santa Monica Canyon, indicating that other possible sources of pollution in this drain are leaks or spills from the sewage system, private septic systems, or homeless populations.

A plan for diverting low flows at Santa Monica Canyon into the sewer system between April and September is currently under consideration by the Los Angeles City Council. This would solve the summer pollution problem at the Santa Monica Canyon beach. A year-round diversion is not under consideration at this time because the receiving wastewater treatment plant could not accommodate flows resulting from heavy rains, and the problem of ensuring that the diversion would be by-passed during storms has not yet been resolved. Most people we interviewed believe that this project will go forward, but a decision has not yet been finalized. Many issues have arisen in the debate over whether to proceed:

- The pros and cons of diversion as compared with source reduction.
- Liability associated with flows directed to the Hyperion wastewater treatment plant.
- Cost sharing.
- Prioritizing which flows to divert.

The City and County of Los Angeles would share the costs of the diversion. Funds from Proposition A in the amount of one million dollars have been earmarked for this project.

Recommendation

4.3 The County and City of Los Angeles should proceed with the planned construction of a seasonal diversion project.

Although there are some unresolved issues related to diversion policy more generally, we believe that it makes sense to go ahead with the diversion at this beach. It is a popular beach and the dry-weather urban runoff is substantial. A source investigation has been done, and no particular sources stood out. It is almost certain that efforts to reduce pollution sources will not yield results any time soon. Small-scale, local treatment is a conceivable alternative to diversion, but the real-world feasibility and cost-effectiveness of these systems has yet to be demonstrated. Diversion is the only way to ensure that water quality at this beach will be good in the near future. Issues relating to low-flow diversions are discussed in more detail in Section 5.6 of this report.

4.4 SANTA MONICA PIER

Findings

Santa Monica Pier is a recreational destination attracting large numbers of tourists with its amusement park rides, games and food, as well as nearby parking and hotels. It is also a popular destination for recreational fishermen.

A storm drain located under Santa Monica Pier discharges runoff from a small drainage area of 0.13 square miles. The predominant land uses are commercial and retail; other land uses include restaurants, hotels and high-density apartments. The Los Angeles County Department of Public Works monitors the water quality in the Santa Monica Pier storm drain as part of its Municipal Stormwater Permit. Monitoring data reveal that water in this drain contains minerals, solids, metals, and pesticides. Tests were not done for hydrocarbons or bacteria.

The beach monitoring station is located 50 yards south of the pier. Both dry and wet weather annual grades at the pier have been almost exclusively Fs over the past 6 years, with the exception of 1994, when the location received a B in dry weather and a D in wet weather (See Table 4.1). Fortunately, the water quality problems at Santa Monica Pier are not characteristic of the other piers in L.A. County. Water quality near these other piers is not consistently poor.

The pollution problem at this location has received much attention over the past several years. Attempts at eliminating sources of pollution have thus far been unsuccessful. The first attempt at reducing pollution was when the City of Santa Monica diverted low flows from the storm drain under the pier to the Hyperion treatment plant during summer months. Flow from the pier storm drain was periodically diverted to Hyperion in 1996. In 1997, a permanent diversion system was installed.

The City of Santa Monica, with funding from the City of Los Angeles and Proposition A, is constructing the Santa Monica Urban Runoff Recycling Facility (SMURRF) just south of the pier and north of the Pico-Kenter storm drain. When the SMURRF is operational, flows from both the pier and the Pico-Kenter storm drains will be diverted to this treatment facility. Low flows from both storm drains will be treated year round. During storm events, flows over the facility's capacity will be discharged to the ocean.

Roughly a year ago, a City of Santa Monica investigation of the sewer lines running underneath the pier resulted in the discovery of several leaks that were subsequently repaired. Birds were also suspected to be a large part of the problem, so a bird entrapment program was launched by the city, resulting in a perceived decrease of the bird population. None of these actions has significantly improved grades south of the pier.

The most recent strategy to reduce pollution has been the placement of signs along the pier warning visitors to avoid littering and improperly disposing of food waste. Mostly by process of elimination, it is thought that littering by pier visitors (including improper disposal of fishing waste), is the primary source of pollution – both the litter itself, and waste from the birds it attracts.

The attempt to track down and eliminate sources of pollution at the pier is ongoing. Recent strategies have focused on ensuring that garbage cans are not leaking polluted water into the ocean.

A Continuous Deflective Separation (CDS) unit was recently installed in the pier storm drain. This device filters out trash and sediment thereby reducing the amount of pollution reaching the beach (when the drain is not diverted). Visual inspections of the unit have revealed that it is operating properly and has been effective at removing most trash and sediment from the storm drain flow.

Recommendation

4.4-A The City of Santa Monica should regularly inspect the sewer lines under the pier.

4.4-B The City of Santa Monica should continue to educate pier visitors about the harmful effects of littering, feeding the birds, and improper disposal of fishing waste.

4.4-C The City of Santa Monica should continue to scrutinize the water quality monitoring data at this location.

4.4-D Until water quality improves, the City of Santa Monica should place permanent warning signs along the beach within 50 yards south of the pier. The signs should

warn swimmers that this beach has consistently poor water quality and they should briefly describe the health risks associated with swimming in polluted water.

4.4-E **Before moving on to very expensive solutions, the City of Santa Monica should reconsider the water quality goals for this beach.**

The minimal success of the city's substantial efforts to improve water quality south of the pier raises the concern that a heavily-visited pier and an adjacent swimming area are not compatible uses. Therefore, if the recent educational efforts do not result in improved water quality, the City of Santa Monica should reconsider its water quality goals for this beach and evaluate whether further efforts to meet the bacteria standards make sense. If the city does decide to relax its water quality goals at this beach, it should make sure that the public is adequately warned about the poor quality of the water and associated health risks. Issues relating to conflicting uses are further discussed in Section 5.1.

A more cautious alternative to posting warning signs would be to close the beach immediately south of the pier altogether. We do not think this is warranted. As discussed in Section 2.2, the demonstrated health risks of swimming in water contaminated at the levels observed are not severe (incidence rates of gastrointestinal problems, earaches, etc. rose from two to four percent), and the risks of swimming in water contaminated with bacteria coming from birds rather than human sewage may be even less. We do think, however, that the persistent nature of the problem south of the pier and the lag time between monitoring and posting discussed in Section 3.1 does warrant permanent posting.

There are a number of strategies that could be considered by the city if current efforts fail and it decides to make further efforts to improve water quality south of the pier. One suggestion is to eliminate bird roosting nests under the pier. Another strategy would be to hire personnel to walk the pier and enforce anti-littering policies. However these approaches are costly, and there is no guarantee that they will work.

4.5 PICO-KENTER

Findings

The Pico-Kenter storm drain is located in the City of Santa Monica, one half mile south of the Santa Monica Pier. This facility drains portions of Santa Monica and Los Angeles. This drain has been diverted in summer months to the Hyperion wastewater treatment facility since the early 1990s. Instances of problems with the diversion system, including leaks and breaks, have prevented this beach from receiving good grades even when the diversion has been in place.

The beach at the foot of this storm drain has received Fs for the past six years during wet weather. During dry weather, the annual grades for the past six years have been poor (see Table 4.1). It is important to remember that the dry weather annual grade takes into account months in the winter when the drain is not being diverted, as well as summer low flows that are diverted. A closer look at the Pico-Kenter monitoring data reveals that when the diversion is in place and functioning properly, the water quality at this beach is very good.

Human enteric viruses have been found in the runoff from Pico-Kenter storm drain, indicating that sewage has infiltrated the storm drain system. Other potential sources of pollution include those typical of most storm drains such as illicit connections, homeless and pet droppings. The City of Santa Monica and the City of Los Angeles share ownership of and maintenance responsibilities for the storm drain.

As discussed above, the City of Santa Monica is constructing a water treatment facility (SMURRF) just south of the pier and north of the Pico-Kenter storm drain. When the SMURRF is operational, flows from the Pico-Kenter storm drain will be diverted to this treatment facility year round. A CDS unit is being installed at Pico-Kenter; flows from the storm drain will be routed through the CDS before being diverted to the SMURRF. Once the SMURRF is operational, dry weather water quality is expected to be good year round.

Recommendation

4.5 No recommendation is required. This storm drain is currently being diverted in the summer and will be diverted year round (low flows only) to the SMURRF.

4.6 MOTHER'S BEACH, MARINA DEL REY

Findings

Mother's Beach is a popular family beach located at the end of one of Marina del Rey's eight basins. Marina del Rey is a man-made marina, housing 6,000 boat slips, numerous restaurants and over 10,000 residents. It is maintained by the Los Angeles County Department of Beaches and Harbors (DBH).

Water quality at Mother's Beach is inconsistent and often very poor. Wet weather grades at the playground monitoring station have been poor during the past six years while annual dry weather grades have been mixed (See Table 4.1).

A major cause of poor water quality at this beach is limited tidal circulation. The breakwater that protects the marina from potentially damaging waves also inhibits tidal flushing in the entire marina. The far reaches of the marina, such as the end of Basin D, are subject to very little flushing action at all. Therefore, when pollutants are introduced into the water at Mother's Beach, they are likely to remain.

Speculation about and investigation into the sources of pollution at Mother's Beach have been ongoing since the 1970s. In the past few years, attention has been directed towards the large bird population that frequents Mother's Beach. The DBH has made several improvements aimed at reducing the bird population. A grid of thin braided nylon lines (often inaccurately referred to as mono-filament lines) has been strung above the beach and is thought to interfere with the birds' flight patterns, thus deterring them from landing at the beach.

Another improvement directed towards bird reduction was the installation of roost-proof buoys. The previous buoys proved an attractive roosting location for birds as they are adequately sized (roughly 36 inches in diameter) and constructed from a black neoprene which absorbs the sun's heat and becomes enticingly warm. The birds would roost and pollute the buoy and surrounding water with bird feces. The new buoys are small on the top and lighter weight and tip over when birds land on them.

The new buoys were installed in the beginning of last summer and the braided nylon grid was upgraded in the spring. The grades at Mother's Beach last summer were much better than in the previous summer, suggesting that the recent strategies may be working. Grades at the beach from April through early November of 1999 were As and A+s. However, the beach has received Fs since the end of November, so it is not clear that the problem has been solved.

Other possible sources of pollution at Mother's Beach are the Oxford Creek storm drain, which discharges to the basin adjacent to Basin D, pollution from the boats in the marina, and improper urban runoff practices by restaurants in the marina. It is not known to what degree these sources contribute to the pollution problem at Mother's Beach.

The DBH has considered other options for Mother's Beach which have been put on the back burner both in light of the recently improved grades and due to cost and technological constraints. One such option is the installation of a filter technology at Mother's Beach to reduce pathogen flow from sources outside the beach. The filter allows water to flow through, but prevents particles larger than 20 microns from passing. Pathogens attached to larger particles could not pass through the screen. The filter would be installed in the water between Mother's Beach and the remainder of Basin D. The drawbacks of the filter technology are that: 1) it is expensive; 2) it would further hinder circulation; 3) whether the pollution is coming from the marina as opposed to the shore is unknown; and 4) even if the pollution is coming from the marina, its effectiveness is uncertain.

Another option that has been considered but is not currently being pursued is the construction of a swimming-pool-like structure, similar to the plunge in Redondo Beach. The facility would be carved out of the beach, enclosed with a sand bottom and filled with salt water. Construction of a bathing pool would allow control of the water quality, thus reducing health risks to swimmers.

Recommendations

4.6-A The County Department of Health Services (DHS) and County Department of Beaches and Harbors (DBH) should continue monitoring to determine whether the recent improvements (additional braided nylon lines, roost-proof buoys) are effective at reducing pollution at Mother's Beach.

4.6-B Until water quality improves, the DBH should place permanent warning signs along this limited-circulation beach. The signs should warn swimmers that this beach has inconsistent and often poor water quality and they should briefly describe the health risks associated with swimming in polluted water

4.6-C Before moving on to very expensive solutions, the DBH should reconsider the water quality goals for this beach.

This beach may be another example of inconsistent land uses. Perhaps a limited circulation beach located adjacent to a marina is not an appropriate swimming beach. The issues at this beach are similar to those discussed under Recommendation 4.4 (Santa Monica Pier). Again, the responsible agency, in this case, Los Angeles County, needs to decide how much money it wants to spend to ensure low bacterial indicator levels at this beach.

If the DBH decides that getting high grades at Mother's Beach is a fiscal priority, options that have been put on the back burner because they are prohibitively expensive or because of technological barriers could be reconsidered. In addition to the options mentioned above, the DBH could consider engineering solutions to improve tidal circulation, such as pumping water into the beach from other, cleaner areas of the marina or ocean. Such enormous expenditures would require a strong mandate that safe swimming at Mother's Beach is a priority to be achieved at even high cost.

4.7 CABRILLO BEACH

Findings

Cabrillo Beach is located on the east side of the Palos Verdes Peninsula, within the San Pedro Breakwater. This is a limited circulation beach, protected from ocean currents by the breakwater and bordered by two jetties. Circulation is also inhibited by eelgrass growing in the water in front of the beach. A portion of the beach is marked by buoys as a swimming beach. Cabrillo Beach is heavily used by an economically diverse population.

Cabrillo Beach is considered the most polluted beach in the county. It has received annual grades of Fs for both dry and wet weather for the past five years (with one exception – it received a dry weather grade of D in 1996).

In November of last year, the City of Los Angeles launched an intensive investigation at Cabrillo Beach to determine the source of the pollution. Possible sources considered were leaks from the sewer lines running to the restrooms on the beach, storm drains, the adjacent marina and pier, the Dominguez Channel, bather loading, and birds.

The study allowed the city to eliminate several possible sources and come to the conclusion that the problem is the birds. Off-shore sources (such as pollution from the marina) were eliminated because bacteria levels were higher at ankle depth than at knee and chest depths. Leaks from the restroom were ruled out by groundwater sampling between the shore and the facilities. Storm drains were eliminated because they do not flow unless it rains, and the problem persists in dry weather. Also, groundwater sampling along a line between the beach and the storm drain outlet did not reveal that the storm drain was a source of contamination. The Dominguez Channel was excluded because bacterial levels were not high in water samples taken at the mouth of the Dominguez Channel.

Humans are not thought to be the primary cause of the problem because bacteria levels are higher in the winter, when there are fewer people and more birds. That is not to say that humans do not contribute to the problem. People leave trash and even diapers along the beach.

To ensure that humans are not the source of the problem, human virus testing will be done by the City of Los Angeles on low-use and high-use days.

The eelgrass contributes to the problem both because it inhibits tidal circulation and because it washes up on the beach and captures organic matter such as bird feces.

The city's options at this beach are limited. They sweep the beach daily to remove eelgrass and all the ensnared organic matter. They are planning on replacing the buoys marking the swim area with a roost-proof model. Installation of a braided nylon grid, such as that the one at Mother's Beach in Marina del Rey, is not an attractive option because this beach is considered a bird habitat.

One option suggested in the city's review is to install a fence between the area where the birds tend to sit and the swimming area. Some believe this might inhibit the birds' movement into the bathing area, reducing pollution in this area.

This issue is currently under consideration by the Los Angeles City Council.

Recommendations

4.7-A The City of Los Angeles should take the measures to limit seagull use of the beach in front of the swimming area (including the fence solution) identified in their recent investigation of Cabrillo Beach.

4.7-B Until water quality improves, the City of Los Angeles should place permanent warning signs along this limited-circulation beach. The signs should warn swimmers that this beach has consistently poor water quality and they should briefly describe the health risks associated with swimming in polluted water.

4.7-C Before moving on to very expensive solutions, the City of Los Angeles should reconsider the water quality goals for this beach.

This beach, again, brings up the question of having two competing uses at one beach – in this case, bird habitat and swimming. Therefore, if measures to limit seagull use of the beach are ineffective, the City of Los Angeles should reconsider its water quality goals for this beach and evaluate whether further efforts to meet the bacteria standards make sense. If the city does decide to relax its water quality goals at this beach, it should post permanent warning signs about the poor water quality and the risks of swimming. Again, the issues discussed for Santa Monica Pier (see Section 4.4) apply also at this beach. How important is it to us as a society to ensure low bacteria levels at this beach? A costly solution could include running a pipe from outer Cabrillo Beach (outside of the breakwater) to inner Cabrillo Beach to improve tidal circulation.

Cabrillo is one of the few beaches in L.A. County in close proximity to lower income neighborhoods. It thus provides an easily accessible recreation opportunity for low-income families. This feature should be kept in mind when determining how much to spend to reduce bacteria levels at this beach.

SECTION 5. RECOMMENDATIONS FOR IMPROVING THE QUALITY OF URBAN RUNOFF

This section evaluates and makes recommendations about efforts in Los Angeles County to improve the water in the rivers, creeks, and storm drains that flow into the ocean. Urban runoff and other non-point sources cause bacteria levels to exceed health standards at almost all L.A. County beaches during wet weather (defined as the period during and the 3 days following rain). Urban runoff also causes high bacteria levels at some beaches during dry weather. In addition, urban runoff contains other contaminants such as metals and organic chemicals (e.g., pesticides) that may pose health risks to swimmers.

As previously mentioned, the Grand Jury cannot investigate nor make recommendations to the Los Angeles Regional Water Quality Control Board; however, recommendations to Los Angeles cities and Los Angeles County must be viewed within the context of Regional Board public programs and policies.

The Los Angeles Regional Water Quality Control Board is responsible for setting water quality standards and issuing permits aimed at reducing pollution in L.A. County's rivers, creeks, and beach waters. Thus, this section is largely about the Regional Board's programs and policies. It also addresses the policies and programs of the County and the cities in L.A. County.

The Regional Board, prodded by several lawsuits by environmental groups, has ambitious plans to improve the water quality of urban runoff in L.A. County. However, we are concerned that the institutions, programs, and resources in place may not be up to the job. Below we make several recommendations for improving the system and urge the Board of Supervisors and city governments to take steps necessary to implement them. At stake is both the speed with which the benefits of cleaner rivers, creeks, and beach waters will be realized and the effectiveness of the billions of dollars that may well be spent by public and private organizations in the cleanup effort.

The following issue areas are examined in this section:

5.1 Setting goals for the uses of rivers, creeks, estuaries, and beach waters.
5.2 Identifying pollution sources.
5.3 The Regional Board's role in designing programs.
5.4 Enhancing incentives to improve water quality.
5.5 Matching authority with responsibility.
5.6 Policies for diverting urban runoff into the sewer system.
5.7 Monitoring and enforcement.
5.8 Funding for water quality programs.

5.1 SETTING GOALS FOR THE USES OF RIVERS, CREEKS, ESTUARIES, AND OCEAN

Issue

The Regional Board specifies beneficial uses for the rivers, creeks, estuaries, and beach waters in L.A. County. Different beneficial uses imply very different water quality objectives and potentially very different compliance costs. What should these beneficial uses be? Are the currently listed beneficial uses appropriate?

Findings

The Regional Board has designated beneficial uses for specific water bodies in L.A. County. These water bodies include rivers, creeks, estuaries, lakes, and beach waters. There are 24 possible beneficial uses, ranging from water-contact recreation, shellfish harvesting, and freshwater habitat to uses of water for municipal drinking water systems. Varying combinations of the 24 beneficial uses have been designated for each of the water bodies in the county.

Many experts we talked to feel that some of the designated beneficial uses are inappropriate. For example, contact recreation is listed as a beneficial use in many of the channelized sections of the L.A. River, even though access to the concrete-lined channels is prohibited. Cleaning water up in Ballona Creek so that shellfish at the mouth of Ballona Creek are safe for human consumption does not seem like a sensible goal to many. And many feel that reducing pollution in the L.A. River so that it can be used in domestic water systems (after standard treatment) is a poor use of society's resources when it is not clear that the State Department of Health Services would ever allow flow in many reaches of the L.A. River to be used directly for drinking water.

Some stakeholders feel that the process through which beneficial uses were designated (mainly in the 1970s) was inadequate. They think that the designations were done haphazardly, without proper quality control on the data and analysis. We have not been able to assess whether the process was really lacking, but regardless of the answer, it is clear that there is not widespread support among the experts we interviewed for many of the beneficial uses. This lack of support stops many from fully supporting and contributing to efforts to improve the quality of urban runoff and may lead to lawsuits that can further slow the process.

Others, mainly from environmental groups, that we talked to feel that most beneficial uses are appropriate. They criticized efforts by the County Sanitation Districts of L.A. County that used taxpayer dollars to try to "delist" drinking water as a beneficial use in several rivers and creeks. Even those that supported most beneficial uses, however, think there are probably some situations where the designated uses do not make sense.

It is very difficult to delist a beneficial use once it has been listed. By design, the barriers are high to discourage backsliding on water quality goals. Supporting the County Sanitation Districts' efforts, the Regional Board submitted a petition to delist drinking water on several reaches, but the petition was denied by California's Office of Administrative Law (the agency responsible for ensuring that proposed regulations comply with required formats and legal standards) in the summer of 1998 as insufficiently documented. We observe that while it may make a great deal of sense to create high barriers to delisting thoughtfully listed beneficial uses, it may not make sense to impose such high barriers if the original listing process was flawed.

Our examination of the beneficial uses in L.A. County also suggests that there may be conflicts among the beneficial uses that have been designated for some water bodies. For example, both water-contact recreation and wildlife are designated as beneficial uses in Malibu Lagoon, but the presence of birds may make it very difficult to meet the bacteria standards for swimming. Similarly, contact recreation and wildlife are listed at Cabrillo Beach, and we have seen how these two uses may not be compatible.

Recommendation

5.1 A meaningful process to prioritize the beneficial uses for the water bodies in L.A. County should be created. Near-term water quality programs should attempt to achieve the high-priority beneficial uses. Programs required to achieve lower priority beneficial uses should be deferred.

The resource costs of the process itself and likely legal challenges make delisting an unattractive way at this point to resolve the inconsistencies between some listed beneficial uses and the lack of support for others. A phased approach leaves the beneficial uses in place, but focuses attention on the most important beneficial uses first. It means that instead of installing treatment technologies or developing pollution prevention strategies that meet the most stringent water quality objectives all at once, goals would at least initially be less ambitious. Decisions to pursue lower-priority beneficial uses would be made once there is more real-world experience with the costs and effectiveness of different pollution reduction technologies and when spending on the high-priority beneficial uses begins to wind down. It may ultimately make sense to delist some beneficial uses if certain water quality objectives are unattainable or attainable only at very high cost. However, we do not need to make the decision to delist now.

When prioritizing, it may make sense to consider beneficial uses separately during wet and dry weather. For example, water-contact recreation may be sensible in dry weather when flows in rivers and creeks are low, but not in the relatively few days of wet weather in Southern California. High flows during wet weather are dangerous, and it will likely be very expensive to reduce the contaminant levels in such large runoff volumes.

The Regional Board is beginning to issue so-called Total Maximum Daily Loads (TMDLs). TMDLs allocate pollutant loads to the different sources on a particular water body and provide the basis for pollution reduction requirements from the various sources. Leaving all beneficial uses on the books will likely mean that Total Maximum Daily Loads (TMDLs) will have to satisfy all beneficial uses, but the decisions to implement the load reductions can still be phased.

A meaningful process to prioritize beneficial uses would involve the participation of the various stakeholders—the county, the cities, industry, and environmental groups—and would create a process and decision-making criteria that all can support and abide by.

5.2 IDENTIFYING POLLUTION SOURCES

Issue

An effective and cost-conscious program for reducing pollution in urban runoff must be based on a solid understanding of the sources of pollution. Without this understanding, the right activities may not be targeted and resources may not be spent in the most effective manner. For example, if leaking sewers are the main source of the bacteria in urban runoff, resources should focus on detecting and fixing leaks. If sewers were not a major problem, investing resources on leak detection would not yield many payoffs. Do we have a good understanding of the sources of pollution in urban runoff?

Findings

Measurements show that urban runoff contains high levels of bacteria and other contaminants both in wet and dry weather. But there is little agreement on the relative importance of the potential sources of pollutants (see Section 2.3 for discussion of possible sources).

There is particular controversy over the source of bacteria. Some (often the people responsible for the city and county storm water programs) put the majority of the blame on the sewer system. Noting that much of the sewer system in the City of Los Angeles is over 50 years old and, in their view, poorly maintained, they believe that blockages or capacity limits frequently cause sewage to come up through manhole covers and then flow into storm drains. Some also believe that leaks in the sewer pipes allow sewage to migrate underground into the storm drain system.

Others (usually people responsible for the sewer system) put the blame for high bacteria levels on contaminants picked up by water running over the surface on its way to storm drains and on illegal discharges and connections to the storm drain system. In their minds, sewers are not the main problem, and resources should be spent reducing these other sources of pollution. Sources of bacteria in surface runoff include pet and bird droppings, the homeless, and food waste washed off restaurant mats. Fertilizers and food from restaurant mats in surface runoff can also provide nutrients that allow the bacteria to multiply.

The lack of agreement reflects a lack of solid information on pollution sources. Even basic characteristics of the system are not well understood. For example, many experts think that there is a "first-flush" effect, that is, that pollution is highest during the first rainfall of the season. However, recent monitoring data suggest that the first-flush effect does not apply to bacteria: bacteria densities observed during the first storm of each rainy season were not necessarily higher than during consecutive storms.

While the beaches and Bay are extensively monitored, there has not been much monitoring inland. L.A. County is required by its storm water permit to collect water quality data at a number of inland sites, but the scope of this effort is limited.[4] Several cities in L.A. County, researchers at UCLA and other organizations, and some environmental groups have analyzed inland water samples, but the efforts are scattered.

There does not appear to be much communication or coordination among the organizations that are doing sampling. There is no well-thought-out division of responsibilities or allocation of costs. Indeed, some organizations are not aware of the sampling other organizations are doing. Sampling procedures and test protocols are not always consistent, making it difficult to compare results (see Section 3.1). There is no central inventory or repository of existing data, making it difficult to know what has been done or learn from the experience of others either in L.A. County or in other parts of the state.

The importance of solid information in designing cost-effective pollution control strategies leads us to recommend that inland monitoring efforts be expanded and coordinated.

Recommendation

5.2 Efforts to identify the sources of the pollution in urban runoff should be coordinated and expanded. In particular:

- **An inventory and assessment of the comprehensiveness and quality of existing water quality data should be compiled.**
- **Water quality monitoring should be expanded to fill gaps in our understanding of pollution sources.**
- **Monitoring efforts should be coordinated and sampling procedures and testing protocols standardized.**
- **A rational formula for sharing costs between the county the cities in the county, and other involved parties should be developed.**

Because human sewage is thought to pose the greatest threat to swimmers, particular attention should be paid to the contribution of the sewer system, the homeless, and illegal connections and discharges to the high bacteria levels in urban runoff. A joint powers authority whose mission is to collect standardized monitoring data both inland and along the shore should be considered. The mission of the Southern California Coastal Water Research Project (SCCWRP), which has been involved in evaluating shoreline monitoring procedures, might be expanded to take on these responsibilities.

[4] During the 1998-99 storm season, L.A. County collected wet weather data at 5 "mass"-monitoring stations, 8 land-use sites, and 9 critical source sites (along with 9 control sites). The mass-monitoring stations sample water that drains from large, or massive, drainage areas; the land-use sites are chosen to be representative of particular land uses; and the critical source sites are chosen to test the effectiveness of BMP implementation at industrial sites thought to generate substantial pollution. Some dry-weather sampling is also done at the mass-monitoring sites.

5.3 THE REGIONAL BOARD'S ROLE IN DESIGNING PROGRAMS

Issue

The Regional Board can take two fundamentally different approaches to reducing the pollution in urban runoff. It can specify performance standards, say in terms of the concentrations of bacteria and other contaminants in discharges to surface waters, and then leave it to the cities, county, and businesses responsible to figure out how to meet them. Or it can require the cities, counties, and businesses to adopt particular pollution reduction programs, the implementation of which will satisfy their responsibilities to reduce pollution. What mix of approaches should L.A. County support?

Findings

As far as urban runoff is concerned, the Regional Board is very much in the business of requiring permittees to develop programs to reduce pollution, approving them and then requiring that they be implemented. It does not write permits in terms of the concentrations or pollutant loads that permittees are allowed to discharge to the storm water system.[5] The Board requires the county and cities to develop storm water management programs and submit them to the Board for approval. The Board reviews and may modify the proposed programs. Once approved by the Board, the programs are then incorporated into NPDES permits.

The current urban runoff permit for the county and cities requires them to develop and implement programs to:

- Eliminate illicit connections and illicit discharges to the storm drain system.
- Control pollution both during and after construction from new development.
- Reduce the impact of public agency activities on urban runoff quality.
- Raise public awareness of urban runoff quality issues.

In all but a few instances, the county and cities are not held directly accountable for the quality of the urban runoff that flows from their jurisdictions into the rivers, creeks, and ocean of L.A. County. Rather, implementation of the Board-approved programs satisfies their responsibilities.

The recently adopted requirement to restrict runoff from new development is an example of a program developed to control pollution. As principal permittee for the municipal urban runoff permit, L.A. County developed (and has implemented in its own jurisdiction) a program that requires certain categories of new development to retain or treat runoff from the first three-quarters of an inch of rainfall on their properties. The county developed the requirement as part of a legal settlement with environmental groups, and the program is very contentious. Even though the county considered a wide range of input in developing the program, many cities and developers think it much too costly. The Regional Board approved the rule with some

[5] The L.A. County urban runoff permit says "Timely and complete implementation by a Permittee of the storm water management programs prescribed in this Order shall satisfy the requirements of this section and constitute compliance with receiving water limitations." If the programs are inadequate to achieve water quality objectives, the permittees "shall submit revised storm water management programs ... that will increase the likelihood of preventing future exceedances of water quality objectives".

modifications, and the program is now mandatory for all the cities and unincorporated areas of the county.

Requiring programs has some advantages. It creates an even playing field across the county and consistency of regulations. It also eliminates the need for water-quality monitoring to measure compliance with a performance-based permit.

The Board's focus on requiring programs rather than setting performance standards raises several concerns, however. First, because the cities, county, and industrial sources do not have direct responsibility for meeting water quality standards, their focus becomes designing and implementing approvable programs, whether or not they are effective. While some agencies and businesses will undoubtedly take their responsibilities very seriously, others will likely try to get by with the least effort possible. Second, the structure and condition of the economy, the types of pollution sources, and geography vary a great deal across the county, and region-wide programs are unlikely to work equally well in all areas. For example, it may be that treatment makes much more sense in some areas, while prevention is the best approach in another. Third, as discussed more below, the Regional Board is very resource constrained. Reviewing, modifying as necessary, and then approving these programs is staff-intensive, as is monitoring whether the programs are actually being implemented as designed.[6] Finally, we are concerned with the focus on programs rather than standards because there seems to be little attention being paid among the regulated as to how well the programs that are approved and implemented really work. This does not bode well for a cost-effective pollution reduction strategy.

These concerns motivate our recommendation that the cities and County agencies focus more on setting limits on the contaminants in effluent and fixing responsibility for meeting them rather than designing programs.

Recommendation

5.3 Los Angeles cities and the County should focus more on setting limits on the contaminants in discharges to surface waters and fix responsibility for meeting them.

Holding cities, the county, and certain types of businesses responsible for numerical water quality objectives will make them very much interested in the design and implementation of water quality programs in their areas. Setting goals will allow regulated entities to design the programs that best fit their situation and encourage them to carefully evaluate the programs' effectiveness.

[6] U.S. EPA has criticized the Regional Board for delays in reviewing the model programs submitted under the L.A. County municipal storm water report. EPA has noted that there was a significant lack of overall progress in implementing the terms and conditions of this storm water permit. The Board had not reviewed and approved the model program components submitted by Los Angeles County, the lead permittee. Five major model programs had been submitted by the county but had not been reviewed and or approved by the Board. EPA's concern was so great that it recommended that neither it nor the Regional Board issue permits which rely on actions by a regulatory agency before requirements can go into effect.

As discussed above, requiring programs has certain advantages, but, particularly in the coming world of TMDLs, we believe that defining compliance in terms of effluent limits is the better approach.

A focus on meeting water quality objectives requires comprehensive monitoring of the water that leaves each regulated entity (the cities, the county and regulated businesses). The intermittent and variable nature of urban runoff creates some difficulties in monitoring, but we are confident that modern automated sampling equipment can be effectively used. Increased monitoring will mean increased costs, but savings from a more efficient program will offset these increased costs.

Because of uncertainties in the sources of pollution and in the cost and effectiveness of different control strategies, some cities will undoubtedly prefer that compliance be defined in terms of implementation of a set of programs rather then in terms of meeting water quality objectives. However, the Regional Board can set or phase in water quality objectives taking into account these uncertainties.[7] There is a movement away from centralized, command-and-control regulations in the United States and toward policies with more flexibility and dispersed responsibility. While some may be comfortable with the old system, the new system promises better results at lower costs.

5.4 ENHANCING INCENTIVES TO IMPROVE WATER QUALITY

Issue

The previous section urged the responsible agencies broad discretion in designing programs to achieve objectives. This section addresses the character of these programs. In particular, it examines the role of incentives for voluntary actions to improve water quality. What mix of incentives versus required programs makes sense in L.A. County?

Findings

The current system relies very little on financial, market, or other incentives to improve water quality. Programs adopted by the cities, county, and Regional Board are in the form of regulatory programs with penalties (at least in principle) for noncompliance. Programs that rely on voluntary response to individual or organizational incentives are being used to address many other resource and environmental problems and could be applied here.

Some incentives that have been used are financial: for example, financial incentives to install low-flow toilets or energy-efficient refrigerators. Sometimes the incentives are reputational. EPA's Green Star program, for example, acknowledges businesses with model environmental programs. These awards can help improve perceptions of the companies in the communities in which they operate or with regulators or consumers. Market incentives have also been used in several areas. The South Coast Air Quality Management District's RECLAIM

[7] By determining what sets of programs are adequate to meet water quality responsibilities, the Regional Board in effect sets interim water quality objectives in the current system.

program assigns rights to emit certain amounts of pollutants which can then be bought and sold on the open market. Such markets provide incentives for firms to reduce emissions beyond their assigned limit (by allowing them to sell their unused emission rights) and encourage the firms that can reduce emissions most cheaply to make the greatest emissions reductions. Incentive-based programs have been successful in other areas and may well make sense in the water-quality area.

Recommendations

5.4-A The L.A. County Department of Public Works and the appropriate city departments should explore programs that rely on incentives for voluntary actions that improve the quality of urban runoff. Approaches that should be explored include:

- **Financial incentives for businesses and homeowners to reduce runoff flows or improve runoff quality. The cities and county should consider imposing storm water fees that could fund such programs.**
- **A county-wide awards program that acknowledges business or government agencies that have adopted exemplary programs to improve urban runoff.**

The City of Los Angeles already has a storm water fee in place that could be used to fund incentive programs. This fee system should serve as a starting point for discussions in other cities and the county for adopting storm water fees.

5.4-B The setting up a market for water quality pollutants should be explored. Dischargers would be assigned pollution limits and could buy rights to emit pollutants if it were too difficult to reduce their own pollutants or sell rights if they reduced pollutants below their cap.

The participants in a market for pollutants would include the cities and county responsible for controlling discharges of urban runoff into the rivers, creeks, and oceans. Businesses with point-source discharge permits or general industrial storm water permits and publicly owned treatment plants would also be included.

There are several important issues that need to be investigated before setting up a market for water pollutants. First, trading raises the concern that pollutants will be concentrated in certain areas. Trading may thus have to be restricted to certain zones (e.g., within defined drainage basins). Second, systematic monitoring will be required to verify that emissions do not exceed the rights to discharge held by the firm. Highly variable urban runoff flows make this a challenge. It is not obvious that a market system will work in the water quality area, but the potential benefits of such a system warrant its consideration.

5.5 MATCHING AUTHORITY WITH RESPONSIBILITY

Issue

The Regional Board is embarking on an ambitious effort to clean up urban runoff. It is unclear, however, that it or the cities, county, and businesses that it regulates have the authority to control some significant pollution sources or adopt some of the more innovative types of treatment technologies, such as in-stream bio-remediation. The result may be reliance on end-of-the-pipe treatment solutions that are more expensive than necessary. Are the authorities of the Regional Board and the entities it regulates properly matched with their responsibilities? Are additional authorities needed? Who should have them?

Findings

There are several important sources of pollution in urban runoff that neither the Regional Board nor the cities, county, and businesses it regulates have the power to reduce at the source. For example, automobile and truck brake pads are thought to be a significant source of the copper that winds up in urban runoff, but neither the Board nor the regulated entities can require that brake pads contain less copper. Likewise, oil leaks and grease drippings from cars and trucks are likely a significant source of the oil and grease that ends up in urban runoff, but the Board, cities, County, or Caltrans (which has its own urban runoff permit) do not have the power to require that oil systems be checked for leaks during vehicle inspection programs or to set standards for the formulation and application of grease on tractor-trailer bearings. Pollutants from vehicle exhaust (which then settle out of the atmosphere) are another example of a potentially important source of pollution over which the water-quality regulators and regulated have no direct control. Chain link fences may be the major source of the zinc that shows up in urban runoff, but controlling the zinc-content of chain link fences is out of reach of the agencies responsible for pollution reduction programs.

Current institutional boundaries restrict the types of remediation strategies that can be considered. Natural attenuation of some pollutants in stream beds and wetlands may make a lot of sense and create multiple benefits, but the Regional Board and regulated entities often do not have the authority to restore to more natural states stream channels that are encased in concrete or to build or restore wetlands.

The lack of authority over important sources of pollution or the ability to implement certain treatment strategies means that certain types of solutions are not even considered, and even if considered, are quickly taken off the table because of the inability to implement them. As a consequence, cities and others may be forced into expensive end-of-the-pipe treatment when other approaches are more sensible.[8] This is not a desirable outcome. We as a society should not let institutional boundaries get in the way of the best solutions.

Recommendation

5.5 **The County should lead an effort to identify what additional powers are needed by the Regional Board, the cities, and the County pertaining to water quality control, determine who should have these powers, and then obtain them.**

It may make sense for the Regional Board to be the lead agency for regulations on consumer products such as brake pads or chain link fences. The South Coast Air Quality

[8] The Regional Board acknowledges that certain pollutants present in storm water and/or urban runoff may be contributed by activities which the Permittees cannot control but Permittees can implement measures to minimize entry of these pollutants into storm water.

Management District (SCAQMD) might provide a model to follow. SCAQMD regulates many consumer products sold in its jurisdiction (paint and barbecue lighter fluid, for example) in an effort to reduce air pollution.

The authorities that result from such a process should be well aligned with the responsibility for reducing particular pollution sources. For example, if the Regional Board has authority and takes responsibility for the copper in brake pads and the zinc in chain-link fences, then removing the pollutants from these sources should not be the responsibility of the cities, the county, or Caltrans. Such exemptions are analogous to current exemptions for runoff from agricultural lands or exemptions for runoff from public schools and universities, which are outside the jurisdiction of cities and the county.

5.6 POLICIES FOR DIVERTING URBAN RUNOFF INTO THE SEWER SYSTEM

Issue

Diversion of low volumes of urban runoff into the sewer system is one of the many policy options being considered as a solution to the beach water pollution problem. Many of those involved in water quality issues consider diversions to be the best way to guarantee clean water in the short term. Others have reservations about the costs and potential liability for failure of sewage treatment plants. Does the current diversion policy in the county make sense? What improvements might be made?

Findings

We first present some background on the advantages and disadvantages of diversions. We then describe current diversion programs in the City of Los Angeles, where the debate over diversions is perhaps the most intense, and in Los Angeles County. We conclude by describing the issues that remain unresolved in developing a sensible diversion policy for the county.

Background. Diversions send polluted urban runoff into the municipal sewer system. Sewer system capacity constraints limit the amount of runoff that can be diverted to the sewers. The chief benefit of diversions is that they immediately eliminate polluted urban runoff from beaches, at least when flows are sufficiently low.

Source reduction is an alternative to diversions, but as we have seen (see discussion of Santa Monica Canyon in Section 4.3), eliminating the causes of the pollution in urban runoff is difficult. Source identification is costly and often unsuccessful. There is not much evidence so far that regulations (Best Management Practices) to reduce pollution in urban runoff are very effective. Public education campaigns that focus on changing people's behavior may ultimately have an effect, but it is likely that this is a long-term solution that may take a generation to yield tangible results.

Small treatment devices are also an alternative to diversions in some locations. We have not been able to compare their costs with those of diversions, but the innovative approaches that have recently been developed are still largely untested in the real world. Siting such facilities

The County and the City of Los Angeles should continue their efforts to develop a cost-sharing formula that considers both the area of origin of the runoff and the incidence of the benefits from the diversion. The state and other cities that contribute to flows in the drains subject to diversion should be also be pulled into the discussions.

Efforts should be made to reduce the possible impacts of the diversion on sewage treatment plants and to clearly assign (and share as appropriate) liability for violations that do occur. One approach that should be considered is to install automatic monitoring stations just upstream of diversions. Readings from the stations could be used when treatment plant permit limits are exceeded to determine the appropriate fine and its allocation.

5.7 MONITORING AND ENFORCEMENT

Issue

No matter how good they may look on paper, efforts to clean up the rivers, creeks, and oceans in L.A. County are only effective to the extent that the responsible organizations translate the words into action. Many of the experts we interviewed are concerned that the Regional Board is not adequately monitoring whether the cities, county, and industries that contribute to pollution in urban runoff are complying with their permit requirements and that the Regional Board does not issue strong enough penalties when they fail to comply. Many are similarly concerned about efforts by the cities and county to enforce municipal ordinances related to urban runoff. How effective are the compliance monitoring and enforcement programs in the county? How might they be improved?

Findings

The L.A. Regional Board regulates urban runoff in L.A. County through a municipal storm water permit (L.A. County is the principal permittee with 86 cities as co-permittees) and approximately 2,600 industrial and 600 construction permits. Regional Board enforcement programs are in four areas: the industrial storm water program, the municipal storm water program, spills, and point source permits. We then examine the monitoring and enforcement programs in the City and County of Los Angeles and their coordination with Regional Board programs.

Industrial Storm Water Program. Some analysts believe that there are many industrial facilities that are required to obtain storm water permits but have failed to do so. For example, based on its own research and that done by UCLA, a report by Heal the Bay concludes that there are 5,000 to 10,000 facilities in the region that have failed to obtain the required permits. While recognizing that increased efforts are underway, U.S. EPA also believes that non-filing is an important issue.

In response to this concern, the Regional Board has mounted an intensive effort to identify non-filing facilities. Preliminary results show that there are fewer non-filing facilities than previous estimates suggested and that the non-filing issue is well on its way to being resolved.

Monitoring for compliance with existing industrial storm water permits consists, first, of checking whether the required annual reports have been submitted and, second, of conducting about 100 or so inspections per year.[10] Compliance with the reporting requirement is not very good. One report states that 29 percent of the firms required to submit annual reports under the terms of their storm water permit failed to do so in 1995/96 and that roughly three-quarters of these were more than one year late. The results of inspections also do not suggest a very effective program. There is evidence that many firms are not doing what is in their storm water plan. Also, at this point, there has been very little assessment of the efficacy and appropriateness of the storm water management plans themselves.

Municipal Storm Water Program. As principal permittee, L.A. County coordinates the annual reporting required of the county and the 86 cities that are co-permittees. Problems with reporting did not come up during our investigation. There is, however, little in-field monitoring of compliance with the terms of the permit or the efficacy and appropriateness of the programs in the various cities. There have been no substantive audits of city programs, and that the review that does exist focuses on reporting and procedural requirements. Programmatic audits of the city and county programs are necessary to ensure that the municipal storm water program is more than a paper program.

Spills. Every day in L.A. County there are several sewage spills. Most of these are small and probably do not reach the storm drain system. A system of permits and reporting requirements enables the Regional Board to monitor the performance of the system at a basic level and provides incentives for system maintenance through fines. It also allows the County Department of Health Services to issue swimming health advisories as appropriate. There is an important gap in this system, however. The county and the cities that have permits with the Board to operate sewage treatment facilities or that hire the county to run their sewage collection systems are required to report spills to the Regional Board, the County Department of Health Services, and the State Office of Emergency Services. The cities that run their own sewage collection systems[11] are required by their municipal storm water permits to report spills to the County DHS, but DHS receives no such reports. There is thus a general lack of information on the performance of these systems and no mechanism in place to issue beach closures if the spills are a threat to public health.

Environmental and public interest groups have raised concerns that the Regional Board is not tough enough on the cities, county, and businesses that spill sewage or water tainted with other contaminants. CalPirg reports that of the 1,857 spills in the L.A. Region in 1997 and 1998, only 46 triggered formal action and only 10 resulted in fines.

According to Heal the Bay, only 4 of the 2,194 spills between 1992 and 1997 resulted in penalties or referrals to the attorney general. Many of these spills do not reach waterways and the Board has a progressive enforcement policy that starts with warnings and culminates with fines for repeat violators. Over the last two years or so the frequency and size of fines for spills,

[10] EPA reports that 50 sites were inspected in 1996/97. Regional Board staff confirmed that inspections were currently running about 100 a year.

[11] About one-half of the cities in L.A. County are not members of the county's consolidated maintenance district and either run their own sewage collection systems or hire private vendors to maintain their sewage collection systems.

particularly on municipal sewage systems, have increased. This may have been in part due to increased spills during wet El Niño winters, but it also suggests that the Board decided that its past enforcement policies were too lax and is moving to remedy the situation.

A state law that took effect on January 1 indicates more general dissatisfaction with the enforcement policies of water quality regulations across the state. SB709 requires mandatory penalties for serious and chronic violations. For better or worse, it severely limits discretion in imposing fines.

Point Sources. We have focused on monitoring and enforcement for urban runoff policies in this section, but one issue of concern arose during our investigation of the water quality monitoring associated with point source permits—permits that regulate discharges from municipal sewage and industrial process-water treatment plants. There is general satisfaction among those we interviewed with the frequency of inspections of the 44 major dischargers and 260 minor dischargers throughout the region. However there is concern that the water samples used to monitor compliance with the permit are not representative of the flows from the facilities. Dischargers are required to collect samples and report results of lab analyses to the Board. Some we interviewed felt that dischargers "game" the system, taking samples during periods when the treatment plant is known to be working well or when inflows into the plant are low or have low pollution levels.

Enforcement in the City and County of Los Angeles. The County visits all restaurants and other businesses in selected Standard Industrial Classification (SIC) codes to inform them of their responsibilities related to urban runoff under municipal codes and the county's municipal storm water permit. Under the terms of the county permit, two such educational visits per site are required between 1996 and 2001. The County has responsibility for businesses in unincorporated areas and in cities that have contracted with the county for this service. Consistent with the education mission, not a large number of citations for runoff-related violations have been issued since the program began.

The City of Los Angeles is also conducting educational visits at approximately 15,000 businesses under its jurisdiction. The city is currently finishing up the second round of visits. In recent months, it has been issuing 10 to 15 notices to comply with urban runoff regulations a month and is gearing up for a greater emphasis on enforcement.

Several issues arose in our investigation of city and county enforcement programs. First, we found little coordination between county and city programs and the Regional Board's industrial storm water permit enforcement program (see above). The county or city staff also separately visits most firms visited by Regional Board staff. There is also an overlap at construction sites. The City and County of Los Angeles inspect construction sites for compliance with runoff requirements. There do not appear to be plans to coordinate visits by the city and county with the Regional Board. Duplication between the cities and county and state programs increases the regulatory burden on the businesses in the county and wastes scarce enforcement resources.

Second, we found that there is an ongoing debate over the division of enforcement responsibilities between the Regional Board and the cities and the county. Negotiations during the last renewal of the municipal storm water permit (which went into effect in 1996), illustrate this tension. The Regional Board wanted the local agencies to enforce the runoff provisions. The cities balked, and the requirement for educational visits, without inspection and enforcement responsibilities, was the compromise. The allocation of enforcement responsibilities will undoubtedly be a topic of debate during the 2001 permit renewal negotiations.

The third issue that arose in our investigation of the enforcement programs of L.A. City and County is whether local agencies should have the power to issue non-criminal infractions or tickets, with associated fines, for urban runoff violations. The city and county have the power to issue notices of noncompliance and notices of violation but have to submit these to the district or city attorney for enforcement. The violations fall under criminal codes and are usually prosecuted as misdemeanors, but can be felonies. The City of Los Angeles has recently approved non-criminal fines for runoff violations. The details are currently being worked out, but plans are for fines to start at $50 for the first violation, increase to $100 for the second, and rise to $250 for the third, along with a notice to comply. Failure to comply can lead to criminal referral to the city attorney at any step of the process. The city plans to start issuing tickets within the next six months. Los Angeles County currently does not have ticketing authority.

Some we interviewed thought that ticketing authority is an important addition to the enforcement tool chest. City and district attorneys are very busy and usually do not view runoff violations as a high priority. Evidentiary requirements for criminal prosecutions are high, increasing the cost of enforcement. Criminal prosecution also seems inappropriate for all but the most flagrant violations. The result, advocates for ticketing authority argue, is not much enforcement. Others we interviewed were leery of ticketing authority. They worry that it would be abused as a way to generate revenue and that it would turn inspections into a much more adversarial process. They worry that the educational element of inspections would be compromised and that voluntary compliance with runoff regulations will decline.

Recommendations

5.7-A **Programmatic audits of city and County storm water programs should be conducted. These audits should verify whether programs outlined in the permits are being implemented and assess their adequacy and effectiveness.**

5.7-B **The cities and County should coordinate and consolidate as appropriate their inspection programs of industrial and construction sites, with the Regional Board. This program should increasingly focus on the adequacy of the storm water management plans and the extent to which they are being implemented.**

5.7-C **More generally, the cities and County should clarify the division of enforcement responsibilities between them and the Regional Board. Enforcement should be delegated to the cities and County, whenever possible.**

5.7-D **The County of Los Angeles Department of Public Works should investigate the advantages and disadvantages of ticketing authority for runoff violations. Based on a review of experiences in the City of Los Angeles and other jurisdictions that have the ability to issue tickets for infractions, the Department should make a** recommendation to the Board of Supervisors on whether the county code should be amended to allow such ticketing.

5.7-E **The Board of Supervisors should insist that cities that operate their own sewage collection facilities should report spills to the Regional Board and the County Department of Health Services.**

To make sure that our pollution control system is more than a paper tiger, additional resources need to be spent on auditing the activities that actually reduce pollution.

5.8 FUNDING FOR WATER QUALITY PROGRAMS

Issue

Many believe that the Regional Board is severely underbudgeted and, as a result, progress in cleaning up the waters in the County has lagged.

Recommendation

5.8 ***The Board of Supervisors should lead an effort to increase funding for the Regional Board.***

Potential funding sources include increased permit fees from the municipalities and businesses in L.A. County and the State General Fund. The Supervisors should appeal to the governor and the State Water Resources Control Board directly as well as enlist the support of the L.A. delegation to the state legislature. While increased funding for the Regional Board means more outlays for a public agency, the savings from better-designed and more effective water quality programs will far outweigh the costs.

RAND

September 25, 2000

Mr. Xavier Swamikannu
California Regional Water Quality Board
Los Angeles Region
320 W. 4th Street, Suite 200
Los Angeles, CA 90013

Dear Xavier:

Attached is the copy of the L.A. Country Grand Jury report on reducing the health risks of swimming at L.A. County beaches.

The Grand Jury report closely follows the draft report we provided them except in one important area—recommendations concerning the Regional Water Quality Control Board. Toward the end of the Grand Jury's term, L.A. County counsel ruled that, because the Board is a state agency, it is beyond the purview of the Grand Jury. Thus, recommendations that were initially directed at the Board were modified to omit reference to the Board (see for example Recommendations 5.3). The Grand Jury report still does ask the Board to consider several recommendations, however (see p. 200). The report also still recommends that funding for the Board be increased, but the discussion in the draft report on what areas are most in need of funding was dropped.

Thank you again for generously contributing your time and expertise to this project. We hope this report has assembled useful information on some of the critical water quality issues in Los Angeles County and has helped move the debate forward. Please feel free to call if you have any questions or comments about the report.

Sincerely,

Lloyd

The Quality of Our Nation's Waters

A Summary of the National Water Quality Inventory: 1998 Report to Congress

overview

States, territories, tribes, and interstate commissions assessed 23% of the nation's 3.6 million miles of rivers and streams for their 1998 water quality assessment reports to EPA. Of the assessed stream miles, 55% are rated as good, 10% good but threatened, and 35% impaired. States and other jurisdictions assessed 42% of the nation's 41.6 million acres of lakes, reservoirs, and ponds and reported that 46% of assessed lake acres are rated as good, 9% good but threatened, and 45% impaired. States and other jurisdictions assessed 32% of the nation's 90,500 square miles of estuaries and reported that 47% of assessed estuary square miles are rated as good, 9% as good but threatened, and 44% as impaired. Principal pollutants causing water quality problems include nutrients, siltation, metals, and pathogens.

Why Do States and Other Jurisdictions Assess Water Quality?

Section 305(b) of the Clean Water Act requires states, territories, tribes, and interstate commissions to assess the health of their waters and the extent to which their waters support state water quality standards and the basic goals of the Clean Water Act. The goals of the Clean Water Act are to achieve and maintain water quality that provides for healthy communities of fish and shellfish and that allows for recreation in and on the water. States collect data and information that allow them to characterize whether water quality meets these and other uses for their waters which are expressed in standards that each state sets.

States and other jurisdictions such as territories, tribes, and interstate commissions submit their water quality assessments to the U.S. Environmental Protection Agency (EPA) every 2 years. EPA summarizes this information in a biennial report to Congress. The *National Water Quality Inventory: 1998 Report to Congress* is the twelfth biennial report to Congress and the public about the quality of our nation's rivers, streams, lakes, ponds, reservoirs, wetlands, estuaries, coastal waters, and ground water.

States' Section 305(b) assessments are an important component of their water resource management programs. These assessments help states:

✓ **Implement** their water quality standards by identifying healthy waters that need to be maintained and impaired waters that need to be restored

✓ **Prepare** their lists of impaired waters under Section 303(d) of the Clean Water Act

✓ **Identify** priority watersheds for protection and restoration using their Watershed Restoration Action Strategies, total maximum daily loads, and pollutant source controls

✓ **Evaluate** the effectiveness of activities undertaken to restore impaired waters and protect healthy waters.

The 305(b)/ 303(d) Connection

Under Section 303(d), the Clean Water Act includes a second reporting requirement—that states provide a prioritized list of all their impaired waters. Current requirements are that states submit these 303(d) lists to EPA every 2 years. The most recent set of 303(d) lists were submitted to EPA in April 1998.

These lists of impaired waters are then used to prioritize state restoration activities. One of the most important restoration tools is the development of Total Maximum Daily Loads (TMDLs)—calculations of the amount of a pollutant that a waterbody can receive and still meet water quality standards. A TMDL is the sum of all available loads of a single pollutant from all contributing point and nonpoint sources. It includes reductions needed to meet water quality standards and allocates these reductions among sources in the watershed.

The 305(b) and 303(d) reporting processes are connected. State 305(b) data is used to assist in the identification and priority ranking of 303(d) waters, although for their 303(d) listings, states may supplement the 305(b) information with other assessments or choose only that data in which they have the highest confidence. As a result, the findings on impaired waters reported by the states in their 303(d) lists build on, and are, in general, consistent with their 305(b) reports to EPA. Both sources find similar amounts of impaired waters and conclude that siltation, nutrients, bacteria, and metals are among the top pollutants causing impairments.

EPA and the states continue to work to improve and harmonize both these assessments through better and more extensive monitoring. Our goal is comprehensive monitoring of all waters for all applicable water quality standards—a challenging task given the demands placed on limited state, tribal, and federal resources, but a particularly vital one because of the important and costly water resource management decisions that depend on high quality water data.

This National Water Quality Inventory report reflects incremental progress toward the goal of comprehensive assessment. It includes information submitted by all 50 states, the District of Columbia, and 5 territories, 4 interstate commissions, and 9 Indian tribes. In addition, the amount of waters assessed for this report has increased slightly since the previous report. States assessed 150,000 more river and stream miles and 600,000 more lake acres in 1998 than in 1996.

How Do States and Other Jurisdictions Assess Water Quality?

Water quality assessment begins with setting goals through water quality standards adopted by states, tribes, and other jurisdictions such as territories. These standards must then be approved by EPA before they become effective under the Clean Water Act.

Water quality standards have three elements:

1. **Designated uses.** The Clean Water Act envisions that all waters be able to provide for recreation and the protection and propagation of aquatic life. Additional uses described in the Act that can be adopted in standards by states and tribes include drinking water supply and fish consumption.

2. **Criteria.** Criteria help protect designated uses. For example, criteria include chemical-specific thresholds that protect fish and humans from exposure to levels that may cause adverse effects. They may also include descriptions of the best possible biological condition of aquatic communities such as fish and insects.

3. **Antidegradation policy.** This policy is intended to prevent waters that do meet standards from deteriorating from their current condition.

After setting water quality standards, states then assess their waters to determine the degree to which these standards are being met and report this information in their 305(b) reports.

Currently states use two categories of data to assess water quality. The first and most desirable category is monitored data. This refers to field measurements, not more than 5 years old, of biological, habitat, toxicity, and physical/chemical conditions in water, sediments, and fish tissue. The second category, frequently used to fill information gaps, is evaluated data. Evaluated data includes field measurements that are more than 5 years old and estimates generated using land use and source information, predictive models, and surveys of fish and game biologists. This type of data provides an indicator of potential water quality.

Because evaluated data varies in quality and confidence, it is used for different purposes by different states. Most states use evaluated data to supplement monitoring data for their 305(b) reports. This information helps states identify waters that need additional monitoring.

After comparing water quality data to standards, states, tribes, and jurisdictions classify their waters into the following general categories:

Attaining Water Quality Standards

- **Good/Fully Supporting**: These waters meet applicable water quality standards, both criteria and designated uses.
- **Good/Threatened**: These waters currently meet water quality standards, but water quality may degrade in the near future.

Not Attaining Water Quality Standards/Impaired

- **Fair/Partially Supporting**: These waters meet water quality standards most of the time but exhibit occasional exceedances.
- **Poor/Not Supporting**: These waters do not meet water quality standards.

Water Quality Standards Not Attainable

- **Not Attainable**: The state has performed a use-attainability analysis and demonstrated that support of one or more designated uses is not attainable due to specific biological, chemical, physical, or economic/social conditions.

How Many of Our Waters Were Assessed for 1998?

This report does not describe the health of all U.S. waters because states and other jurisdictions have not yet achieved comprehensive assessment of all their waters (see Figure 1). Therefore, this report summarizes the health of only the subset of waters that states assessed in their individual 1998 water quality inventories: 23% of river and stream miles, 42% of lake acres, 32% of estuary square miles, 5% of ocean shoreline miles, and 90% of Great Lakes shoreline miles.

Oceans, coral reefs, wetlands, and ground water quality are poorly represented in state monitoring programs. In part, this is due to the fact that few states have adopted water quality standards for these resources. EPA's wetlands and ground water protection programs continue to work with states to develop assessment methods and water quality standards and to improve monitoring coverage. EPA is initiating a coastal monitoring program, Coastal 2000, that will provide a national baseline characterization of coastal waters and data needed to assist in development of water quality standards (particularly biological and nutrient criteria) for these waters.

Figure 1

Percentage of Waters Assessed for the 1998 Report

Rivers and Streams
842,426 miles = 23% assessed
Total miles: 3,662,255 (of which 35% are perennial, excluding Alaska)

Lakes, Ponds, and Reservoirs
17,390,370 acres = 42% assessed
Total acres: 41,593,748

Estuaries
28,687 square miles = 32% assessed
Total square miles: 90,465

Ocean Shoreline Waters
3,130 miles = 5% assessed
Total miles: 66,645, including Alaska's 44,000 miles of shoreline

Great Lakes Shoreline
4,950 miles = 90% assessed
Total miles: 5,521

Source: 1998 Section 305(b) reports submitted by states, tribes, territories, and commissions.

What Is the Status of Our Assessed Waters?

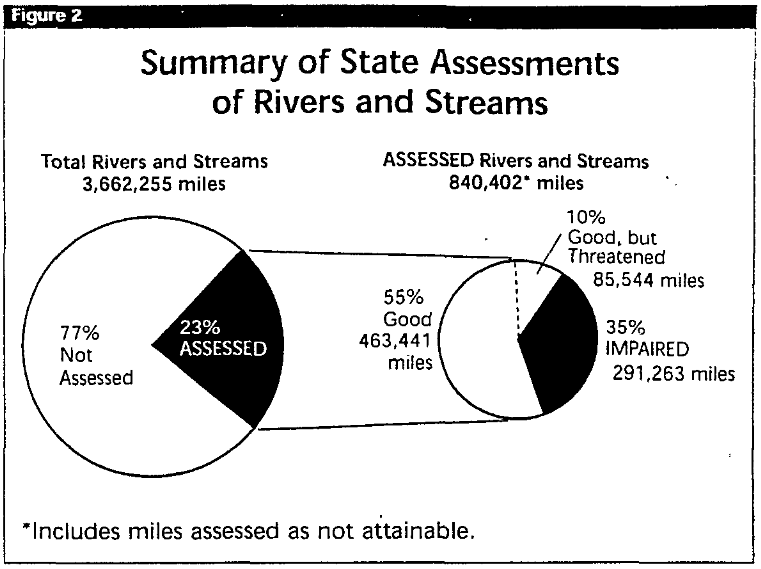
Rivers and Streams

The United States has a total of 3,662,255 miles of rivers and streams. States and other jurisdictions assessed 23% of these river and stream miles, focusing primarily on perennial streams (i.e., those that flow year round). Altogether, the states and other jurisdictions reported that of the 23% of assessed stream miles, 65% fully support designated uses and 35% are impaired. They also report that 10% of the assessed rivers and streams are fully supporting but are threatened for one or more uses (Figure 2). Aquatic life use is the most frequently impaired individual use in assessed rivers and streams (Figure 3).

According to the states and other jurisdictions, siltation and bacteria are the most common pollutants affecting assessed rivers and streams (Figure 4). Siltation alters aquatic habitat and suffocates fish eggs and other bottom-dwelling organisms. Excessive siltation can also interfere with drinking water treatment processes and recreational use of a river. Bacteria provide evidence of possible fecal contamination that may cause waters to be unsafe for swimming and other recreational activities. Both pollutants raise the costs of drinking water treatment to remove them.

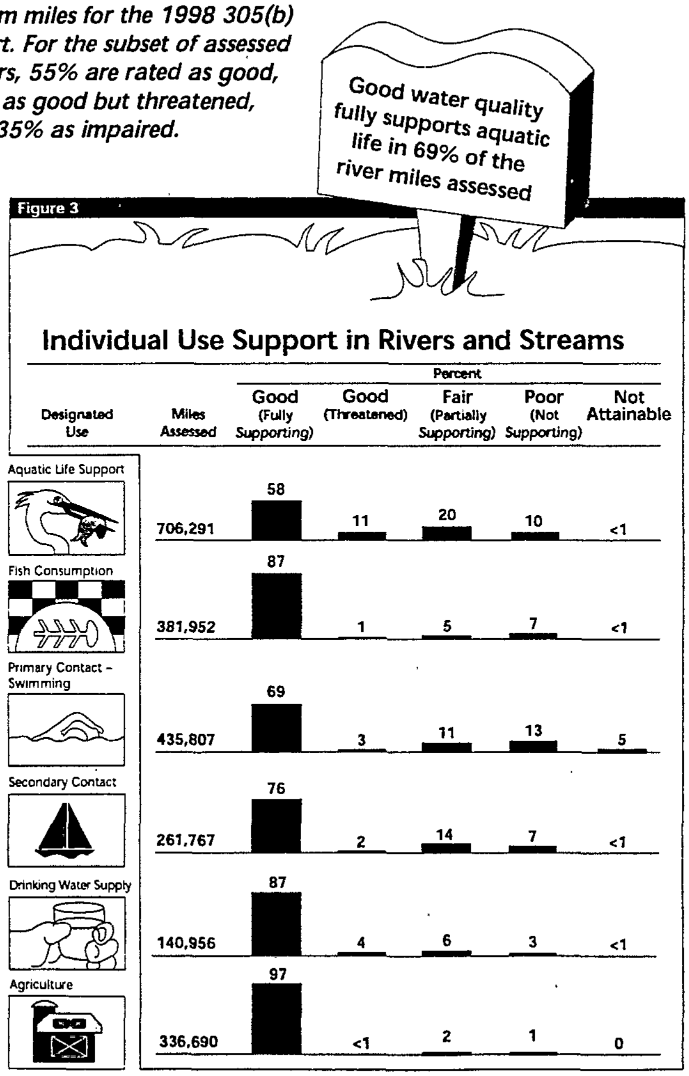
States and other jurisdictions reported agriculture as the most widespread

Figure 2



States assessed 23% of river and stream miles for the 1998 305(b) report. For the subset of assessed waters, 55% are rated as good, 10% as good but threatened, and 35% as impaired.

Figure 3



This figure presents a tally of the river and stream miles for each key designated use. For each use, the figure presents the percentage of assessed waters in each water quality category.

R0011726

source of pollution in assessed rivers and streams. Agricultural activities may introduce siltation, nutrients, pesticides, and organic matter that deplete oxygen in surface water. Nutrients and pesticides can also leach into and contaminate ground water. While the impact of agricultural activities is significant, it should be considered in context of the amount of land supporting agricultural activities. According to the 1997 Census of Agriculture, 41% of the continental United States, about 900 million acres, is used for agricultural production.

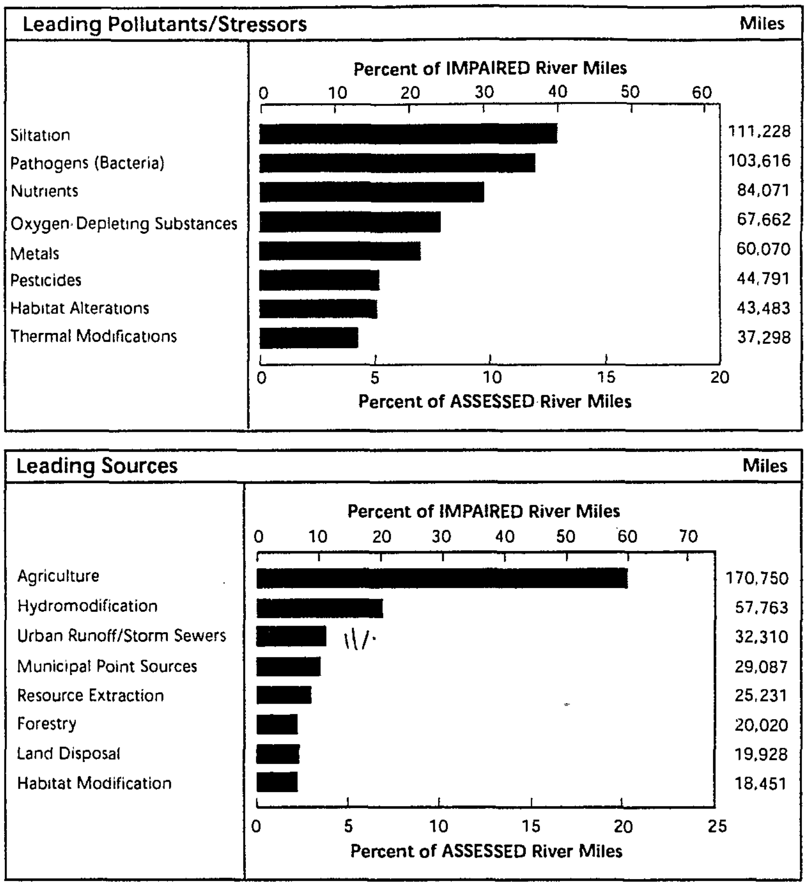
Other leading sources of pollution in assessed rivers and streams include hydromodifications such as flow regulation and modification, channelization, dredging, and construction of dams—which may alter a river's habitat in such a way that it becomes less suitable for aquatic life—and urban area runoff and storm sewer discharges.

Lakes, Reservoirs, and Ponds

There are a total of 41,593,748 acres of lakes, reservoirs and ponds in the United States. In 1998, states and other jurisdictions assessed 42%, or about 17.4 million acres. Altogether, states and jurisdictions reported that of the 42% of lake acres assessed, 55% fully support all of their uses and 45% are impaired. They also reported that 9% of the assessed acres are fully supporting but threatened for one or more uses (Figure 5).

Figure 4

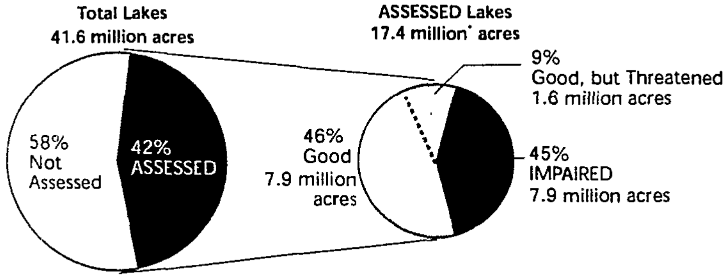
Leading Pollutants and Sources Impairing Assessed Rivers and Streams



These bar charts present the leading pollutants and sources reported by the states. The percent scale on the lower axis compares the miles impacted to the total ASSESSED miles. The upper axis compares the miles impacted to the total IMPAIRED miles.

Figure 5

Summary of State Assessments of Lakes, Reservoirs, and Ponds



*Includes acres assessed as not attainable.

States assessed 42% of lake, reservoir, and pond acres for the 1998 305(b) report. For the subset of assessed waters, 45% are rated as good, 9% as good but threatened, and 45% as impaired.

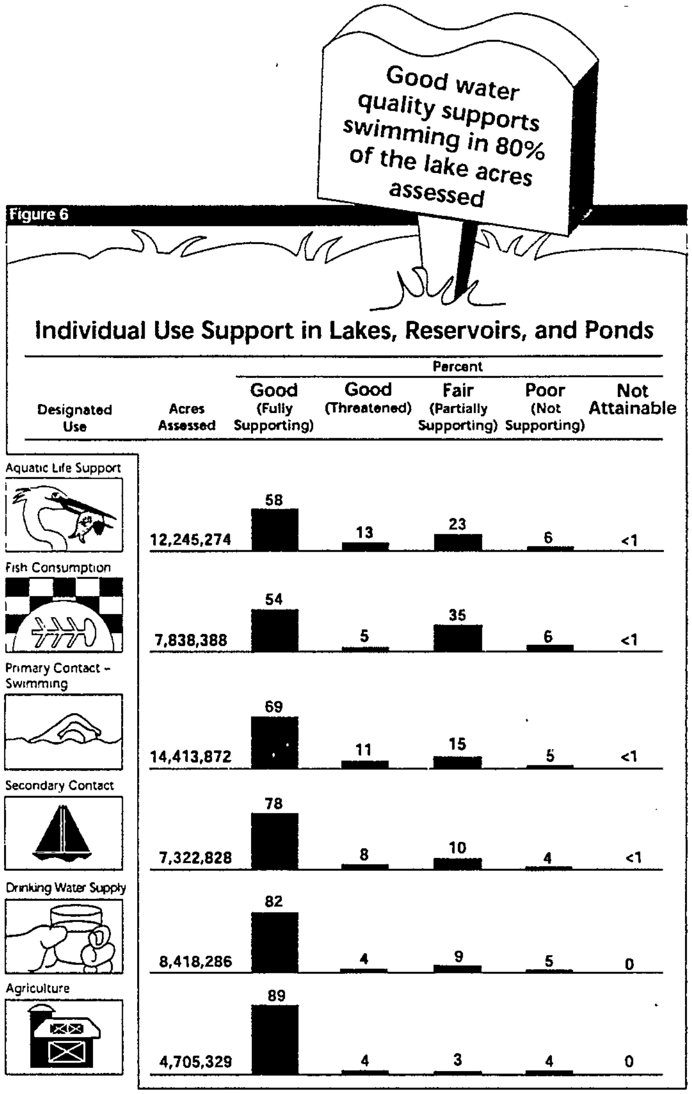
R0011727

More lake, reservoir, and pond acres were reported as impaired for aquatic life use support than any other assessed use (Figure 6). However, where fish consumption use was assessed, it was responsible for a higher percentage of impaired acres. (Many states did not evaluate fish consumption use support in lakes because they have not included this use in their water quality standards.) Through separate tracking of state fish consumption advisories, EPA estimates that about 6.5 million lake acres were under fish consumption advisories in 1998.

According to the states and other jurisdictions, nutrients are the most common pollutant affecting assessed lakes, reservoirs, and ponds (Figure 7). While healthy lake ecosystems contain nutrients in small quantities from natural sources, too many nutrients disrupt the balance of lake ecosystems. Nutrient overenrichment can initiate a chain of impacts that includes algal blooms, low dissolved oxygen conditions, fish kills, foul odors, and excessive aquatic weed growth that can interfere with recreational activities.

Metals are the second most common pollutants in assessed lake acres, mainly due to the widespread detection of mercury in fish tissue samples. The mercury problem is especially complex because it often includes atmospheric transport from power-generating facilities, waste incinerators, and other sources.

The most widespread source of pollution reported for assessed lakes is agriculture, followed by hydrologic modification, urban runoff and storm sewers, municipal point sources, and atmospheric deposition (Figure 7).



This figure presents a tally of the lake, pond, and reservoir acres assessed for each key designated use. For each use, the figure presents the percentage of assessed waters in each water quality category.

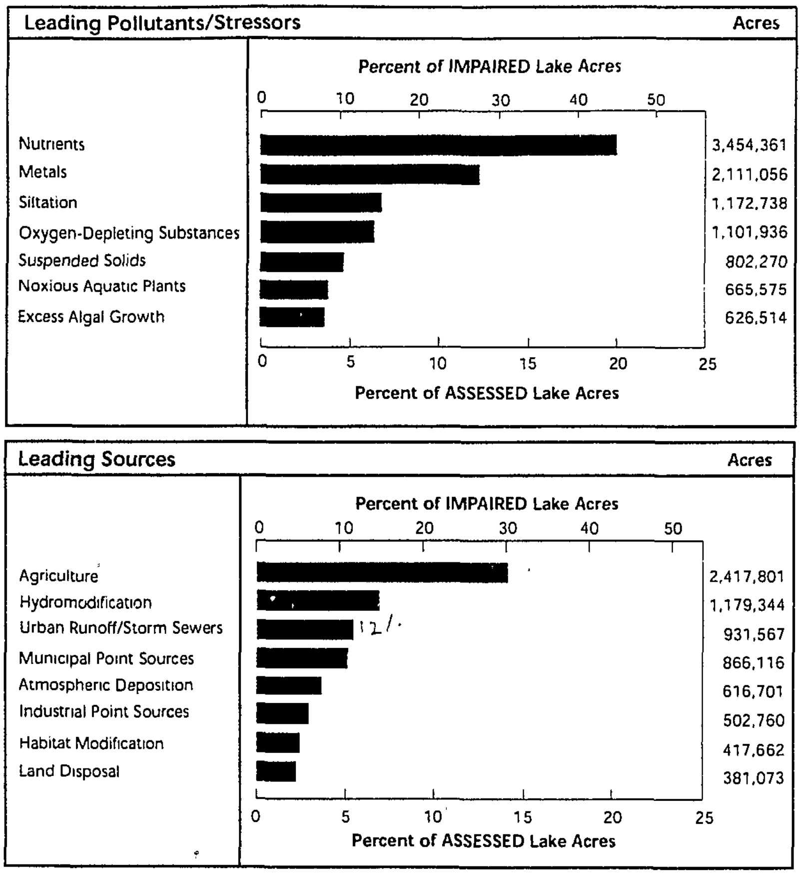
Figure 7

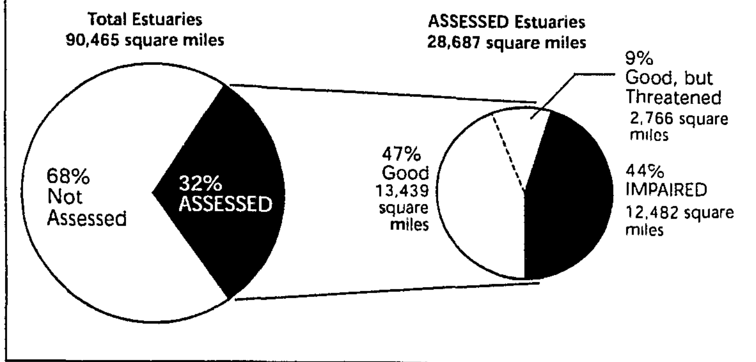
Leading Pollutants and Sources Impairing Assessed Lakes, Reservoirs, and Ponds



These bar charts present the leading pollutants and sources reported by the states. The percent scale on the lower axis compares the acres impacted to the total ASSESSED acres. The upper axis compares the acres impacted to the total IMPAIRED acres.

Figure 8

Summary of State Assessments of Estuaries



States assessed 32% of estuary square miles for the 1998 305(b) report. For the subset of assessed waters, 56% are rated as good, 9% as good but threatened, and 44% as impaired.

Coastal Resources—

Estuaries, The Great Lakes, Ocean Shoreline Waters, and Coral Reefs

The United States' extensive coastal resources include nearly 67,000 miles of ocean shoreline, more than 5,500 miles of Great Lakes shoreline, about 90,500 square miles of tidal estuaries, and extensive coral reef areas.

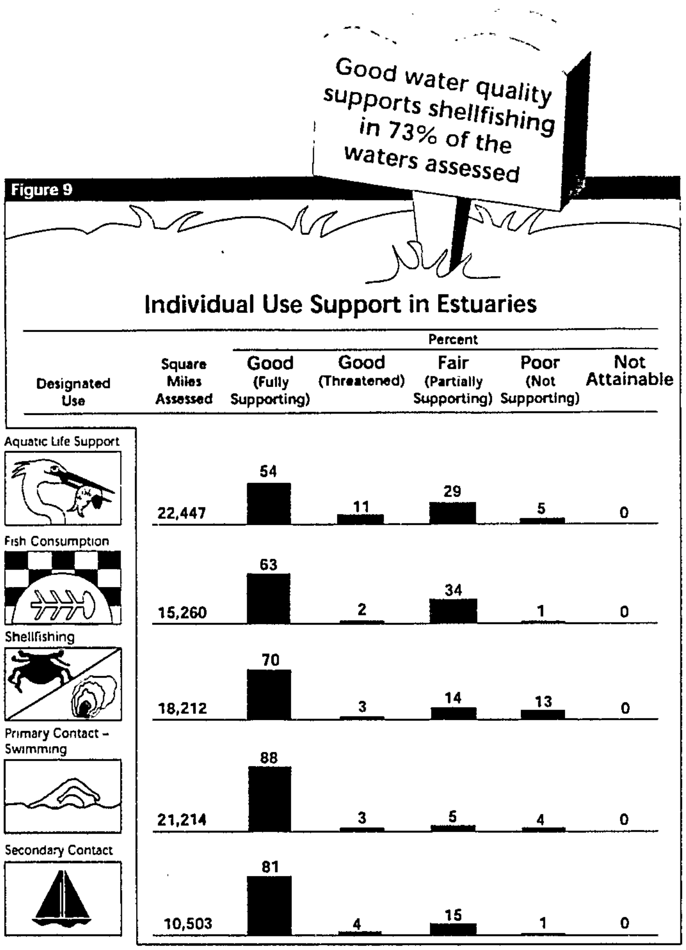
Estuaries

There are 90,465 square miles of estuaries in the United States. Estuaries are where rivers meet oceans, and they include bays and tidal rivers. They serve as nursery areas for many commercial fish and most shellfish populations, including shrimp, oysters, crabs, and scallops. States and other jurisdictions assessed 32% of the total square miles of estuaries in the country (Figure 8). Altogether, states and other jurisdictions reported that of the 32% of estuarine square miles assessed, 56% fully support designated uses and 44% are impaired. They reported that 9% of the assessed square miles are fully supporting but threatened for one or more uses. Aquatic life use is the most frequently impaired individual use in assessed estuaries (Figure 9).

States reported that bacteria (pathogens) are the most common pollutants affecting assessed estuaries. Most states monitor indicator bacteria, such as *Esherichia coli*, which provide evidence that an estuary is contaminated with sewage that may contain numerous viruses and bacteria that cause illness in people. Humans can become exposed to these pathogens by consuming contaminated fish and shellfish or contacting or ingesting contaminated water during swimming.

In addition to pathogens, the states also reported that oxygen depletion from organic wastes, metals, nutrients, thermal modifications, PCBs, and priority toxic chemicals impacts more square miles of estuarine waters than other pollutants and stressors.

Municipal point sources and urban runoff and storm sewers are cited as the most widespread sources of pollution in assessed estuaries (Figure 10). These urban sources are significant contributors to the degradation of estuarine waters because large cities are located near most U.S. estuaries.



This figure presents a tally of the estuary square miles assessed for each key designated use. For each use, the figure presents the percentage of assessed waters in each water quality category.

The Great Lakes

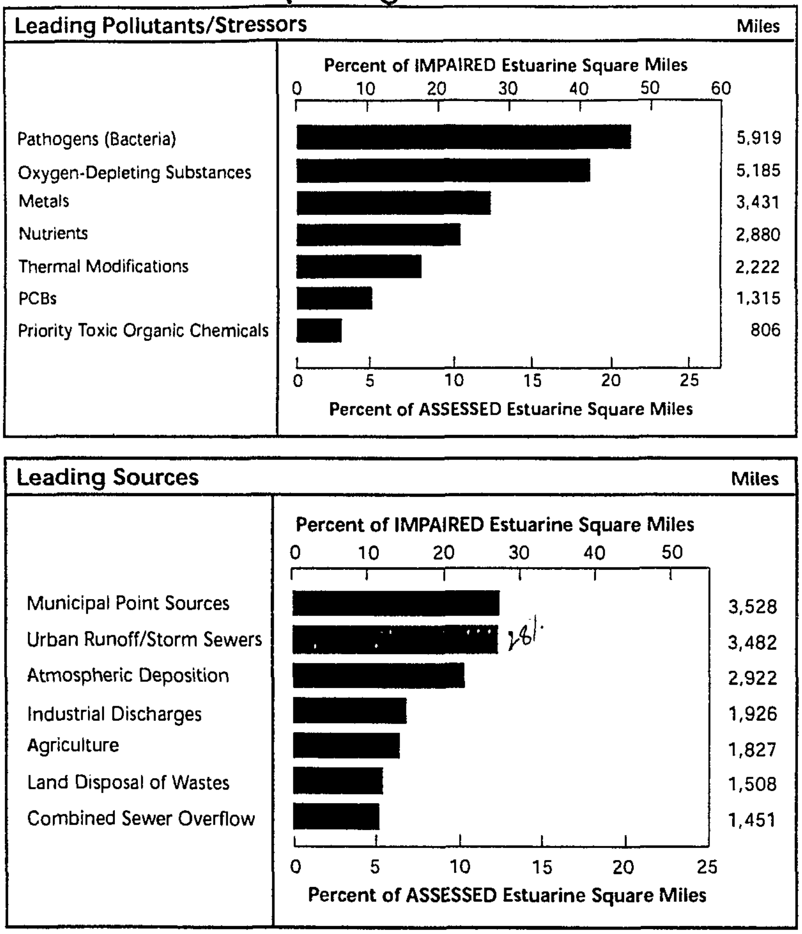
There are 5,521miles of Great Lakes shoreline in the United States. The Great Lakes contain nearly one-fifth of the fresh surface water on earth. Despite their large size, the Great Lakes are sensitive to the effects of a broad range of contaminants that enter the Lakes from polluted air, ground water, surface water, wastewater discharges, and overland runoff. For the 1998 report, five of the eight Great Lakes states assessed conditions of 90% of the nation's total Great Lakes shoreline miles (Figure 11). The states reported that of the 90% of assessed shoreline miles, 4% fully support designated uses and 96% are impaired. They also report that 2% of the assessed waters are fully supporting but threatened for one more uses.

The reporting states indicated that the greatest impacts to Great Lakes shoreline are on fishing activities (Figure 12). The states bordering the Great Lakes have issued advisories to restrict consumption of fish caught along their entire shorelines. Depending upon the location, mercury, PCBs, pesticides, or dioxins are found in fish tissues

R0011730

Figure 10

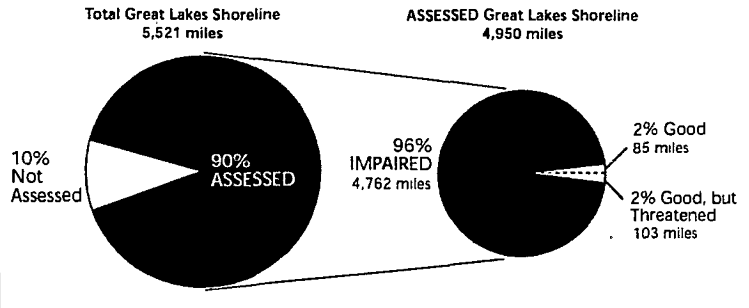
Leading Pollutants and Sources Impairing Estuaries



These bar charts present the leading pollutants and sources reported by the states. The percent scale on the lower axis compares the square miles impacted to the total ASSESSED square miles. The upper axis compares the square miles impacted to the total IMPAIRED square miles.

Figure 11

Summary of State Assessments of Great Lakes Shoreline



States assessed 90% of Great Lake shoreline miles for the 1998 305(b) report. For the subset of assessed waters, 2% are rated as good, 2% as good but threatened, and 96% as impaired.

at levels that exceed standards set to protect human health.

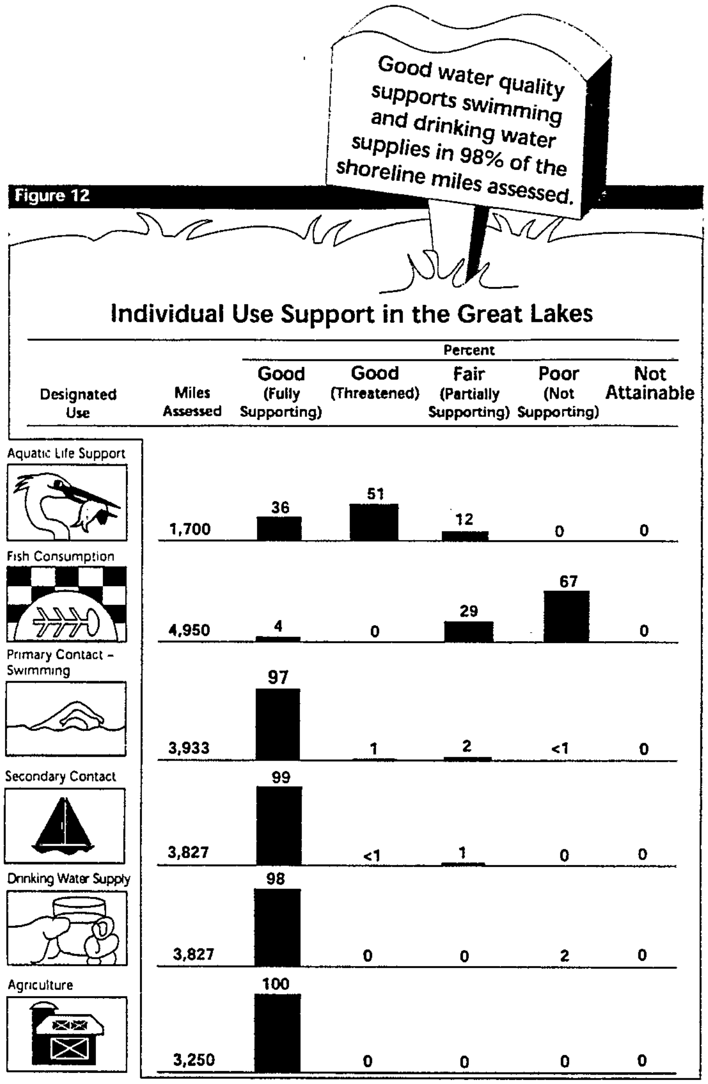
Priority organic chemicals, pesticides, and nonpriority organic chemicals are the most common pollutants affecting the waters along the Great Lakes shoreline, according to the three states that reported on pollutants and sources (Figure 13). These states reported that atmospheric deposition, discontinued discharges from factories that no longer operate, and contaminated sediments are the primary sources of these pollutants.

Ocean Shoreline Waters

There are 66,645 miles of ocean shoreline in the United States, including Alaska. Our ocean shoreline waters provide critical habitat for various life stages of commercial fish and shellfish (such as shrimp), provide habitat for endangered species (such as sea turtles), and support popular recreational activities, including sport fishing and swimming. Despite their vast size and volume, oceans are vulnerable to impacts from pollutants, especially in nearshore waters that receive inputs from adjoining surface waters, ground water, wastewater discharges, and nonpoint source runoff.

Fifteen of the 27 coastal states and territories assessed conditions in 5% of the nation's total ocean shoreline miles (Figure 14). The states and territories reported that of the 5% assessed, 88% of ocean shoreline miles fully support designated uses and 12% are impaired. They report that 8% of the assessed miles are threatened for one or more uses.

Figure 12

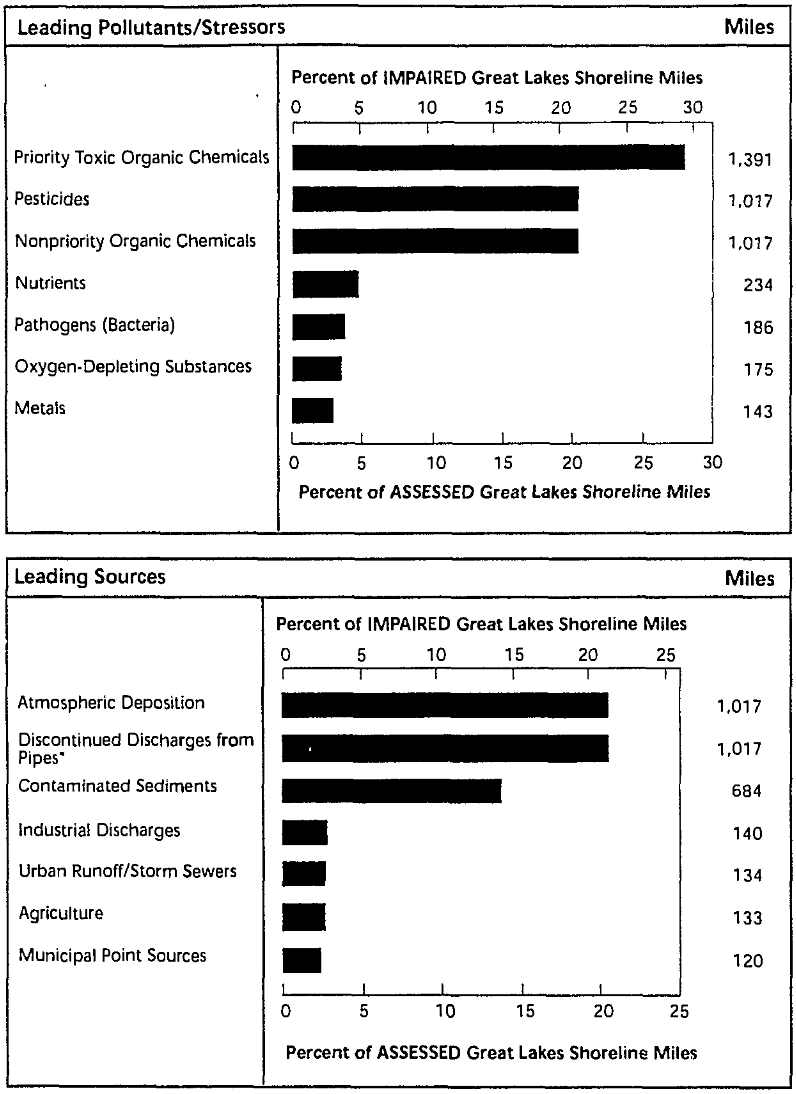


This figure presents a tally of the Great Lakes shoreline miles assessed for each key designated use. For each use, the figure presents the percentage of assessed waters in each water quality category.

R0011732

Figure 13

Leading Pollutants and Sources Impairing Great Lakes Shoreline

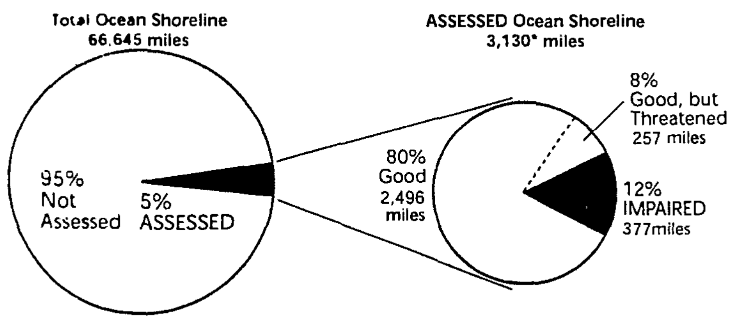


These bar charts present the leading pollutants and sources reported by the states. The percent scale on the lower axis compares the miles impacted to the total ASSESSED miles. The upper axis compares the miles impacted to the total IMPAIRED miles.

States assessed 5% of ocean shoreline miles for the 1998 305(b) report. For the subset of assessed waters, 80% are rated as good, 8% as good but threatened, and 12% as impaired.

Figure 14

Summary of State Assessments of Ocean Shoreline



*Includes miles assessed as not attainable.

R0011733

Swimming was the most frequently assessed use in ocean shoreline waters (Figure 15).

Bacteria (pathogens), turbidity, and excess nutrients are the most common pollutants affecting the assessed ocean shoreline. The primary sources of pollution to assessed shoreline miles include urban runoff and storm sewers and land disposal of wastes (Figure 16).

Coral Reefs

Coral reefs are among the most productive ecosystems in the ocean. They are inhabited by a wide variety of fish, invertebrates, and plant species and provide important economic opportunities, primarily in terms of fishing and tourism. Coral reefs are found in three states—Hawaii, Florida, and Texas, and five U.S. territories—American Samoa, Guam, Northern Mariana Islands, Puerto Rico, and the U.S. Virgin Islands (Figure 17).

Recent evidence indicates that coral reefs are deteriorating worldwide. To prevent further deterioration of coral ecosystems, President Clinton signed Executive Order 13089 on Coral Reef Protection. This order created the U.S. Coral Reef Task Force, composed of representatives from the states and territories with coral resources. In response, these areas have initiated or increased efforts to identify the causes of coral reef degradation and approaches to prevent further loss.

Efforts are under way in Hawaii, Florida, and American Samoa to assess the status of coral reefs and identify pollutants and stressors to coral reef ecosystems.

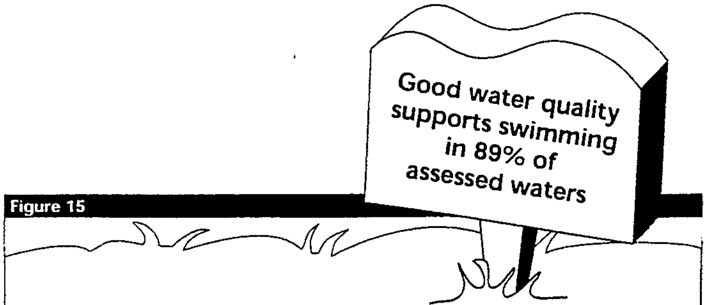


Figure 15

Individual Use Support in Ocean Shoreline Waters

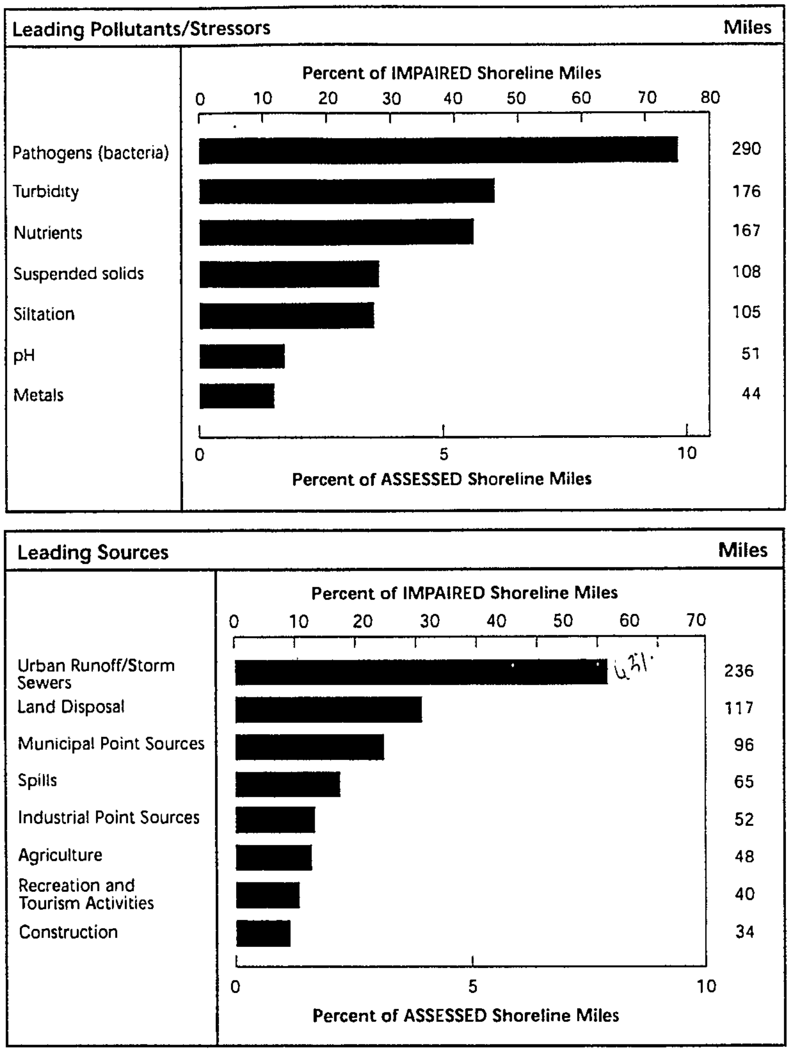
Designated Use	Miles Assessed	Percent: Good (Fully Supporting)	Good (Threatened)	Fair (Partially Supporting)	Poor (Not Supporting)	Not Attainable
Aquatic Life Support	1,707	87	7	4	2	0
Fish Consumption	780	84	2	10	4	0
Shellfishing	1,141	89	0	11	<1	0
Primary Contact - Swimming	2,138	80	9	8	2	0
Secondary Contact	1,646	93	1	5	1	0

This figure presents a tally of the ocean shoreline miles assessed for each key designated use. For each use, the figure presents the percentage of assessed waters in each water quality category.

R0011734

Figure 16

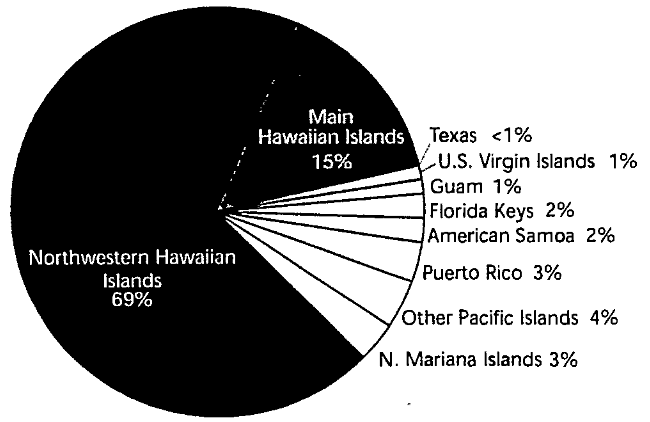
Leading Pollutants and Sources Impairing Ocean Shoreline



These bar charts present the leading pollutants and sources reported by the states. The percent scale on the lower axis compares the miles impacted to the total ASSESSED miles. The upper axis compares the miles impacted to the total IMPAIRED miles.

Figure 17

United States Coral Reef Areas



The findings will be used to develop management actions to protect coral reefs in these areas. Coral reef stressors identified to date include invasive species, marine debris, petroleum spills, nutrient runoff, and septic discharges.

Wetlands

Wetlands are intermittently or permanently flooded areas that are the link between land and water. The functions and values of healthy wetlands include the following:

- **Storage of water –** Wetlands help prevent flooding by storing and slowing the flow of water through a watershed.
- **Storage of sediment and nutrients –** Wetlands act like filters that purify water in a watershed.
- **Growth and reproduction of plants and animals –** Wetlands produce a wealth of natural products, including fish and shellfish, wildlife, timber, and wild rice.
- **Diversity of plants and animals –** Wetlands are critical to the survival of a wide variety of plants and animals, including numerous rare or endangered species as well as many species of great commercial value to man.

It is estimated that over 200 million acres of wetlands existed in the lower 48 states at the time of European settlement. Since then, extensive wetlands acreage has been lost, with many of the original wetlands drained and converted to farmland and urban areas. Today, less than half of our nation's original wetlands remain. Recent federal studies estimate an average net loss of wetlands around 100,000 acres per year in the contiguous United States. Although losses continue to decline, we still have to make progress toward our Administration's goal of an annual net gain of 100,000 wetland acres per year by the year 2005 and every year thereafter.

Eleven states and tribes listed sources of recent wetlands loss in their 1998 305(b) reports. Eight states cited agriculture as a leading source of current losses. Other losses were due to construction of roads, highways, and bridges; residential growth and urban development; filling and/or draining; construction; industrial development; commercial development; and channelization.

The states and tribes are making progress in incorporating wetlands into water quality standards and developing designated uses and criteria specifically for wetlands. But many states and tribes still lack wetland-specific designated uses, criteria, and monitoring programs for wetlands. Without criteria and monitoring data, most states and tribes cannot evaluate use support.

Ground Water

Ground water—water found in natural underground formations called aquifers—is an important component of our nation's fresh water resources. About 77,500 million gallons of the nation's ground water are withdrawn daily for use in drinking and bathing, irrigation of crop lands, livestock watering, mining, industrial and commercial uses, and thermoelectric cooling applications (Figure 18). Unfortunately, this valuable resource is vulnerable to contamination, and ground water contaminant problems are being reported throughout the country. Ground water contamination can occur through relatively well defined, localized pollution plumes emanating from specific sources such as leaking underground storage tanks, or it can occur as a general deterioration of ground water quality over a wide area due to diffuse nonpoint sources such as agricultural fertilizer and pesticide applications, septic systems, and urban runoff.

Based on results reported by states in their 1998 305(b) reports, ground water quality in the nation is good and can support the many different uses of this resource. However, despite these positive results, measurable negative impacts to aquifers across the nation have been detected, and they are usually traced back to human activities.

States identified leaking underground storage tanks as an important potential threat to our nation's ground water resources. This was based on the sheer number of underground storage tanks and the risk posed to human health and the environment from releases. States also report that the organic chemicals found in petroleum products such as gasoline are common ground water contaminants. Other potential sources of ground water contamination include septic systems, landfills, industrial facilities, fertilizer and pesticide applications, accidental spills, surface impoundments, and animal feedlots. Contaminants occur in the form of organic compounds, metals, and nitrate.

Assessing the quality of our nation's ground water resources is no easy task. An accurate and representative assessment of ambient ground water quality requires a well-planned and well-executed monitoring plan. Although the 305(b) ground water program is improving, there is still much to be done. States need to increase their monitoring coverage and focus on collecting ground water data that are most representative of the resource.

Figure 18

National Ground Water Use

How Does Impaired Water Quality Impact Public Health and Aquatic Life?

Water pollution threatens both public health and aquatic life. Public health may be threatened directly through the consumption of contaminated food or drinking water or indirectly through skin exposure to contaminants present in recreational and boating waters. Aquatic organisms can be affected by the presence of toxic chemicals in their environment and are also particularly susceptible to changes in the physical quality of their environments, such as changes in pH, temperature, dissolved oxygen, and habitat.

Public Health Concerns

The 1998 EPA Listing of Fish and Wildlife Advisories listed 2,506 advisories in effect in 47 states, the District of Columbia, and American Samoa (Figure 19). Mercury, PCBs, chlordane, dioxins, and DDT (with its byproducts) caused 99% of all the fish consumption advisories in effect in 1998.

In their 1998 305(b) reports, 11 of the 27 coastal states and jurisdictions reported shellfish harvesting restrictions in over 2,300 square miles of estuarine waters. These areas are monitored for bacteria as part of the National Shellfish Sanitation Program.

Advisories were also issued to warn the public about health risks from water-based recreation. Sixteen states and tribes identified 240 sites where recreation was restricted at least once during the reporting cycle. The states and tribes identified sewage treatment plant bypasses and malfunctions, urban runoff and storm sewers, and faulty septic systems as the most common sources of elevated bacteria concentrations in bathing areas.

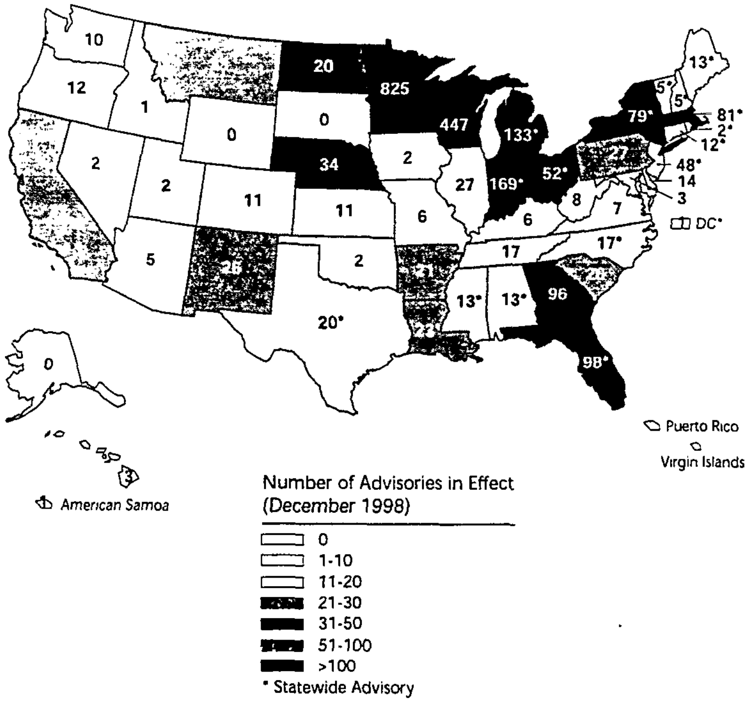
R0011737

Thirty-eight states, tribes, and other jurisdictions provided information about the degree to which drinking water use is met. Of the 23% of river and stream miles assessed, only 3% do not support drinking water where it is a designated use; of the 42% of lake and reservoir acres assessed, 5% do not support drinking water use.

Increasingly, states are coordinating their efforts under the Safe Drinking Water Act (SDWA) and the Clean Water Act (CWA) to assess sources of drinking water. SDWA requires states to determine the susceptibility to contamination of drinking water sources, while the CWA calls for them to assess the ability of waters to support drinking water use. Assessments under both laws will provide the information necessary for states to develop tailored monitoring programs and for water systems to work with states and local governments to protect drinking water sources.

Figure 19

Fish and Wildlife Consumption Advisories in the United States



Note: States that perform routine fish tissue analysis (such as the Great Lakes states) will detect more cases of fish contamination and issue more advisories than states with less rigorous fish sampling programs. In many cases, the states with the most fish advisories support the best monitoring programs for measuring toxic contamination in fish, and their water quality may be no worse than the water quality in other states.

Aquatic Ecosystem Concerns

A fish kill is one of the most obvious effects of pollution on aquatic life. This phenomenon is normally attributed to exceptionally low dissolved oxygen levels—usually due to excessive nutrients in the water—or to the discharge of toxic contaminants to the water column. A more insidious impact of pollution on aquatic organisms is the development of growths, lesions, and eroded fins, or increased body burden of toxic chemicals.

The most common impact of pollution on aquatic life is the shift of a waterbody's naturally occurring and self-sustaining population from one type of aquatic community to another. An example is the shift of a cold water trout stream to a warm water carp-dominated stream. Changes in aquatic community structure and function may occur due to a variety of reasons, but the most common are an elevation of temperature, a lowering of available dissolved oxygen, and an increase in sedimentation due to land use practices within the watershed.

The persistence of chemicals in bottom sediment poses risks to both aquatic life and humans. These chemicals may be toxic to bottom-dwelling aquatic organisms. Some of these chemicals, like mercury and PCBs, bioaccumulate in fish tissue and pose a potential threat to humans and other organisms that consume the fish. In their 1998 305(b) reports, 11 states and tribes listed 115 separate sites with contaminated sediments. These states and tribes most frequently listed metals, PCBs, pesticides, PAHs, and other priority organic chemicals as the source of contamination. They identified industrial and municipal discharges (both past and present), landfills, resource extraction, and abandoned hazardous waste disposal sites as the primary sources of contamination.

What Is Being Done to Restore and Maintain Water Quality?

Public polls consistently document that Americans value water quality. In addition to its economic benefits, clean water provides recreational and aesthetic benefits. As a result, local, state, and federal agencies, the private sector, and other organizations are working to improve water quality. According to President Clinton's *Clean Water Act Initiative: Analysis of Costs and Benefits*, these partners spend between $63 billion and $65 billion dollars each year to improve and protect water quality.

This study estimated that private sources spend a combined total of about $30 billion per year on pollution prevention and control efforts. Agriculture spends another $500 million per year on activities that reduce its impact on water quality, including implementation of best management practices to control the effects of nonpoint source runoff. Municipalities spend a total of $23 billion per year, primarily on wastewater treatment plants, drinking water treatment, and storm water pollution control.

State governments dedicate almost $500 million and federal governments dedicate almost $10 billion to water resource protection and restoration efforts each year. These efforts include developing and revising water quality standards, monitoring and assessing water quality, characterizing causes and sources of impairment, developing total maximum daily loads and allocating these loads to point and nonpoint sources, implementing permitting programs to address point sources, and developing and implementing best management practices to control nonpoint source pollution.

Significant resources are dedicated to restoring and maintaining water quality. Water quality monitoring and assessment is a critical tool to help ensure that these resources are used effectively to achieve water quality goals. EPA and state environmental agencies recognize that water quality monitoring and assessment programs need continued strengthening to be able to evaluate the effectiveness of water quality protection and restoration efforts.

EPA continues to work with states and other partners to increase the quality and comprehensiveness of water quality monitoring and assessment programs. This is achieved through data sharing and development of consistent monitoring designs and assessment criteria. EPA provides technical assistance, guidance, and resources for monitoring design and implementation. EPA and its partners including states, tribes, other federal agencies, and other public and private monitoring organizations are developing a Consolidated Assessment and Listing Methodology (CALM) that will provide a consistent approach for characterizing water quality under both Sections 305(b) and 303(d) of the Clean Water Act.

For more information on CALM, visit EPA's website at **www.epa.gov/owow/monitoring/wqreport.html.**

Water Quality Conditions in the United States: A Profile from the 1998 National Water Quality Inventory Report to Congress

States, tribes, territories and interstate commissions report that, in 1998, about 40% of U.S. streams, lakes and estuaries that were assessed were not clean enough to support uses such as fishing and swimming. About 32% of U.S. waters were assessed for this national inventory of water quality. Leading pollutants in impaired waters include siltation, bacteria, nutrients and metals. Runoff from agricultural lands and urban areas are the primary sources of these pollutants. Although the U.S. has made significant progress in cleaning up polluted waters over the past 30 years, much remains to be done to restore and protect the Nation's waters.

Findings

Recent water quality data finds that more than 291,000 miles of assessed rivers and streams do not meet water quality standards. Across all types of waterbodies, states, territories, tribes and other jurisdictions report that poor water quality affects aquatic life, fish consumption, swimming, and drinking water. In their 1998 reports, states assessed 840,000 miles of rivers and 17.4 million acres of lakes, including 150,000 more river miles and 600,000 more lake acres than in their previous reports in 1996.

Summary of Quality of Assessed Rivers, Lakes, and Estuaries

Waterbody Type	Total Size	Amount Assessed* (% of Total)	Good (% of Assessed)	Good but Threatened (% of Assessed)	Polluted (% of Assessed)
Rivers (miles)	3,662,255	842,426 (23%)	463,441 (55%)	85,544 (10%)	291,264 (35%)
Lakes (acres)	41,593,748	17,390,370 (42%)	7,927,486 (46%)	1,565,175 (9%)	7,897,110 (45%)
Estuaries (sq. miles)	90,465	28,687 (32%)	13,439 (47%)	2,766 (10%)	12,482 (44%)

*Includes waterbodies assessed as not attainable for one or more uses.

Note: percentages may not add up to 100% due to rounding.

Of the assessed ocean shoreline miles, 12% are impaired, primarily because of bacteria, turbidity and excess nutrients. Primary sources of pollution include urban runoff, storm sewers and land disposal of wastes. States assessed only 5% of the Nation's ocean shoreline miles.

States also found that 96% of assessed Great Lakes shoreline miles are impaired, primarily due to pollutants in fish tissue at levels that exceed standards to protect human health. States assessed 90% of Great Lakes shoreline miles.

Leading Pollutants and Sources* Causing Impairment in Assessed Rivers, Lakes, and Estuaries

	Rivers and Streams	Lakes, Ponds, and Reservoirs	Estuaries
Pollutants	Siltation	Nutrients	Pathogens (Bacteria)
	Pathogens (Bacteria)	Metals	Organic Enrichment/ Low Dissolved Oxygen
	Nutrients	Siltation	Metals
Sources	Agriculture	Agriculture	Municipal Point Sources
	Hydromodification	Hydromodification	Urban Runoff/Storm Sewers
	Urban Runoff/Storm Sewers	Urban Runoff/Storm Sewers	Atmospheric Deposition

*Excluding unknown, natural, and "other" sources

Wetlands are being lost in the United States at a rate of about 100,000 acres per year in the contiguous United States. Eleven states and tribes listed sources of recent wetland loss; conversion for agricultural uses, road construction, and residential development are leading reasons for loss.

The states found that ground water quality is good and can support many different uses. However, measurable negative impacts have been detected and are commonly traced back to sources such as leaking underground storage tanks, septic systems, and landfills.

Reporting Under the Clean Water Act

This *National Water Quality Inventory* is the twelfth biennial report to Congress prepared under Section 305(b) of the Clean Water Act. It contains information from each state on the quality of our nation's rivers, lakes, wetlands, estuaries, coastal waters, and ground water, along with information on public health and aquatic life concerns. It serves as a snapshot of water quality conditions across the country.

To assess water quality, states and other jurisdictions compare their monitoring results to the water quality standards they have set for their waters. These standards consist of designated uses (such as drinking, swimming, or fishing), criteria to protect those uses (such as chemical-specific thresholds that should not be exceeded), and an antidegradation policy intended to keep waters that do meet standards from deteriorating from their current condition.

Under Section 303(d) of the Clean Water Act, there is a second reporting requirement -- that states provide lists of all of their impaired waters. These lists are then used to prioritize state restoration activities. This is accomplished through the development of Total Maximum Daily Loads (TMDLs), calculations of the amount of a pollutant that a waterbody can receive and still meet water quality standards. A TMDL is the sum of all allowable loads of a single pollutant from all contributing point and nonpoint sources. It includes reductions needed to meet water quality standards and allocates those reductions among sources in the watershed.

Information reported by the states under the two Clean Water Act reporting requirements is generally consistent, although the 303(d) lists often include specific information from more targeted monitoring activities. This information clearly points to the need to restore polluted waters and maintain the quality of waters that currently meet standards. In August 1999, EPA announced a new proposal for a strengthened TMDL program. Since August, EPA has workec to incorporate comments from stakeholders and to refine the proposal to be an effective, common-sense approach to water restoration led by states, territories, and tribes in partnershir with federal and local governments, and local communities.

Water Quality Conditions in the United States

A Profile from the 1998 National Water Quality Inventory Report to Congress

States, tribes, territories, and interstate commissions report that, in 1998, about 40% of U.S. streams, lakes, and estuaries that were assessed were not clean enough to support uses such as fishing and swimming. About 32% of U.S. waters were assessed for this national inventory of water quality. Leading pollutants in impaired waters include siltation, bacteria, nutrients, and metals. Runoff from agricultural lands and urban areas are the primary sources of these pollutants. Although the United States has made significant progress in cleaning up polluted waters over the past 30 years, much remains to be done to restore and protect the nation's waters.

Findings

Recent water quality data find that more than 291,000 miles of assessed rivers and streams do not meet water quality standards. Across all types of waterbodies, states, territories, tribes, and other jurisdictions report that poor water quality affects aquatic life, fish consumption, swimming, and drinking water. In their 1998 reports, states assessed 840,000 miles of rivers and 17.4 million acres of lakes, including 150,000 more river miles and 600,000 more lake acres than in their previous reports in 1996.

Of the assessed ocean shoreline miles, 12% are impaired, primarily because of bacteria, turbidity, and excess nutrients. Primary sources of pollution include urban runoff, storm sewers, and land disposal of wastes. States assessed only 5% of the nation's ocean shoreline miles.

States also found that 96% of assessed Great Lakes shoreline miles are impaired, primarily due to pollutants in fish tissue at levels that exceed standards to protect human health. States assessed 90% of Great Lakes shoreline miles.

Wetlands are being lost in the contiguous United States at a rate of about 100,000 acres per year. Eleven states and tribes listed sources of recent wetland loss; conversion for agricultural uses, road construction, and residential development are leading reasons for loss.

The states found that ground water quality is good and can support many different uses. However, measurable negative impacts have been detected and are commonly traced back to sources such as leaking underground storage tanks, septic systems, and landfills.

Reporting Under the Clean Water Act

This *National Water Quality Inventory* is the twelfth biennial report to Congress prepared under Section 305(b) of the Clean Water Act. It contains information from each state on the quality of our nation's rivers, lakes, wetlands, estuaries, coastal waters, and ground water, along with information on public health and aquatic life concerns. It serves as a snapshot of water quality conditions across the country.

To assess water quality, states and other jurisdictions compare their monitoring results to the water quality standards they have set for their waters. These standards consist of designated uses (such as drinking, swimming, or fishing), criteria to protect those uses (such as chemical-specific thresholds that should not be exceeded), and an antidegradation policy intended to keep waters that do meet standards from deteriorating from their current condition.

Under Section 303(d) of the Clean Water Act, there is a second reporting requirement—that states provide lists of all of their impaired waters. These lists are then used to prioritize state restoration activities. This is accomplished through the development of Total Maximum Daily Loads (TMDLs), calculations of the amount of a pollutant that a waterbody can receive and still meet water quality standards. A TMDL is the sum of all available loads of a single pollutant from all contributing point and nonpoint sources. It includes reductions needed to meet water quality standards and allocates these reductions among sources in the watershed.

Information reported by the states under the two Clean Water Act reporting requirements is generally consistent, although the 303(d) lists often include specific information from more targeted monitoring activities. This information clearly points to the need to restore polluted waters and maintain the quality of waters that currently meet standards. In August 1999, EPA announced a new proposal for a strengthened TMDL program. Since August, EPA has worked to incorporate comments from stakeholders and to refine the proposal to be an effective, common-sense approach to water restoration led by states, territories, and tribes in partnership with federal and local governments and local communities.

For Further Information

For a copy of the *National Water Quality Inventory: 1998 Report to Congress* (EPA841-R-00-001), visit *www.epa.gov/305b* or call EPA's National Service Center for Environmental Publications at 1-800-490-9198.

Executive Summary

The Quality of Our Nation's Water

Background

The *National Water Quality Inventory Report to Congress* is the twelfth biennial report to Congress and the public about the quality of our nation's rivers, streams, lakes, ponds, reservoirs, wetlands, estuaries, coastal waters, and ground water. This report is prepared under Section 305(b) of the Clean Water Act. Section 305(b) requires states and other jurisdictions to assess the health of their waters and the extent to which water quality supports state water quality standards and the basic goals of the Clean Water Act. This information is submitted to the U.S. Environmental Protection Agency (EPA) every 2 years and summarized in the biennial report to Congress.

States' Section 305(b) assessments are an important component of their water resource management programs. These assessments help states

- Implement their water quality standards by identifying healthy waters that need to be maintained and impaired waters that need to be restored
- Prepare their Section 303(d) lists of impaired waters
- Develop restoration strategies such as total maximum daily loads and source controls
- Evaluate the effectiveness of activities undertaken to restore impaired waters and protect healthy waters.

EPA and the states continue to work to improve these assessments through better and more extensive monitoring. Our goal is comprehensive monitoring of all waters. This is a challenging task given the demands placed on limited state and federal resources. However, this is a vital goal given the important, and costly, water resource management decisions based on state water quality monitoring data. This report reflects incremental progress toward the goal of comprehensive assessment. It includes information submitted by all 50 states and the District of Columbia and 5 territories, 4 interstate commissions, and 9 Indian tribes.

Beverly Manifold, Okeefenoke Swamp, GA

How Do States and Other Jurisdictions Assess Water Quality?

Water quality assessment begins with water quality standards. States and other jurisdictions adopt water quality standards for their waters. These standards must then be approved by EPA before they become effective under the Clean Water Act.

Water quality standards have three elements. First are the designated uses assigned to waters. The Clean Water Act envisions that all waters be able to provide for swimming and the protection and propagation of aquatic life. Additional uses described in the Act and adopted by states include drinking water and fish consumption. Second are the criteria. Criteria help protect designated uses. For example, criteria include chemical-specific thresholds that protect fish and humans from exposure to levels that may cause adverse effects. The third element is called the antidegradation policy. This policy is intended to prevent waters from deteriorating from their current condition.

After setting standards, states assess their waters to determine the degree to which these standards are being met. Currently, states use two categories of data to assess water quality. The first and most desirable category is monitored data. These data are field measurements that are not more than 5 years old. They include field measurements of biological, habitat, toxicity, and/or physical/chemical conditions in waterbodies, sediments, and fish tissue. The other category frequently used to fill information gaps is evaluated data. Evaluated data include field measurements that are more than 5 years old and estimates generated using land use and source information, predictive models, and surveys of fish and game biologists.

How Many of Our Waters Were Assessed for 1998?

This report does not describe the health of all waters of the United States because states have not yet achieved comprehensive assessment of all their waters. States assessed almost 25% of the nation's total river and stream miles; 40% of its lake, pond, and reservoir acres; and 30% of its estuarine square miles for this edition of the biennial report.

Therefore, this report summarizes the health of only that portion of waters that states reported on in their individual 1998 water quality inventories.

States reported fairly significant increases in the amount of rivers and streams assessed between 1996 and 1998. Assessed river and stream miles increased by 21% from 694,000 to over 842,000 miles. This is considerable when you realize that only 1.3 million river and stream miles are perennial waters that flow year round. The remaining 2.3 million miles or so are intermittent or ephemeral, which means they are dry for some or most of the year.

EPA and states recognize that, in spite of the progress made toward comprehensive assessment, we still have a long way to go. Oceans, wetlands, and ground water quality are poorly represented in state monitoring programs. EPA's wetland and ground water protection programs continue to work with states to develop assessment methods and improve monitoring coverage. EPA is initiating a coastal monitoring program, Coastal 2000, that will provide a baseline characterization of coastal waters and data needed to develop water quality standards for these waters.

What Is the Status of Our Assessed Waters?

States focused the majority of their assessment activities on rivers and streams; lakes, ponds, and reservoirs; and estuaries. States reported that 65% of assessed river and stream miles, 55% of assessed lake acres, and 56% of assessed estuarine square miles fully support the water quality standards states evaluated. The remaining assessed waters are impaired to varying degrees. The amount of assessed waters identified as impaired changed somewhat between 1996 and 1998. However, states indicated that these differences more likely reflect changes in monitoring design, assessment methodology, and water quality standards than actual water quality changes.

The states bordering the Great Lakes report on almost 90% of their Great Lake shoreline. The assessments indicate that one or more uses is impaired for about 4,700 shoreline miles. Much of this impairment is due to historic contamination by persistent pollutants that still impact fish consumption.

States assessed very small amounts of ocean and marine resources, wetlands, and ground water. This is due in part to a lack of water quality standards and other assessment tools for these resources. EPA and states are working to develop water quality standards and improve characterization of these resources.

What Do States Identify as the Leading Causes and Sources Affecting Impaired Waters?

For the subset of assessed waters identified as impaired, the report presents the leading pollutants and sources of pollution reported by states, territories, commissions, and tribes. In terms of the nature of impairment, the bottom line did not change significantly from 1996 to 1998. For example, across all waterbody types, states and other jurisdictions reported that

- Aquatic life, swimming, and fish consumption are among the top impaired uses.
- Siltation, nutrients, bacteria, and metals are among the top pollutants causing impairment.
- Pollution from urban and agricultural land that is transported by precipitation and runoff (called nonpoint source pollution) is the leading source of impairment.

It is important to understand the difficulties in identifying causes and, in particular, sources of pollution in impaired waters. For many waters, states and other jurisdictions classify the causes and sources as unknown. EPA and states are working to develop methodologies for both determining the causes and sources of impairment and describing the level of confidence in the classification.

How Does Impaired Water Quality Impact Public Health and Aquatic Life?

Water quality standards are adopted to protect public health and aquatic life. Specifically, water quality standards establish conditions designed to ensure that

- Water quality supports a balanced population of fish, shellfish, and wildlife
- Water is safe to use for drinking water, fish consumption, swimming and recreation, and other beneficial uses.

When waters do not meet water quality standards, one or more of these uses are impaired. Depending on the nature of the impairment, this may mean that certain public uses must be restricted. For example, fish consumption may be prohibited or restricted, beaches may be closed to swimming, and drinking water utilities may have to install more costly treatment devices. Toxic chemicals, as well as viruses and bacteria, threaten human health through the consumption of contaminated fish and shellfish or through contact with contaminated waters.

Toxic chemicals, bacteria, and viruses may also impact aquatic life. In fact, aquatic organisms are more sensitive than humans are to some chemicals. In severe cases, exposure can kill aquatic organisms. Lower levels of exposure can cause deformities and sores and can reduce the reproductive success of organisms. Aquatic life is often impaired by loss of in-stream habitat for organisms and by conventional problems such as low dissolved oxygen, siltation, and excess nutrients. While extremely low dissolved oxygen can result in fish kills, these problems usually exhibit less dramatic, but more long-term, impacts on aquatic life. These stressors result in alteration or loss of the biological integrity of aquatic communities.

What Is Being Done To Restore and Maintain Water Quality?

Public polls consistently document that Americans value water quality. In addition to its economic benefits, clean water provides recreational and aesthetic benefits. As a result, local, state, and federal agencies; the private sector; and other organizations are working to improve water quality. According to President Clinton's *Clean Water Act Initiative: Analysis of Costs and Benefits* (EPA800-S-94-001, 1994), these partners spend between $63 billion and $65 billion dollars each year to improve and protect water quality.

This study estimated that private sources spend a combined total of about $30 billion per year on pollution prevention and control efforts. Agriculture spends another $500 million per year on activities that reduce its impact on water quality including implementation of best management practices to control the effects of nonpoint source runoff. Municipalities spend a total of $23 billion per year, primarily on wastewater treatment plants, drinking water treatment, and storm water pollution control.

State and federal governments dedicate almost $500 million and $10 billion, respectively, to water resource protection and restoration efforts each year. These efforts include developing and revising water quality standards, monitoring and assessing water quality, characterizing causes and sources of impairment, developing total maximum daily loads and allocating these loads to point and nonpoint sources, implementing permitting programs to address point sources, and developing and implementing best management practices to control nonpoint source pollution.

Significant resources are dedicated to restoring and maintaining water quality. Water quality monitoring and assessment is a critical tool to help ensure that these resources are used effectively to achieve water quality goals. EPA and state environmental agencies recognize that water quality monitoring and assessment programs need continued strengthening to be able to evaluate the effectiveness of water quality protection and restoration efforts.

Surface Water Quality

Siltation, metals, nutrients, bacteria, and pesticides impair the most river miles in California. The leading sources of degradation in California's rivers and streams are agriculture, forestry activities, urban runoff and storm sewers, and municipal point sources. In lakes, siltation, metals, and nutrients are the most common pollutants. Hydrologic and habitat modifications, along with urban runoff/ storm sewers, construction, highway maintenance and runoff, and atmospheric deposition pose the greatest threat to lake water quality.

Metals, pesticides, PCBs, and priority organics are the most frequently identified pollutants in estuaries, harbors, and bays. Urban runoff and storm sewers are the leading source of pollution in California's coastal waters, followed by spills, agriculture, resource extraction, and septage disposal.

Ground Water Quality

Salinity, total dissolved solids, and chlorides are the most frequently identified pollutants impairing use of ground water in California, followed by priority organic chemicals, nutrients, non-priority organic chemicals, and pesticides. Leading sources are septage disposal, agriculture, and dairies. Potential sources of ground water contamination include leaking underground storage tanks, septage disposal, agriculture, and industrial point sources.

Programs to Restore Water Quality

Through California's stormwater permit program, two statewide general permits have been adopted addressing stormwater discharges associated with industrial activities. Dischargers are required to eliminate most nonstormwater discharges, develop a stormwater pollution prevention plan to identify and implement control measures to minimize pollutants in stormwater runoff, and monitor their discharges.

The State Water Resources Control Board and Regional Water Quality Control Boards are implementing a Watershed Management Initiative to better coordinate and focus limited public and private resources to address both point and nonpoint source water quality problems especially in high-priority targeted watersheds.

Programs to Assess Water Quality

California has developed a number of programs to monitor water quality in fresh, estuarine, and marine waters of the state. These include a Toxic Substances Monitoring Program that focuses on areas with known or suspected impairment; the Toxicity Testing Program for the identification of high-risk areas as well as the spatial and temporal extent of water quality problems and their causes and sources; an underground storage tank program to study the cleanup of leaking tanks; and volunteer monitoring.

Programs that focus on saltwater monitoring include the California State Mussel Watch Program to detect toxic substances in bays, harbors, and estuaries and the Bay Protection and Toxic Cleanup Program to identify toxic hot spots in enclosed bays and estuaries. California is also developing a comprehensive program for monitoring and reducing pollution in California's coastal zone.

Individual Use Support in California

Designated Use[a]		Percent: Good (Fully Supporting)	Good (Threatened)	Fair (Partially Supporting)	Poor (Not Supporting)	Not Attainable

USGS
science for a changing world

Selected Findings and Current Perspectives on Urban and Agricultural Water Quality by the National Water-Quality Assessment Program

Studies by the USGS National Water-Quality Assessment (NAWQA) program in the last decade describe water-quality conditions in nearly 120 agricultural and 35 urban watersheds ("urban" primarily refers to residential and commercial development over the last 50 years). The findings show that for both urban and agricultural areas, nonpoint chemical contamination is an issue. Much work still needs to be done in urban areas with point source contamination as well, including infrastructure improvements. Appreciable improvements in overall water quality, however, will depend upon effective management of point and nonpoint sources. The findings also show that water-quality conditions and aquatic health reflect a complex combination of land and chemical use, land-management practices, population density and watershed development, and natural features, such as soils, geology, hydrology, and climate. Contaminant concentrations vary from season to season and from watershed to watershed. Even among seemingly similar land uses and sources of contamination, different areas can have very different degrees of vulnerability and, therefore, have different rates at which improved treatment or management can lead to water-quality improvements.

Water Quality in Agricultural Watersheds

- Nitrogen and phosphorus in surface water commonly exceed levels that contribute to excessive algae. For example, average annual concentrations of phosphorus in nearly 80 percent of streams sampled in agricultural areas were greater than the U. S. Environmental Protection Agency (USEPA) desired goal for preventing nuisance plant growth in streams. Excessive plant growth can lead to low dissolved oxygen, which can be harmful to fish and other aquatic life.
- Nitrate is often elevated above background levels in shallow ground water underlying farmland. Concentrations in about 20 percent of shallow wells sampled in agricultural areas exceeded the USEPA drinking water standard. This result is a concern in rural areas where shallow ground water is used for domestic supply; these domestic wells are not regulated and owners often do not know the quality of their well water or whether their wells are vulnerable to contamination. Nitrate is most often elevated in karst (carbonate) areas or where soils and aquifers consist of sand and gravel. These natural features enable rapid infiltration and downward movement of water and chemicals. Some of the more vulnerable areas are the Central Valley of California, and parts of the Pacific Northwest, the Great Plains, and the Mid-Atlantic region. In contrast, ground-water contaminants underlying farmland in parts of the upper Midwest are barely detectable, despite similar high rates of chemical use. In these areas ground-water contamination may be limited because of relatively impermeable, poorly drained soils and glacial till that cover much of the region, and because tile drains provide quick pathways for runoff to streams.
- Pesticides are widespread. At least one pesticide was detected in more than 95 percent of stream samples. Pesticides were detected in more than 60 percent of shallow wells sampled in agricultural areas.
- Pesticides commonly occur in mixtures. Two-thirds of stream samples collected in agricultural areas contained 5 or more pesticides, and more than one-quarter of the samples contained 10 or more. Ground water contained fewer pesticides; about 30 percent of the wells sampled contained 2 or more.
- Concentrations of pesticides generally are low and below drinking-water standards. However, the risk to humans and the environment from present-day low levels of contaminant exposure remains unclear. For example, current standards and guidelines do not yet account for exposure to mixtures, and many pesticides and their breakdown products do not have standards or guidelines.
- Herbicides—most commonly atrazine and its breakdown product desethylatrazine, and metolachlor, cyanazine, and alachlor—occur more frequently and usually at higher concentrations in agricultural streams and ground water than in urban waters. Their occurrence is linked to their use; they rank in the top five in national herbicide use for agriculture.
- Insecticides that were used in the past still persist in agricultural streams and sediment. DDT was the most commonly detected organochlorine compound, followed by dieldrin and chlordane. Their uses were restricted in the 1970s and 1980s and, yet, more than 20 years later, one or more sediment-quality guidelines were exceeded at more than 20 percent of agricultural sites.

U.S. Geological Survey
U.S. Department of the Interior

FS-047-01
April, 2001

- Concentrations of fecal coliform bacteria commonly exceed recommended standards for water-contact recreation.
- Concentrations of total phosphorus are generally as high in urban streams as in agricultural streams. More than 70 percent of sampled urban streams exceeded the USEPA desired goal for preventing nuisance plant growth.
- Insecticides, such as diazinon, carbaryl, chlorpyrifos, and malathion, occur more frequently, and usually at higher concentrations in urban streams than in agricultural streams. Concentrations are low in urban streams, rarely exceeding USEPA drinking-water standards. However, effects on aquatic life may be more of a concern. Concentrations of insecticides exceeded at least one guideline established to protect aquatic life in every sampled urban stream.
- Herbicides are widespread in surface water (detected in 99 percent of urban stream samples) and ground water (detected in more than 50 percent of sampled wells). Most common are those applied to lawns, golf courses, and road right-of-ways, such as atrazine, simazine, and prometon.
- Similar to agricultural areas, pesticides in urban waters commonly occur in mixtures; nearly 80 percent of stream samples contained 5 or more pesticides. Two of the most commonly detected insecticides in mixtures were diazinon and chlorpyrifos; common herbicides detected were simazine and prometon.
- Sediment in urban streams is associated with higher frequencies of occurrence of DDT, chlordane, and dieldrin and higher concentrations of chlordane and dieldrin than sediment in agricultural streams. Sediment-quality guidelines for organochlorine pesticides were exceeded at 36 percent of sampled urban sites.
- Volatile organic compounds, which are used in plastics, cleaning solvents, gasoline, and industrial operations, occur widely in shallow urban ground water. Some of the most frequently detected of the 60 analyzed compounds were the commercial and industrial solvents trichloroethene (TCE), tetrachloroethene (PCE), and methylene chloride; the gasoline additive methyl tert-butyl ether (MTBE); and the solvent and disinfection by-product of water treatment, trichloromethane (also known as chloroform).
- Concentrations of selected trace elements, such as cadmium, lead, zinc, and mercury, are elevated above background levels in populated urban settings, most likely caused by emissions from industrial and municipal activities and motor vehicles. Sediment cores from streambeds and reservoirs, which can be used to track changes over long time periods, indicate that lead increased from 1940s to the 1970s, and began to decrease after it was removed from gasoline. Concentrations are not yet down to background levels. Decreases also are noted for DDT and chlordane.
- In contrast to lead, DDT, and chlordane, sediment cores indicate that zinc and polycyclic aromatic hydrocarbons (PAHs, which result from fossil fuel combustion) are increasing. These increases most likely relate to increasing motor vehicle traffic in watersheds. Sediment-quality guidelines for PAHs were exceeded at more than 40 percent of urban sites.
- Toxic compounds in streambed sediment in urban areas, such as DDT, chlordane, dieldrin, and PCBs, also were found in fish tissue, often at higher concentrations than in the sediment. One or more organochlorine compounds were detected in 97 percent of whole fish samples collected at urban sites, and PCBs were detected in more than 80 percent of whole fish samples. Concentrations of organochlorine compounds exceeded guidelines to protect wildlife at more than 10 percent of urban sites; wildlife guidelines for PCBs were exceeded at nearly 70 percent of urban sites. These findings have contributed to decisions by some states to issue fish-consumption advisories.
- Deteriorated water quality and sediment, as well as habitat disturbances, contribute to degraded biological communities in urban streams. The greatest effects are seen in areas with the highest human population densities and watershed development. Pollution-tolerant algae and aquatic invertebrates (such as worms and midges), as well as omnivorous fish communities, prevail at the affected sites.

Abstract

Direct discharges of pollutants into the ocean and coastal waters from sewage treatment plants, industrial facilities, ships, and the at-sea dumping of sewage sludge and other wastes have been greatly reduced over the past 30 years as a result of the Clean Water Act and other federal statutes. Advances in waste treatment have kept ahead of increases in the volume of wastes, and that trend is likely to continue. Some persistent toxic pollutants, such as DDT and PCBs, were banned for manufacture or use in the United States, and ambient levels of these pollutants have been decreasing in most U.S. marine environments. On the other hand, pollution from land runoff went largely unabated during this period; in some cases it has increased. As a result, diffuse sources now contribute a larger portion of many kinds of pollutants than the more thoroughly regulated direct discharges.

Toxic pollutants, including pesticides, industrial organic chemicals and trace metals, are widespread contaminants of the marine environment. But they produce discernible adverse effects on ecosystems only in limited areas around population centers and ports. Some of these chemicals are known through experimental studies to affect the reproductive, immune, or endocrine systems of marine organisms at low concentrations, and may have subtle effects on marine organisms and populations over a broader area. While some of the most toxic substances have been banned for manufacture and use, material previously released may remain in the environment for decades to centuries. High

Nutrient Overenrichment

The dominant form of plant life in the world's oceans is free-floating, single-celled algae known as **phytoplankton.** Like all plants, phytoplankton need **nutrients—nitrogen, phosphorus,** and other minerals—and light to grow and reproduce. Most of the needed nutrients either wash into the ocean from the land or move from the deeper waters to the surface through upwelling.

The growth of phytoplankton is usually limited by the availability of nutrients. Nitrogen is the nutrient that is usually in the shortest supply. But if nitrogen becomes abundant, the growth of phytoplankton can increase dramatically. An explosive increase in the population of phytoplankton is known as an **algal bloom.** A bloom often contains more phytoplankton than can be eaten by marine animals. The uneaten algae—and wastes from animals that eat the algae—sink to the ocean bottom, and decompose.

Through the process of decomposition, the dissolved oxygen levels in the water near the bottom can decrease substantially.

The long-term increase in the supply of organic matter to an ecosystem—often as a result of excess nutrients, or nutrient overenrichment—is called **eutrophication.**

R0011756

concentrations of persistent contaminants in bottom sediments require careful consideration when removed by dredging or managed in place.

Overenrichment of coastal ecosystems by nutrients, particularly nitrogen, has emerged as the most widespread and measurable effect of pollution on living marine resources and biodiversity in U.S. coastal waters. Excessive nutrient levels (overenrichment or eutrophication; see sidebar on these pages) may result in serious depletion of the dissolved oxygen supplies needed by marine animals, loss of habitat (e.g., seagrasses and coral reefs), and algal blooms. Two-thirds of the surface area of estuaries and bays in the conterminous U.S. suffers one or more symptoms of overenrichment. Because a majority of the nutrients in most regions now come from diffuse sources rather than direct discharges, reversing coastal eutrophication will require management strategies for watersheds reaching far inland from the coastal environment. Feasible measures include advanced treatment of municipal wastewaters, reduction of nitrogen oxide emissions from power plants and vehicles, control of ammonia emissions from animal feedlots, more efficient use of fertilizers and manure, and restoration of wetlands and floodplains that act as nutrient traps.

Eutrophication creates two harmful effects: oxygen depletion and reduced water clarity. When dissolved oxygen levels drop to levels that equal two milligrams per liter or less, a condition called **hypoxia** occurs.

Anoxia refers to a complete absence of dissolved oxygen in the water.

More mobile marine animals, like fish and crabs, can often migrate out of hypoxic areas. Other animals—such as oysters and marine snails—that lack mobility or cannot move quickly enough to escape hypoxia may suffocate. When water clarity is reduced by greater concentrations of algae, less light can penetrate to the ocean bottom where seagrasses and seaweeds live. As a result, these plants may sicken and die.

Increased nutrient levels in surface water (rivers and streams) and in groundwater from the land can be attributed to human activity. Major sources of nitrogen, phosphorus, and other nutrients delivered to the oceans include discharges from wastewater-treatment plants, runoff and groundwater from cropland, urban and suburban stormwater (runoff from paved surfaces), farm animal wastes, and even nutrients found in airborne emissions from power plants, automobile exhaust, and industrial smokestacks.

I. Introduction

"Pollution occurs when a substance, an organism, or energy (e.g., sound or heat) is released into the environment by human activities and produces an adverse effect on organisms or the environmental processes on which they depend."

This report provides background on the effects of pollution on life in the ocean and coastal waters of the United States for the Pew Oceans Commission, which is conducting a national dialogue on policies needed to restore and protect living marine resources. Pollution occurs when a substance, an organism, or energy (e.g., sound or heat) is released into the environment by human activities and produces an adverse effect on organisms or the environmental processes on which they depend.

Marine pollution comes in many forms and from many sources (Table 1). Some pollutants in sufficient concentrations are toxic to marine organisms. These include both naturally occurring chemicals present in much higher concentrations as a result of human activities (e.g., trace metals and oil) as well as compounds that did not exist in nature until manufactured by humans (e.g., pesticides such as DDT).

Other pollutants are harmful not because they are toxic but because they stimulate biological activity or alter habitats. The addition of large amounts of organic matter in the form of sewage or fish-processing wastes, for example, supports the growth of decomposer microbes that can exhaust the available oxygen supply. Inputs of nutrients (particularly forms of nitrogen and phosphorus), while responsible for the rich biological productivity of many coastal waters, can stimulate the production of more organic matter than an ecosystem can assimilate. Turbid waters, depletion of oxygen, and blooms of noxious algae may result. Sediments from land runoff or from dredging can decrease water clarity and smother sensitive bottom habitats such as reefs and seagrass beds.

Pollution emanates from either direct discharges or diffuse sources. Land-based industrial and municipal outfalls discharge wastewater into coastal waters or rivers that drain to the coast. Other direct discharges include those from vessel operations and at-sea waste disposal. Pollutants from diffuse sources include those released into the atmosphere by fossil-fuel and waste combustion; and land runoff of pesticides, toxic-waste products, nutrients, and sediments. Although chemical contaminants—released as a result of human activities—can now be found throughout the world's oceans, most demonstrable effects on living resources occur in coastal waters and are the result of pollution from land.

Table 1

Forms of Marine Pollution

Form	Sources	Effects and Trends
Toxins (e.g., biocides, PCBs, trace metals)	Industrial and municipal wastewaters; runoff from farms, forests, urban areas and landfills; erosion of contaminated soils and sediments; vessels; atmospheric deposition	Poison and cause disease and reproductive failure; fat-soluble toxins may biocencentrate, particularly in birds and mammals, and pose human health risks. Inputs into U.S. waters have declined, but remaining inputs and contaminated sediments in urban and industrial areas pose threats to living resources.
Biostimulants (organic wastes, plant nutrients)	Sewage and industrial wastes; runoff from farms and urban areas; airborne nitrogen from combustion of fossil fuels	Organic wastes overload bottom habitats and deplete oxygen; nutrient inputs stimulate algal blooms (some harmful), which reduce water clarity, cause loss of seagrasses and coral reefs, and alter food chains supporting fisheries. While organic waste loadings have decreased, nutrient loadings have increased (NRC, 1993a, 2000a).
Oil	Runoff and atmospheric deposition from land activities; shipping and tanker operations; accidental spills; coastal and offshore oil and gas production activities; natural seepage	Petroleum hydrocarbons can affect bottom organisms and larvae; spills affect birds, mammals and nearshore marine life. While oil pollution from ships, accidental spills, and production activities has decreased, diffuse inputs from land-based activities have not (NRC, 1985).
Radioactive isotopes	Atmospheric fallout, industrial and military activities	Few known effects on marine life; bioaccumulation may pose human health risks where contamination is heavy.
Sediments	Erosion from farming, forestry, mining, and development; river diversions; coastal dredging and mining	Reduce water clarity and change bottom habitats; carry toxins and nutrients. Sediment delivery by many rivers has decreased, but sedimentation poses problems in some areas; erosion from coastal development and sea-level rise is a future concern.
Plastics and other debris	Ships, fishing nets, containers	Entangles marine life or is ingested; degrades beaches, wetlands and nearshore habitats
Thermal	Cooling water from power plants and industry	Kills some temperature-sensitive species; displaces others. Generally, less a risk to marine life than thought 20 years ago.
Noise	Vessel propulsion, sonar, seismic prospecting, low-frequency sound used in defense and research	May disturb marine mammals and other organisms that use sound for communication.
Human pathogens	Sewage, urban runoff, livestock, wildlife	Pose health risks to swimmers and consumers of seafood. Sanitation has improved, but standards have been raised (NRC, 1999a).
Alien species	Ships and ballast water, fishery stocking, aquarists	Displace native species, introduce new diseases; growing worldwide problem (NRC, 1996).

Adapted from Weber 1993

The report first reviews accomplishments in reducing marine pollution, and then highlights the need for further reductions in the effects of toxic substances and nutrients as remaining major challenges. Diffuse sources of pollution via land runoff and atmospheric deposition are particularly important and have proved difficult to control. To provide grounding for policies needed to restore and protect living marine resources, the report: describes the forms, sources, movements, and effects of pollutants; assesses past and future trends of pollution in the U.S.; considers additional steps that could reduce pollution; and places pollution threats into a broader context of other threats to living resources.

II. Reductions of **Pollution**

Municipal and Industrial Discharges

In 1972, Congress passed the landmark Federal Water Pollution Control Act, which was reauthorized in 1977, 1981, and 1987 as the Clean Water Act (CWA). The goal of the law is to eliminate pollution in the nation's waters. It imposes uniform minimum federal standards for municipal and industrial wastewater treatment based on best available technology. Facilities discharging wastes at discernible points are required to obtain permits from the U.S. Environmental Protection Agency (EPA) or from state pollution-control agencies. Permits include enforceable limits on pollutants in the discharges, and require dischargers to conduct monitoring and to file reports when limits are violated.

Most publicly owned treatment works (POTWs) handle industrial wastes as well as domestic sewage. Because discharges of untreated organic wastes had degraded many rivers, lakes, and coastal waters by depleting dissolved oxygen and causing fish kills, the Clean Water Act required POTWs to achieve at least "secondary" treatment. Secondary treatment adds biodegradation of the organic matter in the wastewater to the solids (sludge) removal and disinfection included in "primary" treatment. Consequently, it significantly reduces the biological oxygen demand (BOD) of wastewater effluent. The CWA provided substantial amounts of money to help pay for the required POTW improvements. About 125 billion dollars have been spent in constructing or expanding POTWs, mainly between 1972 and 1992 when federal grants provided three-quarters of the costs (NRC, 1993a). Waivers to this requirement were allowed for several deep ocean outfalls where it could be demonstrated that the organic wastes would not harm the environment. Additional waste treatment, such as reduction of suspended solids, was often required.

Technology-based standards and the National Pollutant Discharge Elimination System (NPDES) have resulted in a dramatic reduction in the amount of pollutants entering U.S. waters, including coastal waters. Reductions in discharges of organic matter improved conditions in the Delaware River estuary near Philadelphia to the point that low oxygen levels no longer prevent the upriver migration of juvenile striped bass and American shad (Weisberg et al., 1996). Oxygen levels in New York Harbor are approximately 50 percent higher (NRC, 1993a). The most thoroughly documented example of the benefits of improved treatment may be the Southern California Bight, off Los Angeles and San Diego (Box 1), where inputs of many pollutants have been reduced 90 percent or more over a 25-year period. Kelp beds, fish and invertebrate communities, and certain seabird populations have greatly, if not completely, recovered. These improvements have been accomplished despite a steady increase in population and in the volume of wastewater discharged.

Another long-term effort to restore water quality has recently come to fruition with the completion in September 2000 of a new deepwater outfall for treated effluents from the Boston region. The offshore discharge into Massachusetts Bay will result in improvements in environmental quality in Boston Harbor beyond those already achieved as a result of the cessation of sludge disposal, reductions in combined sewer overflow, and secondary treatment of

Box 1
Southern California Bight Ocean Discharges

Wastes from the nation's largest metropolitan center (17 million people) are discharged into a bight of the Pacific Ocean via deepwater (about 200 feet) outfalls. Pollution from publicly owned treatment works (POTWs) has been reduced significantly since the 1970s even though the population served and wastewater volumes grew steadily (Schiff et al., 2000, Figure 1). This reduction was accomplished through source control, pretreatment of industrial wastes, reclamation, and treatment-plant upgrades, including secondary or other advanced treatment (concentrating on chemical removal of suspended solids). Capital improvements to POTWs throughout the Southern California Bight cost more than five billion dollars.

Discharges from POTWs of most pollutants into the bight have decreased: 50 percent for suspended solids and biological oxygen demand, 90 percent for combined trace metals, and more than 99 percent for chlorinated hydrocarbons. Bight sediments show a record of decreasing contamination. Concentrations of contaminants in fish and marine mammals have declined. Kelp beds near the POTWs have returned. The extent of degraded bottom communities has contracted by about two-thirds; and the incidence of tumors and other maladies in bottom fish has returned to background levels.

A unique problem for the bight is the fact that large quantities of the pesticide DDT were previously discharged, particularly through the Los Angeles County's POTW. This facility received wastes from the world's largest DDT manufacturer. In 1971 an estimated 440,000 pounds of DDT were discharged via an outfall off Palos Verdes. Today, only 3 pounds of DDT are discharged from all Southern California POTWs combined (Schiff et al., 2000). Concentrations of DDT and its degradation products have declined greatly in fish and marine mammals. Populations of brown pelicans, which were decimated by the eggshell thinning induced by DDT contamination, have rebounded. However, brown pelicans, bald eagles, and peregrine falcons are still being affected by the residual DDT contamination in the bottom sediments of the bight. Although this "legacy" contamination is slowly being buried, some DDT is still remobilized into the food chain.

wastes. Although recovery is far from complete, liver tumors in flounder are less common, mussels accumulate lower levels of organic contaminants, and bottom invertebrate communities are recovering in the harbor (Rex, 2000). Field studies and computer models predict that moving the discharge offshore to deeper waters will not increase concentrations of pollutants, including nutrients, in Massachusetts Bay.

Although secondary treatment of municipal sewage removes at least 85 percent of the organic material and suspended solids in wastewater, only one-third of the nitrogen and phosphorus is eliminated (NRC, 1993a; NRC, 2000a). These two nutrients are the principal causes of eutrophication of receiving waters (see Section IV). Advanced treatment technologies, capable of eliminating up to 97 percent of the nitrogen and 99 percent of the phosphorus (NRC, 2000a), are being implemented in regions susceptible to nutrient overenrichment from direct discharges.

Pollutant levels have also been reduced in discharges from industries, including oil and gas production, refineries, chemical manufacturing, electric-power generation, and food processing. Although regionally important, industrial discharges contribute a relatively small portion of pollutant

Figure 1

Flow Volume and Pollutant Emissions from Four Largest Publicly Owned Treatment Works in the Southern California Bight, 1971 through 1996.

R0011763

loadings on a national scale. Industrial discharges often have specific waste-reduction requirements that necessitate pollution prevention (elimination or reduction of the source in the industrial process), recycling and reuse, and advanced waste treatment.

Pollution from aquaculture—effluents from ponds or holding tanks on land and materials released from net pens and shellfish racks or rafts—is receiving new regulatory attention with the expansion of aquaculture in coastal waters. Pollutants include uneaten food, fecal and excretory material, and releases of antibiotics, pesticides, hormones, anesthetics, pigments, vitamins, and minerals. Organic deposits under net pens and shellfish rafts often alter the bottom habitat and affect seabed communities in the immediate vicinity. Extensive aquaculture operations can constitute a major source of nutrient inputs to the smaller bays and estuaries in which they are located. Antibiotic, pesticide, and hormone releases can also affect wild organisms in the region (Goldburg and Triplett, 1997).

Additional reductions of pollution from direct discharges will undoubtedly be required and more effective source controls and treatment technologies developed to meet those requirements. Two forces are driving these reductions. First, the Clean Water Act requires dischargers to implement advanced pollution controls where conventional technology is not sufficient to protect aquatic life and the human uses assigned to the water body receiving the discharge. Standards for designated uses are not currently met for one-third of U.S. waters (EPA 2000a). In such cases, the Clean Water Act specifies that total maximum daily loads (TMDLs) be determined and allocated among point and nonpoint sources. Second, ever-closer scrutiny is given to the inputs of chemicals that induce toxicity at very low concentrations, persist in the environment for long periods, and reach high levels of accumulation in the tissues of fish and wildlife.

Vessel Discharges

Pollutants are discharged to the ocean from the routine operations of ships and boats (including discharges of sewage and industrial-processing wastes and the release of petroleum hydrocarbons from engine exhausts and bilge and ballast waters). Vessel-related pollution may also occur as a result of accidental spills and solid-waste disposals.

At-sea release of oily water has been an international issue over the past 30 years and is regulated under the International Convention for the Prevention of Pollution from Ships. Compartments of oil tankers are typically filled with seawater for ballast when emptied of their cargo. Some ports, such as Port Valdez, Alaska, have ballast-water treatment facilities. Although ballast-water discharges may cause problems along some tanker routes and are responsible for tar balls that contaminate the surface of high seas, they comprise a relatively small percentage of oil pollution in the marine environment (NRC, 1985). Exhaust emissions into the water from smaller vessels may be a significant source of petroleum hydrocarbons in more confined coastal waters.

Atmospheric emissions from ships are being recognized as a significant source of global air pollution (Corbett and Fischbeck, 1997), yet they are not subject to the same restrictions for protection of air quality as are land-based power plants and manufacturers. Seagoing vessels are responsible for an estimated 14 percent of emissions of nitrogen from fossil fuels and 16 percent of the emissions of sulfur from petroleum uses into the atmosphere (Corbett and Fischbeck, 1997).

Cruise ships, although not a major source of pollution to U.S. coastal waters as a whole, can cause problems in areas such as Caribbean island harbors, which accommodate intense cruise-ship activity, or relatively pristine areas such as the inland passages of Alaska. Cruise ships generate sewage, gray water, solid wastes, oily wastes, and waste from photo processors, swimming pools and dry cleaners. (EPA, 2000b).

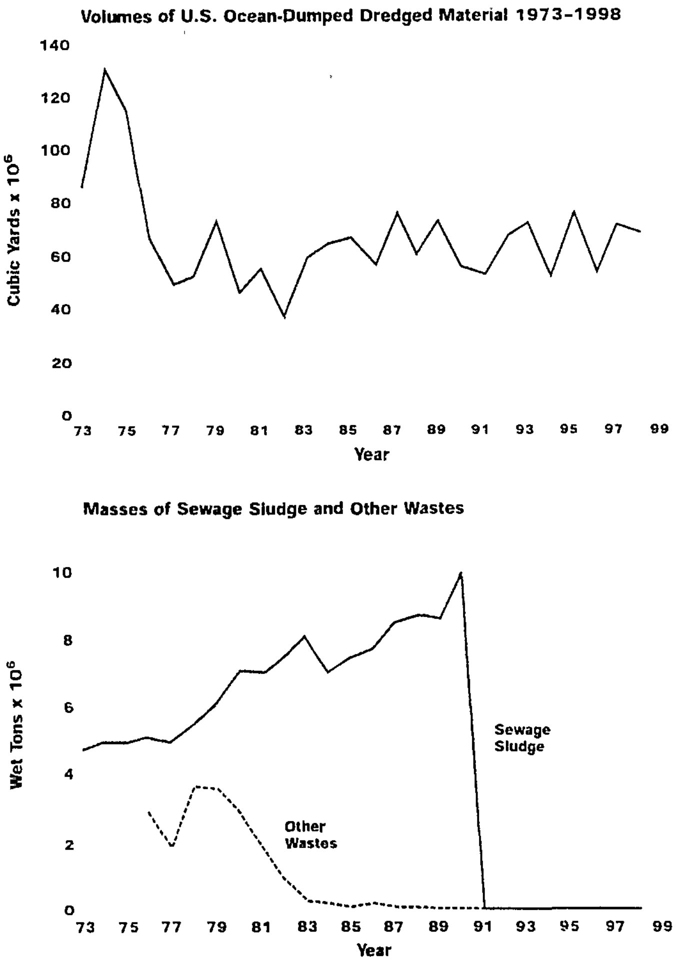
Ocean Dumping

The practice of transporting wastes for disposal in the ocean became a cause for national and international concern in the 1970s (CEQ, 1970). The Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matters, or the London Dumping Convention, came into force in 1975, acknowledging through its regulatory framework that different materials have vastly different impacts on the marine environment. Nationally, ocean disposal in U.S. waters has been regulated under the Marine Protection, Research, and Sanctuaries Act of 1972 (MPRSA) by a permit procedure that prohibits dumping of some materials, establishes criteria to authorize dumping of others, and identifies sites for disposal. The Clean Water Act also regulates discharges into the territorial sea and navigable waters of the United States. In the ten years following passage of the MPRSA, dumping of industrial waste, construction debris, solid waste, and incineration of chemicals remained low, but dumping of sewage sludge doubled (Burroughs, 1988). Although the amount of dredged sediment disposed in coastal waters remained constant, it was approximately an order of magnitude greater in volume than the sludge dumped (Figure 2).

During the 1980s, public apprehension about ocean dumping grew. Sewage sludge dumped in the New York Bight was blamed for an apparent decline in water quality and health risks to bathers. Controversy also erupted over ocean incineration of chemical wastes in the Gulf of Mexico. In 1988,

Figure 2

Amounts of Dredged Material and Other Wastes Dumped in U.S. Waters, 1973 through 1998



Source: U.S. Army Corps of Engineers 1999; EPA 1991

Congress enacted the Ocean Dumping Ban Act that prohibited ocean dumping of sewage sludge and industrial chemicals. Sewage sludge must now be incinerated, disposed of on land, or reused—alternatives that have their own set of environmental impacts, including pollution of the marine environment via land runoff and atmospheric deposition.

Today, virtually all the material dumped into coastal and marine waters is bottom sediment removed by dredging (Figure 2). Under the Clean Water Act, the U.S. Army Corps of Engineers issues permits for disposal of dredged material, subject to guidelines established by EPA. Protocols have been developed to determine whether dredged sediments are suitable for placement in the ocean or coastal environment. These protocols involve an assessment based on the sediment characteristics, contaminant levels, the toxicity of contaminants present, and the potential for the contaminants to accumulate in the tissues of organisms (EPA, 1991). Based on these criteria, dredging may not be permitted at all or the dredged sediments may be deemed unacceptable for overboard disposal. Placement in a landfill, in a confined disposal facility, or in a contained underwater disposal site is then required. Approximately five to ten percent of the sediments dredged require management as contaminated sediments (NRC, 1997).

Although the federal laws governing dredged material disposal have eliminated the practice of discarding heavily contaminated harbor sediments in the marine environment, they have not eliminated controversies. Despite the protections afforded by regulatory requirements and testing

R0011766

protocols, significant controversies surround the overboard disposal of dredged sediments that are deemed acceptably "clean." These controversies are related in part to the physical impacts of dredged sediment placement, including increased turbidity, siltation, burial of bottom organisms, and permanent changes in the quality of bottom habitat. In addition, the public, resource users, and environmental managers are concerned that contaminants in the dredged sediment will be mobilized and made more bioavailable by overboard disposal. As a result, many ports struggled to resolve impasses in selecting and permitting alternatives for dredged sediment placement (Box 2). On one side, there is an aversion to placing wastes of any kind into the ocean and coastal waters; on the other, there are constraints related to costs, limits in the feasibility of beneficial uses, and opposition to disposal alternatives outside of the marine environment.

The volume of commerce moving through U.S. ports is increasing and will continue to do so because of increased world trade and dependence on foreign

Box 2
San Francisco Bay: Long-Term Strategy for Dredged Material

Navigation channels and berths in San Francisco Bay tend to fill in rapidly because of the large amount of mobile sediments in the bay—a legacy of placer mining following the California Gold Rush—and strong tidal currents. Dredged sediments were typically placed back into the bay, mostly at a site near Alcatraz Island, where strong tidal currents dispersed them. However, disposal of large quantities of sediments generated from channel deepening changed the current patterns at the Alcatraz site so that sediments placed there no longer dispersed.

The limitations of this site, the lack of readily available alternatives, public concerns, lawsuits, and fragmented agency management coalesced to create an impasse, or so-called mudlock, that halted most dredging. This caused significant problems for both commercial and military shipping. The U.S. Navy, citing national security requirements, broke the impasse by dumping dredged sediments at a deepwater site in the ocean. Subsequently, EPA designated an ocean disposal site to receive sandy sediments dredged by federally funded projects.

In 1990, federal, state, and regional agencies joined with navigation interest groups, fishing groups, environmental organizations, and the public to develop a Long-Term Management Strategy for Bay Area dredged material (U.S. Army Corps of Engineers, 1998). The strategy emphasizes a balance between ocean disposal and beneficial reuse at upland/wetland sites with limited in-bay disposal. During a transitional period, the amount of dredged material deposited at in-bay sites would be reduced from 80 percent to 20 percent, while upland sites, reuses, and wetland restoration are developed. Toxicity testing and monitoring would be bolstered. Nonetheless, environmental interest groups are calling for the elimination of in-bay disposal altogether.

Figure 3

Sources of Loadings of Trace Metals to the Southern California Bight

energy resources (Bureau of Transportation Statistics, 2000). This is driving a trend toward larger ships with deeper drafts and, thus, continued pressure for deeper channels. Although there has been an effort to develop a national policy for screening dredged material and evaluating disposal options (Maritime Administration, 1994). the U.S. lacks a coherent port development policy that is compatible with the environmental quality objectives articulated in federal environmental statutes.

Diffuse Sources of Pollution

In most U.S. coastal regions, diffuse sources of pollution—including land runoff and atmospheric deposition—are now responsible for most serious water-quality problems (EPA and USDA, 1998). Because of the reduced loadings of many contaminants achieved by point-source controls, land runoff is currently the dominant source of many contaminants in both the Southern California Bight and Chesapeake Bay (Figure 3).

Except where the manufacture or use of a contaminant has ceased or changed dramatically—such as for DDT and some other pesticides, PCBs, or lead additives in gasoline—the contribution of diffuse sources of pollution in coastal and ocean waters has not been significantly reduced by the programs implemented over the last 30 years. Moreover, loadings of some pollutants from diffuse sources, such as nitrogen (Howarth et al., 1996; Goolsby et al., 2000) and mercury

(Swain et al., 1992), appear to have increased during that time period.

The importance of diffuse sources of pollutants has long been recognized. There are provisions in the Clean Water Act and Coastal Zone Management Act intended to achieve reductions in pollution of coastal waters from diffuse sources. Nonetheless, improvements have been slow and difficult. This is due to the diversity of diffuse sources, resistance to regulatory solutions, and the multiple pathways through which the pollutants may reach coastal and ocean environments.

Fallout from the atmosphere is an important and previously under-appreciated source of a number of important pollutants, including nitrogen, lead, mercury, and organochlorine compounds such as DDT and PCBs (Box 3). Some of these pollutants can be transported over long distances before falling onto the ocean or on watersheds draining to the coast. Atmospheric transport is the primary mechanism for contamination of oceanic regions remote from human activities, such as polar seas and the open ocean. In a recent report to Congress, the EPA (2000c) indicated that atmospheric deposition of PCBs, banned and restricted pesticides, and lead has been declining in recent years for the Great Lakes and some coastal waters, but that deposition of other pollutants such as nitrogen has not fallen off.

Contaminants and nutrients in runoff are influenced by: (1) land uses, i.e., whether the land is forested, agricultural, industrial or urban; (2) human activities that involve the purposeful or unintended placement of fertilizers, pesticides, atmospheric contaminants, and wastes on the land surface; and (3) natural phenomena and land-use decisions that affect water infiltration, retention, groundwater movement, runoff, and transport in streams and rivers.

Sediments that erode from the land and reach the coast in runoff carry various contaminants bound to sediment particles, including trace metals, organic compounds, and phosphorus. The sediments themselves can constitute a serious form of pollution, silting up shallow water environments, increasing the need for dredging, altering benthic habitats, and decreasing water clarity. Alternatively, improved soil conservation practices and the entrapment of riverine sediments behind dams have resulted in decreased delivery of sediments to many U.S. coastal environments over the last half century (Meade, 1982). For some coastal environments, this has improved the conditions for living resources by increasing water clarity and decreasing sedimentation; however, other coastal ecosystems, such as sandy beaches and subsiding deltas (Milliman, 1997), are experiencing problems because a continued supply of sediments is needed to sustain them. *(Continued on page 14)*

Box 3
The Atmosphere: An Important Pathway for Some Pollutants

Atmospheric deposition of pollutants involves a variety of physical processes that transport chemicals to the Earth's surface (Baker, 1997; Figure 4). Wet deposition involves processes by which gases and airborne particles are washed from the atmosphere during precipitation. Dry deposition results from the impact of fine particles (aerosols) on surfaces and on gas exchange at terrestrial and aquatic surfaces. The magnitude of atmospheric deposition depends directly on the concentration of pollutants in the atmosphere, the form of each chemical (gas or particulate), the size of the aerosol particles, and the extent of precipitation and physical mixing.

Pollutants are introduced into the atmosphere from a variety of sources, travel through several pathways, and reach various fates. Materials such as soot, NO_X, and SO_2, are released from natural sources (forests, volcanoes, and fires) as well as from human activities (anthropogenic sources) However, many atmospheric pollutants (e.g., PCBs, CFCs) are only derived from anthropogenic sources. Sources of air pollutants are commonly categorized as stationary (e.g., power plants, refineries, and incinerators), mobile (vehicles, aircraft, locomotives, and ships), or area (e.g., volatilization of ammonia from manure).

The lifetime of a pollutant in the atmosphere is dependent on its chemical reactivity and its partitioning among gas, liquid, and solid phases. In general, chemicals on particles or in liquid water have a shorter lifetime in the atmosphere and are not transported far from their source, while gaseous chemicals may remain in the atmosphere a long time and travel great distances. Persistent chemicals that are revolatilized after being deposited can travel like a grasshopper over great distances. Because these chemicals are more prone to evaporation under warmer temperatures, they tend to be redistributed to higher latitudes (Wania and Mackay, 1996).

Atmospheric deposition is an important source of nitrogen, some trace metals (e.g., lead and mercury), and organochlorine compounds (e.g., DDT and PCBs) to coastal and ocean environments:

- Lead emissions to the atmosphere in the U.S. and Europe are now orders of magnitude lower than in the early 1970s due to ending the use of leaded additives to gasoline. The impact can be seen in the reduction of lead concentrations in surface waters of the open ocean (Wu and Boyle, 1997), coastal sediments (Bricker, 1993; Cochran et al., 1998; Hornberger et al., 1999), and shellfish tissues (Lauenstein and Daskalakis, 1998).
- The global reservoir of atmospheric mercury has increased by a factor of two to five since the beginning of industrialization (Boening, 2000) and is dominated by anthropogenic emissions (Mason et al., 1994). Principal sources (>80 percent) are combustion processes, primarily coal burning and municipal and medical-waste incineration (EPA, 1997). Higher mercury concentrations in wet deposition are found in urban areas, reflecting local power plant and incinerator sources (Mason et al., 2000). Surface waters of the North Atlantic have higher mercury concentrations compared to the equatorial Pacific (Mason and Fitzgerald, 1996), probably as a result of long-distance transport of gaseous forms of mercury from sources in North America.
- The discovery of organochlorine pesticides such as DDT and industrial chemicals such as PCBs in the waters and biota of the Arctic and Antarctic ecosystems fundamentally altered our view of the role of the atmosphere in distributing pollutants on a global scale (Wania and Mackay, 1996).

Conversion of lands to urban and suburban uses has been proceeding at a rate far greater than the rate of population growth in many coastal communities as a result of the U.S. tendency for low-density residential development (sprawl). The conversion of previously undisturbed land surfaces that allowed the infiltration and slow release of water to impervious surfaces such as roofs, driveways, roads, and parking lots results in higher peak runoff, which carries greater pollution loads and alters the salinity balance in bays and estuaries during both wet and dry weather periods.

While direct discharges still contribute significant toxic contaminants and nutrients to coastal waters, it is clear that protecting the marine environment from the many adverse effects of pollution will require more effective control of land runoff and atmospheric deposition—now the principal sources of the most damaging pollutants in many coastal ecosystems.

III. The Challenge of **Toxic Contaminants**

"The historic use of some compounds no longer manufactured or used in the United States—like DDT, PCBs, and lead additives in gasoline—has left a legacy of contamination."

Nature of Toxic Contaminants

Toxic pollutants include trace metals (e.g., cadmium, copper, lead, and mercury), a variety of biocides (e.g., DDT, tributyl tin) and their by-products, industrial organic chemicals (e.g., PCBs and tetrachlorobenzene), and by-products of industrial processes and combustion (e.g., polycyclic aromatic hydrocarbons, or PAHs, and dioxins). Those pollutants meriting greatest attention are widespread and persistent in the environment, have a propensity to accumulate in biological tissues, or induce biological effects at extremely low concentrations.

The historic use of some compounds no longer manufactured or used in the United States—like DDT, PCBs, and lead additives in gasoline—has left a legacy of contamination. Generally, legacy contaminants in U.S. coastal environments have declined. However, these compounds are still in use in other countries and they continue to run off the land. For example, it has been estimated that less than 10 percent of the total lead deposited from the atmosphere onto the Sacramento and San Joaquin river basins has yet been delivered to San Francisco Bay (Steding et al., 2000). As the concentrations of some heavy metals and organochlorine compounds decrease in the marine environment, other contaminants are still being released and do not show a clear downward trend. Some may even be increasing. For example, analyses of lake and reservoir sediments show increasing levels of PAHs associated with suburban development (Van Metre et al., 2000). PAHs come from multiple sources, including petroleum and the combustion of fossil fuels and biomass, some of which have been reduced (e.g., coal coking) and some of which continue (e.g., urban runoff and atmospheric deposition of combustion by-products).

Humankind will be dealing with legacy contaminants of the marine environment well into the future. Repositories of persistent contaminants in marine sediments can be sources of long-term exposure to marine life well after the inputs of these contaminants have largely ceased. Examples of this include DDT in the Southern California Bight (Box 1) and PCBs in San Francisco Bay (San Francisco Estuary Institute, 1996). The deep sea may be the final sink for some persistent organic pollutants (Looser et al., 2000).

Biological Effects

Toxic effects, both lethal and sublethal, have been extensively documented in laboratory experiments, but concrete examples of contaminant effects on populations of marine organisms are limited (McDowell et al., 1999). Key issues considered here include the potential for bioaccumulation of toxicants by marine life; the effects of disruptions of organisms' immune, endocrine, and reproductive systems on their populations; and the effects on marine communities of chronic exposure to the high concentrations of contaminants found in coastal sediments.

Organisms may accumulate contaminants from water, sediments, or food in their tissues. This can result in concentrations of the contaminant many times higher than those found in the environment. The degree of bioaccumulation depends on the level of exposure and the mechanisms by which the organism expels, stores, or metabolically breaks down the contaminant. Compounds such as organochlorine pesticides and PCBs tend to accumulate in fatty tissues (lipophilic compounds), where they may remain for long periods of time. Animals in the upper levels of the food web may accumulate these compounds from prey until lipid storage sites are saturated. Their metabolism is then challenged to degrade and excrete the contaminants or their metabolic by-products, some of which are much more toxic than the original form. In this way, highly persistent and bioaccumulative compounds can magnify through the food web, having little noticeable toxic effect except at the highest trophic levels. Trace metals are also subject to bioaccumulation, but except for metal-containing organic compounds (e.g., methyl mercury) do not biomagnify in marine organisms.

Bioconcentration and biomagnification of toxicants pose particular risks to predators of fish, including birds, marine mammals, and humans. High concentrations of toxicants, such as PCBs and mercury, necessitate health advisories for frequent consumers of fish in some regions (EPA, 1999). Perhaps the most widely recognized effect of persistent contaminants on marine populations is the decline of populations of bald eagles and brown pelicans during the 1960s and 1970s. DDT and its breakdown products accumulated in adult birds from their prey, leading to changes in calcium metabolism in breeding females. The birds produced abnormally thin eggshells and ultimately experienced reproductive failures (Hickey and Anderson, 1968; Blus et al., 1971).

Extensive evidence demonstrates that toxicants can disrupt the metabolic, regulatory, or disease defense systems of an organism, eventually compromising its survival or reproduction. For example, genetic damage, malformations, and reduced growth and mobility were observed in Pacific herring embryos exposed to PAH (from weathered oil) levels as low as 0.7 ppb (Carls et al., 1999). Mollusks exposed to PCBs in New Bedford Harbor, Massachusetts, experienced both a loss of reproductive output and increased susceptibility to disease (McDowell et al., 1999). Accumulation of PCBs and PAHs in Puget Sound rock sole has been correlated with reductions in spawning success (Johnson et al., 1998). Bioconcentration of PCBs has also been linked with impaired immune defenses that lead to disease and death in marine mammals, including seals and dolphins (Kuehl and Haebler, 1995).

Particular attention is currently being devoted to the disruption of endocrine systems by toxic contaminants. Some organochlorine pesticides, PCBs, dioxins, and other compounds functionally mimic or alter the production of hormones (NRC, 1999b). Tributyl tin (TBT), a biocide used in antifouling paints, has been shown to disrupt hormones controlling sexual development in mollusks exposed to concentrations as low as 10 parts per trillion, leading to irreversible reproductive abnormalities (e.g., females developing male sex organs) and reproductive failures (NRC, 1999b). Significant declines in marine snail populations have been documented in regions of North America and Europe where use of TBT was intense (Matthiessen and Gibbs, 1998; Nehring, 2000). Most uses of TBT paints in the U.S. were discontinued as a result of these findings. Feminization of males due to exposure to estrogen mimics and masculinization of females exposed to estrogen blockers have been observed in various animals, including mollusks, fish, reptiles, birds, and mammals (NRC, 1999b; Royal Society, 2000). For example, endocrine-disrupting chemicals have been implicated in the incidence of hermaphroditism in Norwegian polar bears and St. Lawrence beluga whales (De Guise et al., 1994).

Toxic substances in sediments appear to have localized effects in U.S. bays and estuaries and in certain offshore regions that received wastes, such as the New York and Southern California Bights. In the past decade, EPA's Environmental Monitoring and Assessment Program (EMAP) and National Sediment Quality Survey and NOAA's National Status and Trends Program have extensively measured the concentrations of contaminants in bottom sediments in the nation's bays and estuaries, collected collateral data on the communities of benthic organisms living in those sediments, and assayed toxicity of sediments to sensitive amphipod crustaceans. Using these three components—contaminant concentrations (and their probable effects based on an extensive database), the health of the communities living in the sediments, and experimental toxicity—Long (2000) concluded that biologically significant chemical contamination and toxic responses occurred throughout the nation's coastal waters, especially in the most urbanized and industrialized regions. Chemical concentrations exceeding guidelines for probable effects occurred in 26 percent of samples, representing 7.5 percent of the bays and estuaries surveyed. Generally, sediments proved toxic to the crustaceans where contaminant concentrations were high and benthic communities degraded.

This three-pronged approach involving field studies does not fully resolve which contaminants and other factors are actually responsible for the toxicity and community degradation. The synergistic, additive, or antagonistic interactions among contaminants are poorly understood and challenging to assess, thus making it difficult to predict biological responses simply based on knowledge of the types and concentrations of contaminants present in a given area (Yang, 1998).

Pollution Abatement and Remediation

The most effective way to reduce the harmful impacts of toxic contaminants on marine ecosystems is to eliminate or restrict their use or production. The experiences with lead additives in gasoline, DDT, and PCBs show that in the long term this approach can reduce environmental concentrations and exposure for marine organisms. In addition to discontinuing the use or production of these substances, source controls, recycling and reuse, and other forms of "pollution prevention" provide the first line of defense (NRC, 1993a). Treatment and removal of pollutants from effluents and atmospheric emissions provide a second line of defense. Improved knowledge of the fate and effects of various classes of compounds and screening processes for new chemical products have reduced, but not totally eliminated, the risk of "surprises" such as DDT, PCBs, and TBT.

Legacy contaminants must be managed for decades to centuries into the future. Options include control of losses from waste sites and contaminated soils on land, treatment of urban stormwater, and remediation of contaminated sediments. Contaminated sediments exist in many ports, where they pose a risk of reintroduction of toxicants into the water column by physical disturbance of sediments or transferal through the food chain. Options for managing contaminated sediments include: leaving them in place to allow recovery to proceed through degradation and burial, capping them with clean sediments, treating them in place, and removing them for containment or treatment (NRC, 1997).

In the case of the pesticide kepone in the James River estuary, Virginia, the decision was to leave the contaminated sediments in place, and subsequent reductions of contaminants levels in the ecosystem and organisms were observed (NRC, 1997). However, when contaminant levels are high and the risks of reintroduction are great, capping may speed recovery of the ecosystem. The EPA has proposed placing clean sediments atop portions of the DDT deposits off Palos Verdes, California, in order to test the feasibility and effectiveness of this remediation method. Representatives of the DDT manufacturer have criticized this method because DDT concentrations in surface sediments have been declining and the process may expose heavily contaminated sediment below the surface (Whitaker, 2000). A similar controversy surrounds proposals to cap the dredged sediment disposal site in the apex of the New York Bight. These cases exemplify the dilemma faced in making decisions regarding remediation of contaminated sediments.

IV. The Challenge of **Nutrient Pollution**

Nutrient Overenrichment

An increase in the supply of organic matter in a water body is termed eutrophication (Nixon, 1995; see sidebar in Abstract). Over the last 30 years the discharge of organic wastes from municipal and industrial sources declined as a result of improved treatment. At the same time, eutrophication in many areas became more extensive due to increased loadings of mineral nutrients, particularly nitrogen and phosphorus, which stimulate the production of organic matter within the marine ecosystem. There are many consequences of this increased organic production, both beneficial and harmful. The latter include hypoxia, or stressfully low dissolved oxygen, reductions of seagrass beds and corals, and, potentially, noxious or toxic blooms of algae.

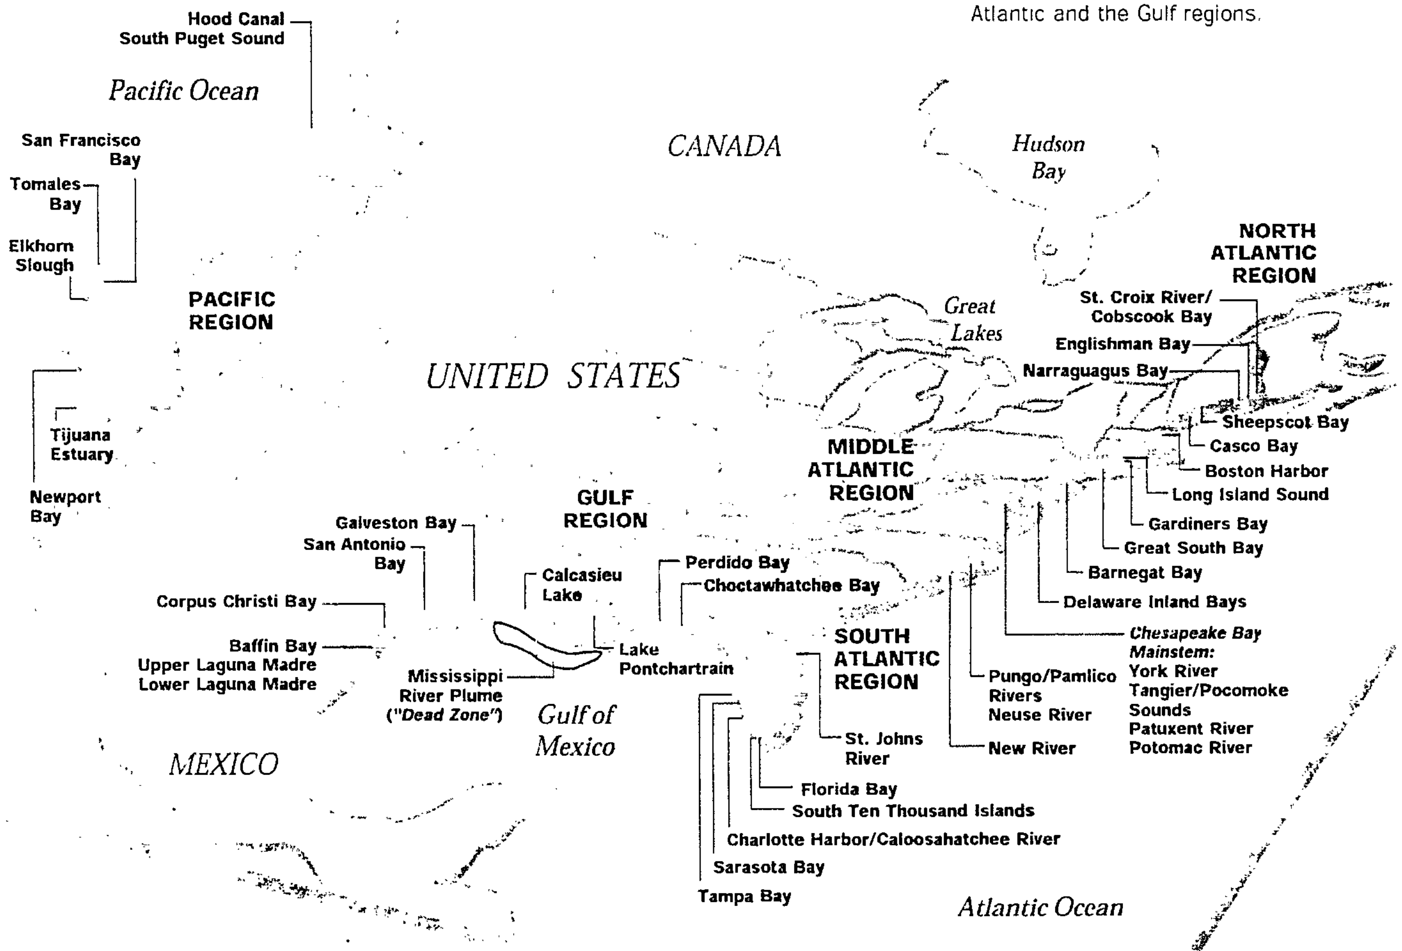
Nutrient pollution has been increasingly recognized as a key threat to coastal environments over the past 20 years because of both new scientific understanding and declining trends in water quality (Nixon, 1995). Loadings of nitrogen flowing in rivers to the Atlantic and Gulf coasts of the United States have increased four to eight fold from the time of European colonization (Howarth et al., 1996). Most of that increase came in the last half of the 20th century. Scientific research has demonstrated that nutrient overenrichment was a major contributor to the extensive changes observed in coastal ecosystems during that period. Three recent scientific assessments addressed nutrient pollution in U.S. coastal waters.

The National Oceanic and Atmospheric Administration characterized the symptoms of eutrophication for 138 bays and estuaries around the U.S. coast based on data review and expert consultations (Bricker et al., 1999). Approximately one-third of the water bodies had high expressions of eutrophic conditions (Figure 5). Altogether, 82 water bodies, representing 67 percent of the combined surface area of these bays and estuaries exhibited moderate to high degrees of depleted dissolved oxygen, loss of seagrasses, or harmful algal blooms. Moreover, it was predicted that eutrophic conditions would become more severe in 86 of these ecosystems by 2020. Systems having low inflow, poor flushing, or strong stratification are particularly susceptible to eutrophication. While this assessment was limited to estuaries and bays in the conterminous states, nutrient pollution has also resulted in loss of coral reef habitat and seagrasses in U.S. tropical regions (Bell, 1992; Lapointe, 1999). *(Continued on page 22)*

Figure 5

Areas of Significant Eutrophication in U.S. Coastal Waters

A recent National Oceanic and Atmospheric Administration (NOAA) study examined 138 estuaries along the coasts of the conterminous United States. A group of experts identified 44 estuaries and coastal areas (labeled on the map below) with high levels of eutrophication and found an additional 40 estuaries (not shown) with moderate symptoms of eutrophication. The highest percentage of estuaries with high levels of eutrophication occurs in waters along the coasts of the Middle Atlantic and the Gulf regions.



Map design by Robert Cronan, Lucidity Information Design, LLC

Eutrophication is the long-term increase in the supply of organic material to an ecosystem, often as a result of excess nutrients. Signs of eutrophication in coastal waters include increased phytoplankton growth, increased growth of macroalgae and epiphytes (plants that overgrow other plants), low dissolved oxygen, harmful algal blooms, and loss of seagrasses. Typically one or more of these symptoms is seen over large areas and/or persistently within the estuary. The "Dead Zone" in the Gulf of Mexico refers to an extensive area of seasonal hypoxia, or depletion of dissolved oxygen, in the bottom waters.

Adapted from Bricker et al., 1999

Box 4
Gulf of Mexico's "Dead Zone"

In a large region of the inner continental shelf off the coast of Louisiana and Texas, the bottom water oxygen levels fall too low (<2 mg/L) to support fish, crustaceans, and many other invertebrates during the warmer months of April to September. This hypoxic zone, or Dead Zone, has been as large as 12,000 square miles (20,000 km^2) but varies in dimensions from year to year and within years, depending on river runoff, and meteorological and oceanographic factors. A recently completed integrated assessment conducted under the auspices of the President's National Science and Technology Council (CENR, 2000) concluded that:

1. the hypoxia is caused primarily by excess nutrient runoff (particularly of nitrogen) from the Mississippi-Atchafalaya River Basin in combination with stratification of Gulf waters;
2. landscape alterations and river channelization during the late 19th century and first half of the 20th century reduced the river basin's hydrologic buffering capacity;
3. eutrophication and hypoxia increased during the latter half of the 20th century during which the flux of nitrate-nitrogen almost tripled (between 1955–1970 and 1980–1996), concomitant with the rapid increase in the use of chemical fertilizers;
4. about 90 percent of the nitrate load comes from diffuse sources, particularly from agricultural lands along the upper Mississippi and Ohio rivers, nearly 1000 miles upstream from the river's mouth; and
5. Gulf ecosystems and fisheries are affected by hypoxia, but economic impacts are difficult to quantify.

Models predicted significant reductions in hypoxia would occur with a 20 to 30 percent nitrogen load reduction. Two approaches are required to achieve that level of reduction: (1) improved agronomic practices that reduce nitrogen losses from farm fields and (2) trapping nitrogen lost from fields in restored wetlands, vegetated buffers, reconnected floodplains, and coastal wetlands. These recommendations have been met with considerable controversy regarding both the certainty of the science and the costs and impacts on food production among midwestern states and agricultural interests. In October 2000, a task force including senior policymakers from eight federal agencies, nine states, and two tribal governments set a general goal to reduce the average area experiencing hypoxia to less than 5,000 km^2 (1,930 square miles or about 40 percent of its average dimensions during the 1990s), which the task force recognized would probably require the reduction of nitrogen inputs by 30 percent.

The President's National Science and Technology Council produced an integrated assessment of large-scale hypoxia in the northern Gulf of Mexico (CENR, 2000) (Box 4). The assessment concluded that diffuse sources of nutrient pollution have caused more extensive hypoxia, covering up to 12,000 square miles of the northern Gulf continental shelf, since the 1950s. It identified more efficient use of fertilizers and restoration of wetlands in the river basin as effective means to reduce the extent and severity of hypoxia in the Gulf.

Finally, the National Research Council (2000a) recently published an in-depth evaluation of the causes and effects of overenrichment in coastal waters and of abatement strategies, including monitoring and modeling, goal setting, and source reduction and control. Noting the substantial adverse impacts of nutrient pollution and the likelihood that nutrient loads will increase as human populations grow, the NRC calls for a nationwide strategy for reducing impairment by nutrient pollution and protecting unimpaired waters. One goal suggests a 10 percent reduction by the year 2010 in the number of coastal water bodies demonstrating severe impacts and a 25 percent reduction by 2020.

Large-scale eutrophication has also occurred in seas around other developed nations, including the Baltic Sea, eastern North Sea, northern Adriatic Sea, northwestern Black Sea, and Japan's Seto Inland Sea. As in the U.S., these problems also developed during the last half of the 20th century with expanded use of chemical fertilizers and combustion of fossil fuels. Coastal eutrophication is but one dimension of the significant modification of the nitrogen cycle (Vitousek et al., 1997). Globally, the amount of biologically available nitrogen added to the biosphere each year has more than doubled the amount made available by the natural sources of plant fixation and lightning. In addition to impacts on marine ecosystems, acid rain, loss of forest soil fertility, emissions of nitrous oxide (a greenhouse gas), and reduction of plant biodiversity are other consequences of the increasing flow of biologically available nitrogen in the biosphere.

Consequences for Living Marine Resources

Nutrients are generally in short supply in most ecosystems and microscopic and macroscopic plants have adapted mechanisms to assimilate them and grow when they are available. The addition of nutrients to an ecosystem affects not only how fast plants grow but also which plants grow most rapidly. These responses are affected by many factors, including light, temperature, mixing and stratification of the water column, the ratio of the various nutrients, and grazing by animals. In marine ecosystems, the rate at which plants create new organic matter (primary production) is closely related to nitrogen inputs (NRC, 2000a). Primary production doubled from the beginning of the 1960s to 1990 in the southern Kattegat between Denmark and Sweden (Richardson and Heilman, 1995), one of the few areas where primary production has been consistently measured. Similar dramatic increases in primary production in the Chesapeake Bay (Cooper, 1995) and the northern Gulf of Mexico (Rabalais et al., 1996) have been inferred based on chemicals and fossils laid down in bottom sediments.

Although much of the increased organic matter is consumed by zooplankton, bacteria, and bottom filter feeders, the amount of organic matter that falls to the bottom in the form of dead plant cells and fecal matter from grazing organisms is also increased. This changes the food regime of organisms living on the bottom or within bottom sediments, initially increasing the abundance of animals and microorganisms that consume the rich organic deposits. However, the respiration of these decomposer organisms consumes oxygen. At first oxygen is depleted in bottom sediments and, if organic loading is heavy enough, the deficit of oxygen reaches into the water column above the seabed. The severity and persistence of resulting hypoxia depend on the stratification of the water column. Less dense (warmer or fresher) surface waters overlying more dense (colder or saltier) bottom waters, with little mixing between the layers, prevents supplies of oxygen from surface waters from replenishing the oxygen consumed by decomposers.

Severe hypoxia near the bottom has become a more regular and extensive seasonal phenomenon in ecosystems such as the Louisiana continental shelf (Rabalais et al., 1996), Chesapeake Bay (Boesch et al., in press), the western basin of Long Island Sound (Long Island Sound Study, 1998), and many other parts of the world (Diaz and Rosenberg, 1995).

As bottom oxygen is depleted, many organisms unable to swim away succumb. Crustaceans, echinoderms, and mollusks are particularly sensitive to the lack of oxygen and the hydrogen sulfide that emanates from putrefying sediments. Consequently, benthic communities experiencing eutrophication and hypoxic stress are altered and have less species diversity. Substantial changes in the production and composition of benthic communities may be evident well before severe hypoxic conditions occur in overlying waters (Diaz and Rosenberg, 1995).

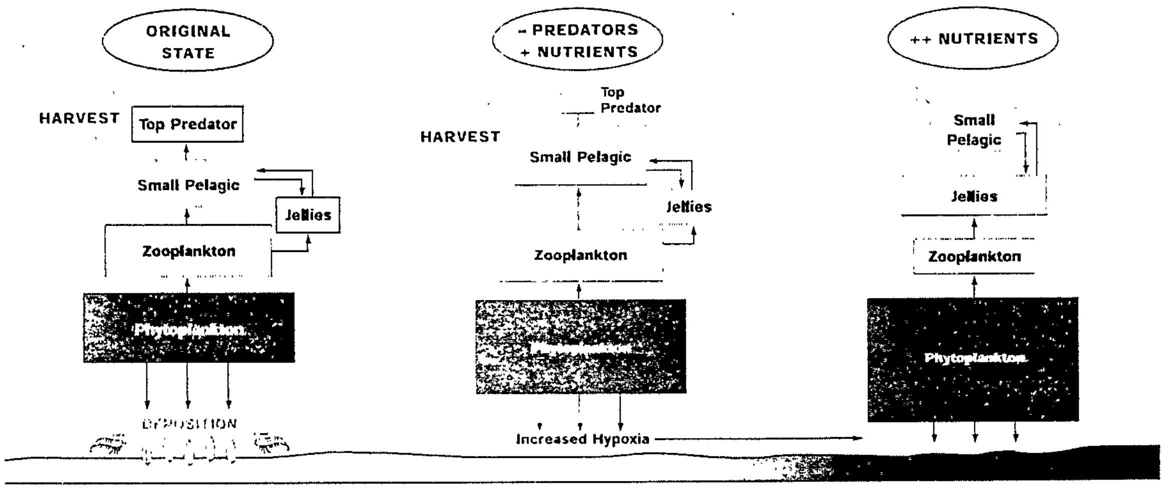
Hypoxic conditions in waters above the seabed force fish and swimming invertebrates to avoid the stressful conditions. Catches of fish and shrimp in bottom trawls in the Gulf of Mexico are dramatically lower or nonexistent where bottom dissolved oxygen levels fall below 2 mg/L (CENR, 2000). Fish and crustaceans often move up in the water column, where they are more susceptible to predation. Hypoxia can also block normal onshore-offshore migration. Despite these apparent obstacles to survival, large-scale hypoxia has not decimated the important shrimp fisheries of the northern Gulf of Mexico (CENR, 2000), although it may have reduced the catch of brown shrimp (Zimmerman and Nance, in press). Many other [illegible] affect shrimp populations, [illegible] less-than-catastrophic effects due [illegible] difficult to detect. Bottom hypoxia has [illegible] in declines in the catches in de[illegible] (living near the bottom) fisheries in Europe and Japan (Caddy, 1993, 2000).

Nutrients are necessary to support the productivity of marine food webs. Across the full range of marine ecosystems, the supply of nutrients—particularly nitrogen—is positively correlated with fisheries yield (Nixon et al., 1986). Although the general relationship is undeniable, the strength of coupling between nutrients and the production of animals within a given ecosystem has been called into question (Micheli, 1999). Nonetheless, increases in the catch of some fisheries have been observed in the North and Baltic Seas and Seto Inland Sea in Japan, concurrent with increases in nutrient loading (Caddy, 1993). While some increases are attributable to increased fishing pressure or more efficient fishing paralleling increased nutrient loadings, greater yields appear to be at least in part due to nutrient stimulation of the food chains supporting the fisheries. Other factors can affect fisheries yield, however, including climatic variation and the effects of fishing itself on the food chain. There is a strong global trend of "fishing down the food chain," wherein fishing is targeted on smaller species once stocks of higher predators are depleted (Pauly et al., 1998). Under these conditions there is less predation on mid-trophic level species, allowing them to become more abundant. These factors may result in increased yields measured as biomass, but the economic value of the fishery is typically smaller.

Eutrophication combined with increased fishing intensity, results in higher yields of small pelagic (living in the water column) species and reduced yields of top

Figure 6

imultaneous Effects of Eutrophication and Fishery Harvest on Marine Food Chains



ource Caddy, 2000

R0011782

predators and demersal (living near the bottom) species (Figure 6). In the extreme case, severe hypoxia and highly enriched food chains favor gelatinous predators (jellyfish and comb jellies) and result in the virtual elimination of demersal resources and reduction in small pelagic fish stocks (e.g., anchovies in the Black Sea). European seas can be ordered based on relative harvests of demersal and pelagic fisheries from the Irish Sea, with low nutrient inputs and proportionally greater demersal fisheries, to the Adriatic and Black Seas, with high nutrient inputs and predominantly pelagic fisheries (Caddy, 2000). In the U.S., enriched systems such as the Chesapeake Bay and northern Gulf of Mexico exhibit high yields of a small pelagic fish (menhaden). These systems have also experienced overharvesting of top predators such as striped bass, red snapper, and red drum and face current management problems for demersal crustaceans such as blue crabs and penaeid shrimp. The interactions between fishing pressure and eutrophication require that fisheries resources be managed not only in a multispecies context but also within an ecosystem framework. That framework may need to take into account human activities and natural processes extending even into the watersheds that deliver fresh water and nutrients to the sea (Caddy, 2000).

Seagrasses, seaweeds, and coral reefs create important habitats that provide food and shelter for a rich diversity of marine organisms, but are very sensitive to nutrient pollution. High nutrient levels in the water column can stimulate luxuriant growth of seagrass leaves, but there is insufficient rhizome growth to tide the plants over during periods of reduced photosynthesis. Reductions in available light caused by increased phytoplankton density and the proliferation of microscopic and macroscopic algae growing on seagrass blades also adversely affect the plants (Duarte, 1995). Seagrasses sometimes give way to fast growing macroalgae. Ultimately, conditions may become too turbid to support any macroscopic plants. As seagrass beds are lost, sediments are more easily eroded, causing the pace of loss to accelerate. Significant seagrass losses caused by excessive nutrient loadings have been observed in bays and coastal lagoons in New England, the mid-Atlantic region, Florida, Texas, and California (Bricker et al., 1999), as well as in Europe, Australia, and Japan (Duarte, 1995). On the other hand, partial recovery of seagrass beds in Sarasota, Tampa, and Chesapeake Bays has been observed as a result of efforts to abate nutrient pollution.

In the Baltic Sea, shallow rocky areas once covered with brown seaweeds that provide important spawning sites for fishes changed to a plant community dominated by rapidly growing green algae of little habitat value (Jansson and Dahlberg, 1999).

In the northwestern Black Sea, an extensive meadow of red algae covering 4,000 square miles in the 1950s was reduced to 200 square miles by the 1990s, causing a loss of a harvested resource, the disappearance of a unique fauna, and reduction in an important source of oxygen (Zaitsev, 1999).

Reef-building corals have a symbiotic relationship with algae (zooxanthellae) that live in coral tissue and efficiently recycle available nutrients. This relationship allows corals to build reefs in clear waters with low nutrient levels. Even small increases in nutrient loads can stimulate phytoplankton and reduce light availability for zooxanthellae in the deeper parts of the reef. Elevated nutrient levels or reduced light availability may make already temperature-stressed corals more prone to expelling zooxanthellae, producing a "bleaching" effect (Brown, 2000).

Increased availability of nutrients can shift an ecosystem dominated by corals and coralline algae toward dominance by algal turf and macroalgae (Bell, 1992; Lapointe, 1999). Nutrient stimulation due to sewage additions was responsible for overgrowth of coral reefs by macroalgae in Kaneohe Bay, Hawaii, during the 1960s. Redirecting sewage out of the bay reversed this situation (Smith et al., 1981). Grazing animals normally prevent algal overgrowth, so when overfishing reduces grazers, reefs may be particularly susceptible to nutrient pollution (Lapointe, 1999). Overenrichment may also contribute to environmental stresses that make corals susceptible to diseases that appear to be increasing in distribution and virulence (Harvell et al., 1999). Finally, a recent study in Barbados found that boring sponges, which weaken coral structures, were more common in reefs experiencing eutrophication (Holmes, 2000).

Probably no effect of nutrient pollution has captured more public attention than harmful algal blooms, though, in fact, the causes of these blooms are complex and incompletely understood. Harmful blooms involve a variety of unicellular organisms that create nuisance conditions in high concentrations, cause mass mortalities of marine organisms, or illness—or even death—in humans (Smayda, 1997). Included are microscopic organisms (including red tides, brown tides, and the notorious phantom dinoflagellate, *Pfiesteria piscicida*) that result in shellfish poisoning of humans, cause fish kills, and jeopardize aquaculture operations. The distribution, incidence, and severity of harmful algal blooms have been rising in recent decades, not only in the United States but also in Europe, Japan, and China (Hallegraeff, 1993). While nutrient pollution is clearly not the cause of some blooms, in other cases there is evidence that changes in nutrient supplies and ratios are a contributing factor (NRC, 2000a).

The chemical form and relative ratios of available plant nutrients can cause shifts

R0011784

in phytoplankton composition and unusual algal blooms. Organic nitrogen seems to favor the organism causing brown tides and possibly *Pfiesteria* in mid-Atlantic bays. A shortage of silicon, a nutrient needed for diatom growth, relative to the supplies of nitrogen and phosphorus favors the growth of flagellated phytoplankton, some species of which are toxic (NRC, 2000a). Even if the species favored are not toxic, changes in the proportions of various nutrients delivered to coastal waters could change the type as well as the amount of phytoplankton that grows, with significant consequences throughout the food web. Inputs of silicon from land have declined in many regions as a result of sediment entrapment behind dams, while phosphorus inputs have remained steady and nitrogen inputs have increased (Justić et al., 1995; CENR, 2000).

Eutrophication usually results in reductions in species diversity of the affected ecosystems and, if extensive and severe, can impact biodiversity on a regional scale. In the northwestern shelf of the Black Sea, for example, only one-third as many benthic animal species could be found within a given depth zone in the 1980s as were found in the 1960s (Diaz and Rosenberg, 1995). There is at this point no evidence that eutrophication is threatening the global extinction of any species. However, by isolating distinct subpopulations, local extinction of a species in one or two estuaries along a coast could affect the genetic flow within the regional population (NRC, 1995).

Eutrophication can also adversely affect the services provided by marine ecosystems. Nutrient removal by denitrification and burial in bottom sediments may be one of the most important services provided by coastal ecosystems (Costanza et al., 1997). However, when severe seasonal hypoxia occurs, both phosphorus and ammonia are released from bottom sediments, turning an important sink for nutrient pollution into a source—thereby fueling more hypoxia (Boesch et al., in press). Through this and other feedback mechanisms, eutrophic ecosystems appear to be less resilient, i.e., they have less capacity to buffer changes and recover from disturbances more slowly.

Sources and Trends

Human activities have increased the flow of phosphorus to the world's ocean by a factor of three over natural rates and the flow of nitrogen to U.S. coastal waters by four to eight times (NRC, 2000a). The largest human-controlled addition of nitrogen to the environment is the manufacture of inorganic nitrogen fertilizer. However, other activities, including the combustion of fossil fuels and cultivation of nitrogen-fixing crops, also convert atmospheric nitrogen into reduced, oxidized, or organic forms that are more biologically available than the gaseous nitrogen that comprises most of the air we breathe. About 20 percent of the fertilizer nitrogen applied in North America leaches into waters and 65 percent is removed in crops (NRC, 2000a). Most of the crops (70 percent) are fed to animals rather than humans; thus the amount of nitrogen reaching water bodies from animal wastes probably exceeds that from fertilizer runoff. Ammonia released into the air from animal wastes can be an important pathway though which nitrogen reaches coastal waters (Box 5). Human sewage is also an important avenue for nitrogen originally contained in crops or meat to reach coastal waters.

The relative importance of the sources of nutrients varies greatly among U.S. coastal regions, depending on the characteristics of their drainage basins, human populations, intensity of agricultural activities, and amount of atmospheric deposition. The percentages in Figure 7 are based on relating source estimates to fluxes measured through stream monitoring. Other statistical analyses across many watersheds (NRC, 2000a) suggest that atmospheric sources are a somewhat more significant contributor to diffuse source inputs than shown here, but the interregional differences depicted are in any case similar. Direct discharges of sewage dominate nitrogen inputs in northeastern bays; otherwise diffuse sources predominate. Agricultural sources generally are

Box 5
Ammonia Emissions: An Emerging Issue

Atmospheric deposition of nitrogen has been considered primarily in terms of the nitrogen oxides (NO_X) produced by fossil-fuel combustion. However, recent evidence shows that ammonia emissions from agricultural operations can be a significant pathway for nitrogen inputs to coastal waters, accounting for as much as half of the total nitrogen deposition in regions with extensive livestock production (Walker et al., 2000).

In the Chesapeake Bay watershed, agriculture and livestock contribute an estimated 81 percent of the total atmospheric burden of ammonia (Chimka et al., 1997). Ammonia volatilizes from animal wastes in feeding operations, waste-storage facilities, and application of manure. Increases in deposition of ammonia have occurred with expanding animal production. For example, a 60 percent increase in ammonia wet deposition was observed on the Delmarva Peninsula during the past two decades when this region experienced a 20-fold increase in poultry production (Scudlark and Church, 1999). In eastern North Carolina, ammonia wet deposition more than doubled over the same time period (Paerl and Whitall, 1999) in a region in which swine production tripled during the last ten years (Mallin, 2000).

Ammonia emissions also occur from various urban sources, including combustion, POTWs, and chemical plants. Recent modifications to gasoline-powered vehicles designed to reduce NO_X emissions (i.e., three-way catalytic converters running rich air-fuel conditions) actually increase ammonia emission rates (Fraser and Cass, 1998).

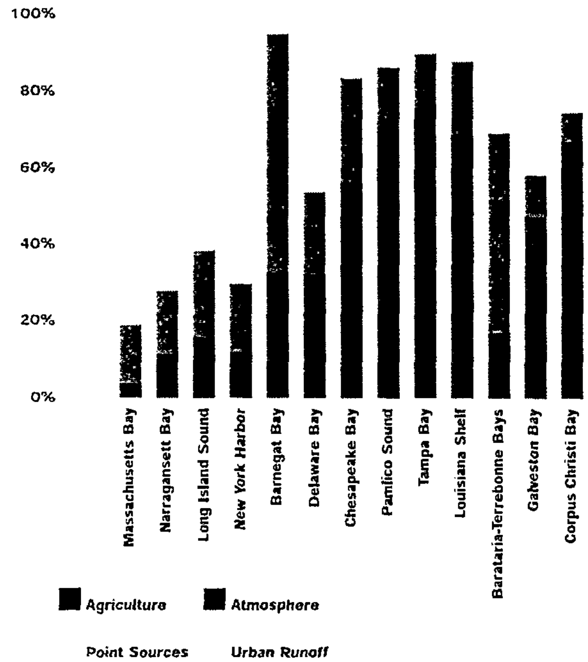
most important from the Chesapeake Bay south, while atmospheric sources are greater than agricultural sources in the Northeast.

Although global additions of nitrogen to the biosphere are continuing to increase rapidly (Vitousek et al., 1997), current trends in nitrogen loadings to U.S. coastal waters are in aggregate generally stable or growing slowly (NRC, 2000a), while inputs of phosphorus are stable or declining. Although the worldwide use of chemical fertilizers is growing and projected to increase substantially to support an expanding world population and increased meat consumption (Forsberg, 1998), the use of chemical fertilizers in the U.S. nearly plateaued in the 1980s (NRC, 2000a). However, increased inputs of both nitrogen and phosphorus have occurred in regions of the country experiencing an expansion and intensification of animal-feeding operations or human population growth. Future consumption of fertilizers and generation of animal wastes in the U.S. could increase, depending on global market forces. Atmospheric deposition of nitrogen from combustion of fossil fuels in vehicles and power plants has stabilized over much of the country as a result of pollution controls imposed under the Clean Air Act, and future efforts to improve air quality should result in reductions (EPA, 2000c).

Population growth increases the amount of sewage generated—a problem for rapidly growing parts of the country.

Figure 7

Estimated Nitrogen Loadings to Selected Atlantic and Gulf Coast Bays and Estuaries and Their Sources



Source: Castro et al., 2000

However, where eutrophication is a recognized problem, implementation of advanced nitrogen removal technologies in POTWs can keep pace with population increases. In many coastal regions of the U.S., however, the rate at which land that produces relatively little nutrient runoff is converted into suburban development, roads, and parking lots, [illegible] increase water and nutrient [illegible] has been progressing much faster [illegible] population growth.

[illegible] NOAA national eutrophication assessment estimated that eutrophic conditions are likely to worsen in two-thirds of the bays and estuaries examined

R0011787

(Bricker et al., 1999). However, the prospect that emerges from the preceding analysis is not one of runaway increases in nutrient loading such as the nation experienced between 1960 and 1990, but one of stability or slower growth. This offers the real potential for substantial reductions with aggressive application of technologies. This outlook varies, of course, among regions, and coastal population growth near presently unaffected but susceptible bays and estuaries could greatly increase nutrient pollution in those areas. One should not infer from this that nutrient pollution is no longer a serious problem. The effects of eutrophication on coastal ecosystems are severe and widespread, making its abatement worthwhile, while at the same time challenging.

Pollution Abatement

Significant reduction in nutrient pollution may be achieved by approaches that: (1) reduce the use of the nutrients in the first place; (2) control losses to the environment at the point of release (e.g., farm field, animal feeding operation, lawn or subdivision, vehicle, power plant, or POTW); and (3) sequester or remove pollutants as they are transported to the sea.

Phosphorus can be almost completely removed from wastewaters by additional chemical and biological treatment. Phosphorus removal from discharges into the Potomac estuary below Washington, D.C., produced substantial improvements in water quality and living resources (Jaworski, 1990). Significant nitrogen removal has been achieved in Chesapeake, Tampa, and Sarasota Bays by biological nutrient removal—a process in which one group of microorganisms convert wastewater ammonia to nitrate and another converts nitrate to nitrogen gas (NRC, 1993a, 2000a).

Reductions in nitrogen oxide (NO_X) emissions to the atmosphere have been driven by air quality considerations generally outside the influence of water quality or coastal ecosystem managers. For example, in 1987 the Chesapeake Bay Program established a goal to reduce the controllable nitrogen inputs by 40 percent, but specifically excluded atmospheric deposition from the sources considered "controllable." Nitrogen oxide emissions from power plants and vehicles are regulated under the Clean Air Act (CAA); a key goal of the 1990 amendments of the act is to reduce ground-level ozone that poses human health risks and stresses forests and crops. Significant reductions in NO_X emissions from stationary and mobile sources are in the offing to meet CAA requirements. The EPA estimates that a 40 percent reduction in NO_X emissions can ultimately be achieved as a result of new standards, technologies, and efficiencies being pursued under the Clean Air Act. Atmospheric deposition of nitrogen may be far more "controllable" than previously thought.

Abatement of agricultural sources of nutrient pollution may prove to be a more difficult challenge. To be practical, abatement of agricultural sources of nutrients must focus not only on reducing fertilizer use but also on plugging the many leaks in agricultural nutrient cycles. Efficiencies in fertilizer use in U.S. agriculture, measured by the ratio of nitrogen in harvested crops to nitrogen in fertilizer applied, have been slowly but steadily increasing since the mid-1970s (Frink et al., 1999). Nevertheless, about one-third of the nitrogen applied is not recovered in harvested crops (NRC, 2000a). Not all of the missing nitrogen contributes to eutrophication of coastal waters. Much is denitrified in soils or aquatic systems en route to the sea or is stored in soils or groundwater. In addition to increasing the efficiency of nitrogen uptake by crops, the return of nitrogen gas to the atmosphere can be enhanced through management practices.

Various agricultural practices affect nitrogen and phosphorus runoff and losses to groundwater (which ultimately seeps into surface waters). Practices employed to reduce soil erosion, such as contour plowing, timing of cultivation, conservation tillage (little or no tilling), stream-bank protection, grazing management, and grassed waterways also reduce nutrient pollution. Other practices are more specifically targeted to the efficient use and retention of nutrients: (1) soil testing to precisely match fertilizer applications to crop nutritional needs (many farmers still overapply to ensure maximum crop yields); (2) applying fertilizer only at the time the crop needs it; (3) crop rotation; (4) planting cover crops in the fall; (5) using soil and manure amendments; and (6) specialized methods of application (NRC, 1993b, 2000a). Landscape practices such as maintaining buffer strips between cultivated fields and nearby streams, moderating excessive drainage by ditches and tile lines, and maintaining wooded riparian areas can further reduce the leakage of agricultural nutrients to surface waters. By combining these approaches a significant portion of the edge-of-field nitrogen losses can be reduced (Boesch and Brinsfield, 2000).

Often, animal wastes are the most significant source of nutrient pollution from agriculture. Although the total production of livestock in the U.S. has not dramatically increased in recent years, the number and size of concentrated animal feeding operations have. Enclosures or trapping devices may eventually be required to stem ammonia emissions from animal wastes. Manure management also presents a risk of pollution if holding facilities fail or do not function properly (Mallin, 2000). Finally, frequently too much manure is produced within a geographic area for it to be applied to nearby land without overloading soils with nutrients (NRC, 2000a).

Urban runoff can also be an important diffuse source of nutrients. Reduction and control of urban and suburban diffuse sources can be achieved through: (1) reductions in the use of fertilizers; (2) effective and well-maintained stormwater collection systems (retention ponds can remove 30 to 40 percent of the total nitrogen and 50 to 60 percent of the total phosphorus); and (3) improved septic systems that promote denitrification (NRC, 2000a). Preservation and restoration of riparian zones and streams within urban and suburban areas is also an important aspect of effective nutrient control. However, the ability of streams to function effectively in nutrient removal is compromised when a significant portion of their watersheds is covered by impervious surfaces and the amplified runoff scours the streambeds (Booth and Jackson, 1997).

Removing or sequestering pollutants as they are transported downstream can also abate nutrient pollution. Many American watersheds were once sponge-like, containing extensive floodplains and wetlands that slowed the flow of water and served as sinks for dissolved and suspended nutrients. However, well over half of the wetlands present in the conterminous United States at the time of European settlement have been converted to other land uses and the percentage of inland swamps and riparian wetlands lost is even greater (Mitsch and Gosselink, 2000). Many floodplains have been disconnected from their rivers by flood-control projects or agricultural conversion and no longer serve as nutrient sinks.

Reducing and controlling diffuse sources of land runoff must involve large-scale landscape management, including restoration of riparian zones and wetlands (NRC, 1999c). The integrated assessment of hypoxia in the Gulf of Mexico estimated that 5 million acres of restored wetlands in the Mississippi River Basin would reduce nitrogen loading to the Gulf by 20 percent. Coupled with feasible controls in agriculture, this would achieve a nearly 40 percent reduction in nitrogen delivered to the Gulf. Similarly, the Chesapeake Bay Program is striving to reforest 2,000 miles of riparian zones and restore 25,000 acres of wetlands by 2010 in order to achieve nutrient-reduction goals (Boesch et al., in press).

Geographically targeting riparian and wetland restoration is critical to its effectiveness in nutrient control. Statistical models based on water quality measurements throughout the Mississippi River Basin show that the percentage of nitrogen leached from a field that reaches the Gulf of Mexico depends greatly on its proximity to larger streams and rivers (Alexander et al., 2000). Biological uptake and denitrification are already effective in small watercourses; therefore restoration of riparian and wetland habitats along moderate to large streams should be more cost-effective. However, because of equity considerations, both incentives (subsidies and cost sharing, technical assistance, and insurance) and disincentives (regulatory controls, taxes, and fees) for abatement tend to be applied uniformly.

Watershed Approaches

A given body of coastal water (bay, estuary, or continental shelf region) receives nutrients from numerous sources; thus an integrated strategy for effective abatement of nutrient pollution is required. Because of the importance of diffuse sources, the strategy should encompass the catchment basin, or watershed, draining into the coastal waters. Moreover, it may have to consider nutrients originating outside the watershed but

Box 6
Nonpoint Sources: Acts and Actions

Provisions of both the Clean Water Act (CWA) and Coastal Zone Management Act (CZMA) address diffuse, or nonpoint, sources of nutrient pollution; however, neither law has been very effective in controlling these sources. The implementation of provisions has been poorly funded, and arguably too much discretion is granted to states and local authorities (Adler, 1995; Johnson, 1999) A central programmatic shortcoming is the fundamental difficulty of influencing local land uses in order to obtain water-quality objectives. Under Section 208 of the 1972 CWA amendments, states were provided support and wide latitude in developing regional plans that identified point and nonpoint sources of pollution and methods, including land-use requirements, to control the sources (Anderson, 1999). However, the plans developed proved difficult to implement (Adler, 1995).

Section 319 of the 1987 CWA amendments requires the states to report on waters where nonpoint sources are problematic and identify best management practices and programs for source control. Section 319 moved toward, if not fully embraced, a watershed approach. State participation remained voluntary and EPA did not require states to penalize nonpoint-source polluters failing to adopt best management practices (Johnson, 1999). Lack of authority, enforcement, and monitoring clearly limited the effectiveness of the 319 efforts (Ruhl, 2000; Anderson, 1999).

In 1990 the reauthorized CZMA included Section 6217, under which states were required to implement enforceable policies to control nonpoint sources affecting coastal waters. Plans were originally required by 1995, but difficulties in implementation and coordination arose. Greater flexibility in plans was allowed and the period of implementation was extended to 15 years (NOAA, 2000).

Section 303 of the CWA requires the determination of a total maximum daily load (TMDL) of pollutants, including those from nonpoint sources, that can be accommodated by an impaired water body in order for it to meet water-quality standards for its designated use (Healy, 1997). A waste-load allocation then apportions the TMDL among the sources. This provision was not applied until lawsuits in the 1990s mandated EPA to establish TMDLs. Technical difficulties in determining TMDLs, legal issues regarding allocating loads among the sources, and the weak authority to regulate nonpoint sources remain serious barriers (Ruhl, 2000). Meanwhile, Congress prohibited EPA expenditures on further implementation of TMDLs during Fiscal Year 2001 (Copeland, 2000).

transported into it through the atmosphere. These are nonconventional units for ocean and coastal resource management and pose numerous challenges.

Recognition of the importance of diffuse-source pollution within a watershed is not new. Federal water-quality and coastal-management statutes include provisions for the assessment and control of nonpoint source pollution (Box 6), but to date they have been largely ineffective in limiting or reversing nutrient pollution of coastal waters. Their implementation has been long on planning and short on actions needed to control diffuse sources. In addition to the difficulties in determining management goals, acceptable nutrient loads, and efficient and equitable allocations among sources, substantial reliance on voluntary rather than mandatory reductions of diffuse sources has constrained the effectiveness of source-reduction efforts (NRC, 2000a).

These shortcomings are evidenced by the fact that 44 percent of the estuarine area assessed in 1998 did not fully meet the standards to support the designated uses (EPA, 2000a). Pathogens, organic enrichment, low dissolved oxygen, municipal point sources, urban runoff, and atmospheric [illegible] were the primary reasons, and [illegible] source pollution was a common [illegible]

Concerted efforts to reverse [illegible] pollution have been undertaken in some watersheds. In 1987 Pennsylvania, Maryland, Virginia, the District of Columbia, and the federal government committed to a 40 percent reduction in the "controllable" inputs of both nitrogen and phosphorus into the Chesapeake Bay by the year 2000. At about that same time, commitments were also being made for reductions of 50 percent of nutrient inputs into the North and Baltic Seas (Boesch and Brinsfield, 2000). Current estimates for the Chesapeake are that a 34 percent reduction in controllable phosphorus and a 28 percent reduction in controllable nitrogen will have been achieved by the end of 2000 (equivalent to 31 and 15 percent of the total loads, respectively; Blankenship, 2000). These are model simulations, but significant reductions in nutrient concentrations in rivers flowing into the Chesapeake Bay and in point-source discharges have been documented (Boesch et al., in press). These gains for the Chesapeake and European waters indicate that a watershed approach to reducing nutrient pollution can work, but so far successes have relied disproportionately on point-source controls. Under a new Chesapeake Bay agreement, more significant load reductions necessary to attain water-quality goals are being determined through a TMDL process (Box 6). Achieving these reductions will require a more rigorous effort to control diffuse sources.

Nitrogen inputs to Tampa Bay have also been reduced, again largely as a result of advanced treatment of sewage. Seagrass beds showed some recovery as a result (Lewis et al., 1998). A decrease in anthropogenic nitrogen inputs of 58.5 percent is the management goal for Long Island Sound (Long Island Sound Study, 1998). Direct discharges dominate nutrient sources there, thus biological nutrient removal at POTWs—at an estimated capital cost of more than 300 million dollars—is being counted on for most of this reduction.

Watershed approaches are being pursued in controlling diffuse sources of nutrients and other pollutants in many other U.S. bays and estuaries. In most, voluntary approaches to the pollution abatement are preferred; however, regulatory approaches are becoming more necessary, particularly as a result of the TMDL process (NRC, 2000a).

Watershed approaches place a premium on environmental modeling and monitoring (NRC, 2000a) in an adaptive management framework (Lee, 1993; CENR, 2000). Models are needed to track sources through the watershed, target abatement, and relate pollutant inputs to marine ecosystem responses. Monitoring is critical in determining the effectiveness of abatement strategies, evaluating responses of the ecosystem, and placing these responses in the context of ecosystem variability.

V. Implications for **National Ocean Policy**

Pollution in Context

Determining the degree to which pollution affects marine living resources, biodiversity, and ecosystem services and comparing these effects to those due to fishing, habitat modification, and global climate change are extremely difficult. Effects of pollution must be separated from those due to natural variability and other human activities. Furthermore, the broader consequences of sublethal or localized effects for populations and ecosystems are seldom clear. The ramifications for biodiversity and living resource production of localized toxic effects or even the more extensive effects of nutrient pollution are difficult to quantify.

For the most part, the effects of pollution are reversible and respond to pollution abatement. The exception may be when marine mammals and birds are endangered by mass mortalities or reproductive failures resulting from toxic contaminants. Recovery can, however, be problematic and recovery times long, particularly with regard to persistent contaminants and permanent landscape changes that affect the delivery of pollutants from the watershed.

The nation's ocean and coastal ecosystems are being simultaneously affected by fishing activities (exploitation of target species, "bycatch," and effects of trawling), habitat modification from coastal development, and climate change, as well as by pollution. The relative importance of pollution as a threat to living resources depends on the region. Pollution is a fundamental concern in areas such as Boston Harbor, the northern Gulf of Mexico continental shelf, or the Chesapeake Bay. It is difficult to imagine environmental restoration and adequate resource management without controlling pollution. In other areas, pollution is much less a factor and habitat modification or fishing effects are far more important.

Most coastal ecosystems, in fact, experience multiple stresses. These stresses interact and, consequently, require integrated management solutions. Many coastal bays, for example, have been made less resilient to nutrient pollution because their oyster populations, which can filter out substantial amounts of organic matter, have been depleted. Furthermore, eutrophication will be influenced by the effects of climate change on freshwater runoff and water stratification (Justić et al.,1996; Najjar et al., 2000). And, overfishing of grazers makes coral reefs more susceptible to nutrient pollution (Lapointe, 1999). Multiple

R0011794

stresses can influence biodiversity on regional scales. For example, of 31 species of mammals, birds, and fish that have disappeared along the coast of the Netherlands over the past 2,000 years, 18 to 22 were as a result of overexploitation, 9 to 12 due to physical destruction of habitat, and 3 to 5 attributable to pollution (Wolff, 2000).

Priorities

Considerable strides have been made in reducing "conventional" forms of pollution over the last 30 years by implementation of the Clean Water Act and other federal, state, and local programs. Although further improvements are undoubtedly needed, technology-driven requirements and discharge permitting have been successful in greatly lowering the inputs of many contaminants into U.S. coastal waters. The dumping of sewage sludge and other wastes in the ocean was eliminated. The adverse effects of several manufactured chemicals (DDT, PCBs, and TBT) were uncovered and their use was discontinued or severely restricted.

This is not to say that protection of living marine resources from toxic wastes is no longer an important consideration for ocean policy. Decisions about managing legacy contamination and allowing the use of new chemicals still confront us. Atmospheric deposition and runoff from urban, suburban, and agricultural lands are now predominant pathways for toxic contaminants entering many coastal ecosystems. Abating these sources will require major commitments and innovative approaches.

We now realize that nutrients leaking from our land-based economy—from agriculture, transportation, power generation, and people—are having profound effects on coastal marine ecosystems over larger scales than imagined 30 years ago. The National Research Council (2000a) recommended that reducing nutrient pollution should be a national priority. Our society has just barely begun to accept and address this problem. Significant challenges lie ahead, particularly in ameliorating nitrogen pollution from diffuse sources.

Scales of Pollution Abatement

Meeting environmental quality objectives for the coastal ocean will require pollution abatement efforts at several scales. At the largest scale, managing anthropogenic alterations of the atmosphere and landscape well beyond the traditional "coastal zone" is required. Abating diffuse sources of pollution necessitates national laws and programs that harmonize agriculture, water resource, air quality, transportation, and land conservation policies with coastal environmental quality objectives. For example, the next reauthorization of the Farm Act should contribute to the reduction of nutrient pollution of coastal waters by targeting incentives, subsidies, and assistance while also ensuring economically and socially viable agriculture for the nation.

At the programmatic scale, controlling diffuse sources is clearly the principal challenge for marine pollution abatement. The missing link for the next level of environmental advance is the design and implementation of sustained programs and institutions that address these diffuse sources and provide solutions that are acceptable to American society. Watershed approaches provide a framework but are constrained by weak authorities and the preeminence of traditional governance at state and local levels. The National Research Council (2000a) noted that effective control of multiple sources of nutrients and contaminants on watershed scales would require a mix of voluntary and mandatory approaches and hybrids of these two extremes. Incentives and disincentives included in statutes and management practices can be very important in promoting and shaping voluntary actions involving agriculture and land uses. At the same time, more effective compliance with mandates, such as those already applicable to urban stormwater runoff, should be required.

At the individual scale, many discrete gains may be realized. More demanding treatment standards than those generally applicable can be required where water quality is seriously impaired. Such case-specific requirements generally force technological innovations that are eventually applied more broadly.

Marine Ecosystem Management and Science

Effective ocean resource policies and management regimes must be integrated. Not only must they manage the fish, habitats, and pollution of the coastal ocean more compatibly, but they must also consider and coordinate with land-based activities. Existing regional programs that link activities in the watershed with coastal ecosystem management represent an important start, but much more remains to be accomplished to achieve full integration.

Recognizing inherent uncertainties, policies, and management regimes must also be precautionary and adaptive. As stated in the United Nations' Rio Declaration, the precautionary principle requires that: "where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation." Environmental decision-making in the United States has increasingly adopted a more precautionary approach—for example, in the testing of new pesticides and other chemicals before their release in the environment. While application of the precautionary principle may be straightforward in the screening of new chemicals or determining the suitability of dredged material for ocean disposal, it is harder when the ecosystems are already degraded or decisions concern which of many pollutant sources to reduce. Adaptive management involves periodic reevaluation and adjustment of the abatement approach based on careful observation of outcomes.

Integration, precaution, and adaptation in environmental policies and management all rely heavily on science. Scientific research and assessment must not only integrate across scientific disciplines but also address the interactions among the atmosphere, watersheds, and the ocean and relate pollution and other stresses to living marine resources and ecosystem services. The precautionary principle challenges science to quantify risk and determine the level of potential harm required to trigger its application. Adaptive management depends heavily on careful observations and comparison of outcomes to predictions.

Research, monitoring, and assessment relevant to marine pollution need improved strategic focus, organization, and commitment in order to fulfill these roles. The fundamental underpinnings of knowledge of complex environmental processes must be bolstered. The National Research Council (2000b) has identified grand challenges for environmental sciences, several of which are appropriate to marine pollution issues: biogeochemical cycles, biological diversity and ecosystem functioning, climate variability, hydrological forcing, land-use dynamics, and reinventing the use of materials.

Traditional environmental monitoring programs have emphasized relatively static parameters (e.g., contaminant concentrations in sediments or shellfish) rather than the dynamic parameters (e.g., primary production and dissolved oxygen) associated with the effects of nutrient pollution. Observing and understanding the effects of pollution should be an important objective of the sustained, integrated coastal ocean-observing system that is being developed for the nation (Nowlin and Malone, 1999). New sensor technologies, satellite measurements, and vast data storage and computational capabilities provide breakthrough opportunities to observe the environment on the appropriate space and time scales needed to address phenomena, such as eutrophication and harmful algal blooms, which occur over large areas but are highly variable in time.

Observations and research must be brought together in assessments that address key management questions and make useful predictions of probable outcomes. Predictions and observations must continually interact [illegible] adaptive management. This will [illegible] institutional arrangements and [illegible] commitments that support scien[illegible]gration and applied predictions.

R0011797

VI. Conclusions

"Overenrichment by plant nutrients, particularly nitrogen, has emerged as the most pervasive pollution risk for living resources and biodiversity in coastal ocean ecosystems."

Significant accomplishments were realized during the last 30 years in reducing the pollution of U.S. ocean and coastal waters by improving the treatment of waste discharges, ceasing most ocean dumping, and eliminating or restricting the use of certain persistent toxicants. Substantial reductions were realized in the inputs of a number of potentially toxic contaminants and organic wastes. Pollutant inputs from regulated discharges will likely continue to decline in order to attain water-quality standards. However, except for the banned and restricted chemicals, inputs of pollutants from diffuse sources—including land runoff—were largely unabated or actually increased during the same 30 years. Diffuse sources now contribute more than direct discharges for many pollutants.

Although it is difficult to extrapolate effects observed in laboratory experiments, it is clear that toxic contaminants chronically affect marine organisms at least over limited, but widely distributed areas in U.S. coastal waters near heavily populated areas. Toxicants can also affect marine mammals and birds that concentrate organic compounds in fatty tissues, sometimes far from the pollution source.

Persistent and bioaccumulative toxicants remain in the ocean and coastal environment for long periods after their sources have been eliminated or substantially reduced. In many cases little can be done until the substances are gradually degraded or removed from the ecosystem. However, isolated sites have extremely high concentrations of toxicants in bottom sediments, from which they can be reintroduced to the ecosystem. Capping and removal options should be thoroughly evaluated by carefully weighing risks of alternative options.

Overenrichment by plant nutrients, particularly nitrogen, has emerged as the most pervasive pollution risk for living resources and biodiversity in coastal ocean ecosystems. Many of the nation's coastal environments exhibit symptoms of overenrichment, including algal blooms (some of which may be toxic), loss of seagrasses and coral reefs, and serious oxygen depletion. Consequences include reduced production of valuable fisheries, threats to biodiversity on regional scales, diminished ecosystem services, and less resilient ecosystems.

Hard-to-control, diffuse sources—often from far inland—dominate nutrient inputs into most overenriched ecosystems. These sources grew dramatically in the last half of the 20th century as a result of increases in the use of chemical fertilizers, more intensive animal agriculture, and the combustion of fossil fuels that release nitrogen oxides into the air. Only recently has nutrient removal been incorporated in advanced treatment of point sources of wastes. New emission standards to meet air-quality objectives, if fully implemented, could reduce atmospheric deposition of nitrogen by 40 percent. Reduction of agricultural sources of nutrients has been more recalcitrant but it is feasible through improved practices and watershed restoration.

Reversing and controlling diffuse sources of pollution, including nutrients, requires an integrated approach on the scale of an entire drainage basin. The legal and institutional mechanisms available for reducing diffuse-source pollution have thus far been only modestly successful, but watershed management approaches are beginning to have an effect. A combination of voluntary and mandatory actions will be required, assisted by governmental incentives such as tax benefits and subsidies and disincentives. To be most effective, these incentives and disincentives should be targeted geographically. From the broadest policy perspective, effective ocean policy must extend well beyond the ocean and coastal zone to influence agricultural, energy, transportation, water resources, and land-use policies.

Science must play a key role in advancing marine ecosystem management that is integrated, precautionary, and adaptive. Sustained observations of changes related to pollution should be a key part of the nation's integrated ocean-observing system. These results should be coupled with strategic research and models to improve predictions needed for adaptive ecosystem management.

Sources of Urban Stormwater Pollutants Defined in Wisconsin

For the past two decades, most urban runoff monitoring activity has been focused at the end of a pipe or storm drain. Consequently, our knowledge about the concentration of pollutants in urban runoff has been confined to broad land use categories, such as residential, commercial, industrial, or combinations thereof.

With recent advances in runoff micro-monitoring pioneered by Roger Bannerman and his colleagues, we are starting to get a better resolution of the various source areas in the urban landscape that collectively contribute to the pollutant levels measured at the end of the pipe. Urban source areas include lawns, driveways, rooftops, parking lots, and streets.

Using specialized sampling devices, Bannerman *et al.* (1993) collected over 300 runoff samples from 46 micro-sites in two watersheds (Figure 1). The samplers collected runoff from lawns, driveways, rooftops (both residential and industrial), commercial and industrial parking lots, and a series of street surfaces (feeder, collector and arterial).

Up to nine samples were collected at each of the micro-sites over a two month period, characterized by small and moderate sized rainfall events. Geometric means of pollutant concentrations were calculated for each of the micro-sites (see Table 1). Runoff volumes were obtained by hydrologic simulation models that were calibrated for each subwatershed.

The monitoring revealed that streets were the single most important source area for urban pollutants in residential, commercial, and industrial areas. Not only did streets produce some of the highest concentrations of phosphorus, suspended solids, bacteria, and several metals, but they also generated a disproportionate

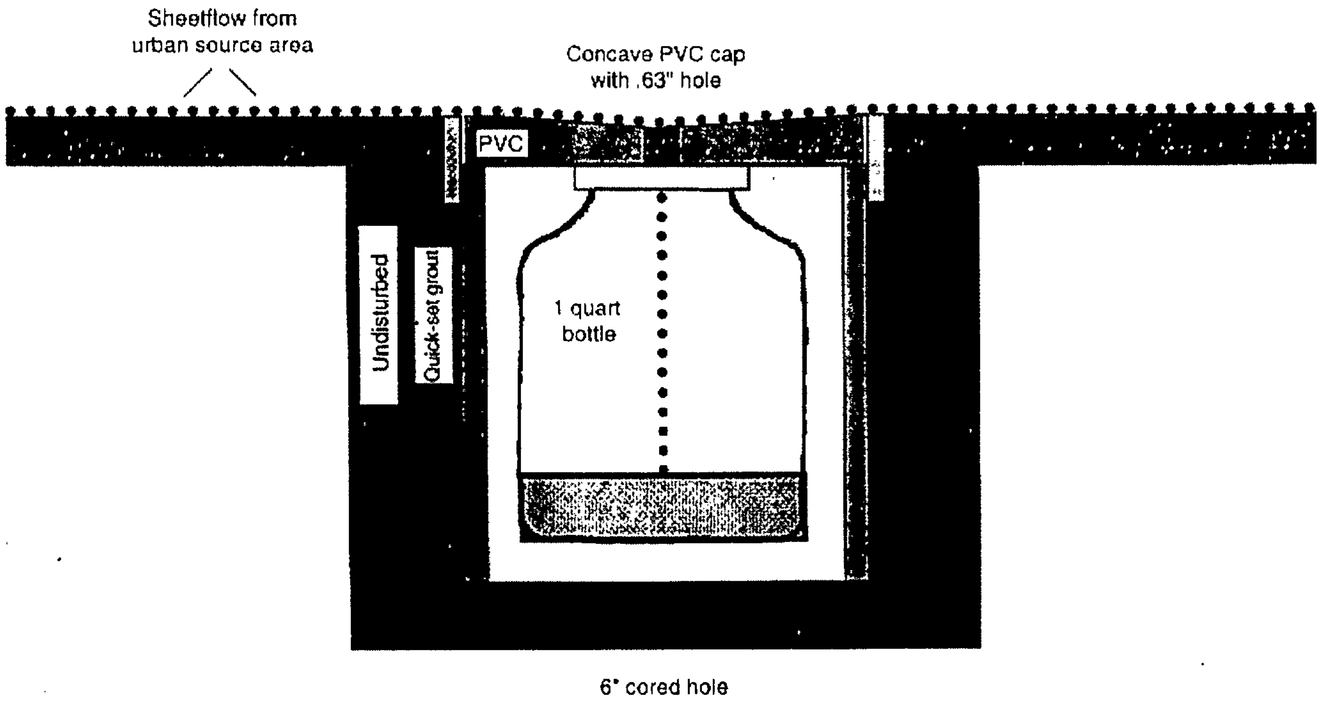

Figure 1: Diagram of a Street Sampler (Bannerman *et al.* 1993)

R0011809

Table 1: Geometric Mean Concentrations of Pollutants in Stormwater Runoff From Selected Urban Source Areas (Bannerman *et al.*, 1993)

Source Area	Total P (mg/l)	Solids (mg/l)	E. coli (C/100ml)	Zinc (μg/l)	Cadmium (μg/l)	Copper (μg/l)
Residential Feeder Street	1.31	662	92,000	220	0.8	46
Residential Collector Street	1.07	326	56,000	339	1.4	56
Commercial Arterial Street	0.47	232	9,600	508	1.8	46
Industrial Collector Street	1.50	763	8,380	479	3.3	76
Industrial Arterial Street	0.94	690	4,600	575	2.5	74
Residential Roofs	0.15	27	290	149	ND	15
Commercial Roofs	0.20	15	1,117	330	ND	9
Industrial Roofs	0.11	41	144	1,155	ND	6
Residential Lawns	2.67	397	42,000	59	ND	13
Driveways	1.16	173	34,000	107	0.5	17
Commercial Parking	0.19	58	1,758	178	0.6	15
Industrial Parking	0.39	312	2,705	304	1.0	41

amount of the total runoff volume from the watershed. Consequently, streets typically contributed four to eight times the pollutant load that would have been expected if all source areas contributed equally.

The importance of street runoff for urban pollutant loading is due to a number of factors. First, as streets are directly connected to the drainage system, they possess a very high runoff coefficient. Second, the curb and gutter system along streets is very effective at trapping and retaining fine particles that blow into them. In addition, as most other source areas are "upstream" from streets and their gutters, pollutants delivered from sidewalks, driveways, rooftops, and lawns ultimately pass through street gutters on their way to the storm drain.

Lastly, streets are strongly influenced by local emissions and leaks from vehicular traffic. Metals that are strongly linked to cars, such as copper and cadmium, reached their highest levels on streets and parking lots. The same pollutants were rarely encountered in roof and lawn runoff.

Rooftop runoff tended to be relatively clean. Low concentrations of phosphorus, solids, coliforms, and metals were observed. A major exception was zinc, which was found at higher concentrations in runoff from rooftops than any other source areas. This was presumably due to leaching from galvanized roofing material, particularly on flat industrial roof sites.

Runoff from lawn areas yielded the highest overall phosphorus concentrations, which may be attributed to excessive lawn fertilization. Lawns typically were a very important source area for fecal coliforms, as were residential streets. Parking lot source areas had moderately high concentrations of all pollutants, but did not exhibit the "hotspot" levels that have been noted in other regions of the country.

As more runoff micro-monitoring data is gathered, it may soon be possible to select and size stormwater treatment practices to control the runoff and pollutants for specific source areas in the urban landscape. **See also article 15.**

Technical Note #105 from Watershed Protection Techniques. 3(1): 609-612

Stormwater Pollution Source Areas Isolated in Marquette, Michigan

Much of our knowledge about the source of stormwater pollutants in urban watersheds is confined to broad land use categories, such as residential, commercial, or industrial. Often, engineers need much more detailed information on the individual source areas of pollutants to design more effective stormwater management practices or to craft better pollution prevention plans. For example, residential land use is actually a mosaic of streets, driveways, rooftops and lawns. Each of these individual source areas can contribute vastly different runoff volumes or pollutant concentrations. Consequently, engineers are interested in discovering precisely which source areas in the urban landscape contribute the bulk of the pollutant loads measured at the end of the stormwater pipe, particularly for those pollutants that are potentially toxic.

Urban source area monitoring methods were first pioneered by Roger Bannerman and his colleagues at the Wisconsin DNR (see article 7). They typically involve the installation of very small and specialized sampling devices that collect stormwater runoff from a few thousand square feet of each source area. Several hundred samples are collected, and then geometric mean concentrations are computed. The first major source area monitoring study was conducted in a subwatershed located in Madison, Wisconsin (Bannerman *et al.*, 1993).

A second major source area monitoring study was recently completed in Marquette, Michigan by Jeff Steuer and his colleagues (1997). They investigated a 289 acre subwatershed that drains to Lake Superior. The subwatershed is primarily residential with most of the development built 50 to 100 years ago (Table 1). Although the subwatershed had 37% impervious cover, its sandy soils generated relatively little surface runoff (runoff coefficient of 0.14 during the course of the study).

Steuer and his team deployed 34 different source area monitoring devices in the subwatershed and collected more than 550 source samples during 12 storm events. The source area monitoring was performed during the growing season (i.e., snowmelt and winter runoff were not sampled). Eight key source areas were targeted in the sampling effort: commercial parking lots; low, medium and high traffic streets; commercial and residential rooftops; residential driveways and lawns. More than 40 different pollutants were measured in the study, including sediment, nutrients, total and dissolved metals and a wide range of polycyclic aromatic hydrocarbons (PAHs). The study team also sampled pollutant levels at the bottom of the entire subwatershed. This enabled them to calibrate the Source Load and Management Model (SLAMM). The SLAMM model simulates subwatershed hydrology and source area pollutant concentrations to relate the how pollutant loads from individual source areas compared to the subwatershed as a whole (Pitt and Voorhees, 1989).

Table 1: A Profile of the Marquette, a Michigan Subwatershed

Drainage Area	289 acres
Land Use	
Residential	55 %
Open Space	29 %
Commercial	9 %
Institutional	7 %
Pervious Area	63 %
Impervious Area	37 %
Soil Type	Sandy, HSG "A"
Runoff Coefficient	0.14
Age of Development	50 to 100 years
Average Annual Precipitation	31.9 inches
Total Rainfall During Source Sampling	13.2 inches

The SLAMM model did an excellent job of predicting pollutant loads from for the subwatershed. Typically, the pollutant load computed from component source areas was within 90 to 110% of the total subwatershed pollutant load measured over the 12 storm events.

Source Areas: Runoff Production

The load of a stormwater pollutant from any source area is a product of its pollutant concentration and its runoff volume. Thus, it is of considerable interest to discover how much runoff volume a particular source area actually generates. The team employed the SLAMM model to assess the relative runoff contribution from the eight primary source areas within the Marquette subwatershed (Table 2). The "effective runoff coefficient" was dramatically different for many source areas, ranging from 0.01 to 0.58. As might be expected, the sandy soils of the residential lawns had the lowest runoff coefficient observed during the monitoring study. Despite the fact that lawns comprised more than 60% of subwatershed area, they generated only 6% of subwatershed runoff. The highest runoff coefficient was recorded for commercial parking lots, followed by streets. In contrast, residential rooftops and driveways had relatively low runoff coefficients, suggesting that these source areas were only partially connected to the storm drain system.

Table 2: Relative Runoff Contribution From Different Source Areas During 12 Storm Events

Source area sampled	Percent of total area	Percent of runoff	Effective runoff* coefficient
Commercial Parking Lot	4.6	19.1	0.58
High Traffic Street	1.4	4.5	0.45
Med. Traffic Street	1.8	5.5	0.43
Low Traffic Street	8.9	26.9	0.42
Commercial Rooftop	3.5	10.2	0.41
Residential Driveway	4.2	9.8	0.32
Residential Rooftops	9.8	12.8	0.18
Residential Lawns	62.4	5.8	0.01
Sidewalks	3.0	ns	ns
Basin Outlet	100.0	95.0	0.14

* Effective runoff is defined as the relative contribution of the source area to the total runoff volume produced in the basin over the 12 storm events.
ns = not sampled

Nutrients and Oxygen Demand

One of the clear trends in the Marquette source area monitoring was that pervious areas had higher nutrient concentrations than impervious ones (Table 3). In particular, nitrogen and phosphorus concentrations in residential lawn runoff were five to 10 times higher than any other source area. Rooftop runoff, on the other hand, had the lowest nutrient concentration of any source area, which is not surprising given that atmospheric deposition is probably the only pollutant pathway. The study also confirmed the strong relationship between greater street traffic and higher nutrient and organic matter concentrations first observed by Bannerman *et al.* (1983). The Marquette team found that nutrient and organic matter concentrations in runoff from high traffic streets were two to three times higher than runoff from low traffic streets.

Hydrocarbons and Metals

The Marquette study also provided our first glimpse about hydrocarbon source areas in the urban landscape (Table 4). One might suspect that source areas dominated by vehicles would have the highest hydrocarbon levels, and this indeed was found to be the case. The highest PAH levels were recorded at the commercial parking lots (75 µg/l) and the high traffic streets (15 µg/l). In contrast, PAH levels at rooftops, driveways and low traffic streets were generally less than 2 µg/l. The team also monitored individual hydrocarbon compounds that comprise PAHs, some of which are known or suspected carcinogens, such as Pyrene. In general, the

Table 3: Geometric Means of Conventional Pollutants at Marquette Source Areas (mg/l)

Source area sampled	Total phosphorus	Total nitrogen	Total Kjeldahl nitrogen	BOD_5
Commercial Parking Lot	0.20	1.94	1.6	10.5
High Traffic Street	0.31	2.95	2.5	14.9
Med. Traffic Street	0.23	1.62	1.3	11.6
Low Traffic Street	0.14	1.17	0.9	5.8
Commercial Rooftop	0.09	2.09	1.6	17.5

Residential Lawns	na	na	na	na
Basin Outlet	21.0	3.36	23	7.0

Notes: Pyrene is one component of PAH's./ All measured in units of micrograms/liter (= ppb)
na = not analyzed at the source area

greatest concentrations of these compounds were also detected at commercial parking lots and high traffic roads.

The team also investigated source area concentrations of total and soluble metals. While no clear trends were observed in total metal levels among most source areas, sharp differences were frequently noted for soluble metals. This is significant as soluble metals are much more likely to exert a toxic effect on aquatic life. Interestingly, the key source areas for soluble zinc were rooftops. Commercial and residential rooftops typically had soluble zinc concentrations that were three to four times higher than other source areas, which is consistent with other research on rooftop runoff.

Moderate levels of soluble zinc were also associated with commercial parking lots and high traffic street. Source areas for soluble copper, on the other hand, were distributed rather evenly across the subwatershed, with the highest concentrations recorded at commercial roofs and parking lots, high traffic streets, and residential driveways. A strong relationship between greater street traffic and higher hydrocarbon and metal concentrations was also found.

Contributions of Individual Source Areas to Subwatershed Pollutant Loads

Using the SLAMM model, the team was able to analyze which source areas contributed most of the stormwater pollutant loads for the subwatershed (Table 5). The team discovered that some source areas delivered a disproportionate share of the total load. Most notable were commercial parking lots, which produced 64% of the PAH load, 30% of the total zinc load and 22% of the total copper load, despite the fact they comprised less than 5% of subwatershed area. Similarly, medium and high traffic streets each generated about six to 10% of the subwatershed PAH, zinc and copper load even though each source area comprised less than 2% of subwatershed area. Surprisingly, residential driveways produced from 14 to 18% of the total phosphorus, copper and zinc load, despite the fact that driveways comprised less than 5% of subwatershed area.

Although residential lawns comprised 62% of subwatershed area, they were not believed to contribute to total load of many pollutants, such as PAH and metals. Lawns were the greatest source of phosphorus in the subwatershed (26%), which reflected the fact that while the sandy soils produced very little runoff, lawn runoff still had a very high phosphorus concentration. It is worth noting that if the study site had less permeable soils, lawns probably would have emerged as an even more important source area for nutrients and organic matter.

Summary

The Marquette source area monitoring study generally reinforced the findings of an earlier source monitoring study conducted in Madison, Wisconsin (Bannerman *et al.*, 1993). While the pollutant concentrations for each source area were not always the same, the relative rank among the source areas was basically the same in each study. This finding supports the notion that stormwater managers should seriously consider pollutant source areas when designing stormwater management practices or devising pollution prevention plans.

R0011815

Table 5: Comparisons of Source Area Loadings for Selected Pollutants, as Computed by the SLAMM Model

Source area sampled	% Watershed area	Percent of Total Subwatershed Load: Copper	PAH	Zinc	Total phosphorus
Commercial Parking Lot	4.6	22	64	30	8
High Traffic Street	1.4	6	7	10	2
Med. Traffic Street	1.8	8	6	8	5
Low Traffic Street	8.9	17	5	19	15
Commercial Rooftop	3.5	11	3	16	5
Residential Rooftop	9.8	5	1	15	3
Residential Driveway	4.2	18	3	18	14
Residential Lawns	62.4	ns	ns	ns	26
Basin Outlet	97%	87%	89%	116%	77%

ns = not sampled, as early monitoring indicated non-detection

Of particular concern are parking lots, which emerged as the dominant pollutant source for commercial areas in both studies. Parking lots produced a disproportionately high load of hydrocarbons and metals compared to all other source areas. As such, watershed managers can justifiably classify many parking lots as stormwater "hotspots." It may make sense to treat the quality of parking lot runoff directly at the source, using filtering practices such as sand, compost and bioretention filters. In any event, designers should probably avoid infiltrating stormwater runoff from parking lots.

Watershed managers should also take note of the strong relationship between pollutant concentrations and higher traffic streets. Runoff from more heavily traveled roads may require greater treatment volumes to control this important source area. Infiltration of roadway runoff should also be avoided, unless effective and reliable pretreatment can be assured.

The Marquette study also provides strong support for focusing the message of residential pollution prevention programs. Lawns and driveways were both implicated as key source areas for nutrients, organic matter and bacteria. Clearly, homeowners have an important role to play in residential source control. Less lawn fertilizer, more pet cleanups, safer car washing and more frequent driveway sweeping could collectively reduce the importance of residential areas as a source of stormwater pollution. —*TRS*

Designation: D 3977 – 97

Standard Test Methods for Determining Sediment Concentration in Water Samples[1]

This standard is issued under the fixed designation D 3977; the number immediately following the designation indicates the year of original adoption or, in the case of revision, the year of last revision. A number in parentheses indicates the year of last reapproval. A superscript epsilon (ε) indicates an editorial change since the last revision or reapproval.

1. Scope

1.1 These test methods cover the determination of sediment concentrations in water and wastewater samples collected from lakes, reservoirs, ponds, streams, and other water bodies. In lakes and other quiescent-water bodies, concentrations of sediment in samples are nearly equal to concentrations at sampling points; in most instances, sample concentrations are not strongly influenced by collection techniques. In rivers and other flowing-water bodies, concentrations of sediment in samples depend upon the manner in which the samples are collected. Concentrations in isokinetically-collected samples can be multiplied by water discharges to obtain sediment discharges in the vicinity of the sampling points.

1.2 The procedures given in these test methods are used by the Agricultural Research Service, Geological Survey, National Resources Conservation Service, Bureau of Reclamation, and other agencies responsible for studying water bodies. These test methods are adapted from a laboratory-procedure manual[2] and a quality-assurance plan.[3]

1.3 These test methods include:

	Sections
Test Method A—Evaporation	8 to 13
Test Method B—Filtration	14 to 19
Test Method C—Wet-sieving-filtration	20 to 25

1.4 Test Method A can be used only on sediments that settle within the allotted storage time of the samples which usually ranges from a few days to a few weeks. A correction factor must be applied if dissolved-solids concentration exceeds about 10 % of the sediment concentration.

1.5 Test Method B can be used only on samples containing sand concentrations less than about 10 000 ppm and clay concentrations less than about 200 ppm. The sediment need not be settleable because filters are used to separate water from the sediment. Correction factors for dissolved solids are not required.

1.6 Test Method C can be used if two concentration values are required: one for sand-size particles and one for the combination of silt and clay-size particles. The silt-clay fraction need not be settleable.

1.7 These test methods must not be confused with turbidity measurements discussed in Test Method D 1889. Turbidity is the optical property of a sample that causes light rays to be scattered and absorbed; it is not an accurate measure of the mass or concentration of sediment in the sample.

1.8 These test methods contain some procedures similar to those in Test Methods D 1888 which pertains to measuring particulate and dissolved matter in water.

1.9 *This standard does not purport to address all of the safety concerns, if any, associated with its use. It is the responsibility of the user of this standard to establish appropriate safety and health practices and determine the applicability of regulatory limitations prior to use.*

3. Terminology

3.1 *Definitions*—For definitions of water-related terms used in these test methods refer to Terminologies D 1129 and D 4410.

3.2 *Definitions of Terms Specific to This Standard:*

3.2.1 *dissolved solids*—soluble constituents in water. The quantity is determined by evaporating a water sample to visible dryness at a temperature slightly below boiling. The temperature is then raised to 105°C and held for about 2 h. This is followed by cooling in a desiccator and weighing the residue.

3.2.2 *fluvial sediment*—particles that are (a) derived from rocks or biological materials and (b) transported by flowing water.

3.2.3 *sediment concentration*—(a) the ratio of the mass of dry sediment in a water-sediment mixture to the mass of the mixture or (b) the ratio of the mass of dry sediment in a

R0011817

water-sediment mixture to the volume of the mixture. As indicated by Table 1, the two ratios differ except at concentrations less than 8000 mg/L.

3.2.4 *supernate*—clear, overlying liquid in a sediment sample.

3.2.5 *suspended sediment*—sediment supported by turbulent currents in flowing water or by Brownian movement.

3.2.6 *tare*—weights of empty containers used in analysis procedure.

4. Significance and Use

4.1 Suspended-sediment samples contain particles with a wide variety of physical characteristics. By presenting alternate approaches, these test methods allow latitude in selecting analysis methods that work best with the particular samples under study.

4.2 Sediment-concentration data are used for many purposes that include: (*1*) computing suspended-sediment discharges of streams or sediment yields of watersheds, (*2*) scheduling treatments of industrial and domestic water supplies, and (*3*) estimating discharges of pesticides, plant nutrients, and heavy metals transported on surfaces or inside sediment particles.

5. Sampling

5.1 Flows and concentrations in river cross sections are usually unsteady; consequently, in a strict sense, samples represent conditions only at the time and location of sample collection.

5.2 A sample may consist of a single container of a water-sediment mixtures collected at (*1*) a specific point in a river cross section, (*2*) a specific vertical in a cross section (a depth-integrated sample), or (*3*) several verticals in a cross-section. If the verticals are equally spaced and the sample is collected at equal transit rates, it is referred to as an EWI sample. The acronym EWI (equal-width-increment) is synonymous with ETR (equal-transit-rate) which appears in many older reports. A sample may also consist of several containers filled at different points or verticals in a cross-section. If the containers are filled at centroids of equal discharge in a cross section, they are referred to as EDI samples. Details on sampling are given in Guide D 4411.

TABLE 1 Factors for Conversion of Sediment Concentration in Parts per Million (ppm) to Grams per Cubic Metre (g/m^3)[A] or Milligrams per Litre (mg/L)

Range of Concentration, 1000 ppm	Multiply By	Range of Concentration, 1000 ppm	Multiply By	Range of Concentration, 1000 ppm	Multiply By
0–7.95	1.00	153–165	1.11	362–380	1.30
8.0–23.7	1.01	166–178	1.12	381–398	1.32
23.8–39.1	1.02	179–191	1.13	399–416	1.34
39.2–54.3	1.03	192–209	1.14	417–434	1.36
54.4–69.2	1.04	210–233	1.16	435–451	1.38
69.3–83.7	1.05	234–256	1.18	452–467	1.40
83.8–97.9	1.06	257–278	1.20	468–483	1.42
98.0–111	1.07	279–300	1.22	484–498	1.44
112–125	1.08	301–321	1.24	499–513	1.46
126–139	1.09	322–341	1.26	514–528	1.48
140–152	1.10	342–361	1.28	529–542	1.50

[A] Based on water density of 1.000 g/mL and specific gravity of sediment of 2.65.

The following equation also applies:

$$C_l = C/(1.0 - C\ 622 \times 10^{-9})$$

where:

C_l = sediment concentration, mg/L, and

C = sediment concentration, ppm.

6. Sample Handling

6.1 When samples arrive at the laboratory, group them according to gaging stations and then arrange each group in chronological order according to times of sample collection. Separate the samples to be analyzed for concentration from those to be analyzed for particle-size distribution or other properties. A data sheet should then be completed for each concentration sample. Examples of three commonly used forms are shown on Fig. 1. Expanded notes can be written on the front of the forms in spaces reserved for other bottles or, if even more space is needed, remarks can be written on the back of the forms along with reference numbers keyed to the appropriate bottles.

6.2 Check each sample for: (*1*) loss of water caused by leakage or evaporation, (*2*) loss of sediment which is sometimes revealed by the presence of particles on the outside of the sample bottle, (*3*) accuracy of sample-identification notes, and (*4*) a container tare which is usually etched on the bottle. Enter all appropriate notes, observations, and data on the laboratory form. Be particularly careful to enter the etched tare reading on the form under the heading Weight of Sample—Tare.

6.3 Remove the bottle caps then weigh each container along with its water-sediment mixture to the nearest 0.5 g. Record each reading on the corresponding bottle and on the laboratory form under the heading Weight of Sample—Gross.

6.4 Replace the caps then store the samples in a cool, dark place to minimize microbiological and algal growth. Inspect the bottles frequently; if the sediment does not settle within about 14 days, use Test Method B (filtration procedure) for the analysis. If settling proceeds at an acceptably rapid rate, use Test Methods A, B, or C.

7. Reagents and Materials

7.1 *Purity of Water*—Unless otherwise indicated, references to water shall be understood to mean reagent water as defined by Type III of Specification D 1193.

7.1.1 Requirements can usually be met by passing tap water through a mixed cation-anion exchange resin or by distillation.

TEST METHOD A—EVAPORATION

8. Scope

8.1 This test method can be used only with sediments that settle under the influence of gravity. This test method is applicable to samples ranging from 0.2 to 20 L in volume, from 5 to 550 000 mg/L in sediment concentration, and having less than 35 000 mg/L in dissolved-solid concentration.

9. Summary of Test Method

9.1 After the sediment has settled, most of the supernatant water is poured or siphoned away. The volume of water-sediment mixture remaining is measured so that a dissolved-solids correction can be applied later. The sediment is then

FIG. 1 Alternate Forms for Recording Field and Laboratory Data for Sediment Samples

dried and weighed. Sediment concentration is calculated in accordance with Section 12.

10. Apparatus

10.1 *Evaporating Dishes or Beakers*—Preweighed containers of porcelain or glass with capacities of about 150 mL are needed for holding the sediment and water during drying.

10.2 *Vacuum System*, trapped to prevent sample carry-over to the vacuum source during removal of supernate.

10.3 *Drying Oven*, equipped with a 90 to 120°C thermostat is needed to control temperatures while evaporating water from the sediment. A gravity-convection type oven is preferred but a mechanically ventilated (forced draft) style can be used if air-flow rates are low.

10.4 *Desiccator*, for preventing air-borne moisture from collecting in the sediment specimens while they are cooling.

10.5 *Laboratory Balance*, top-loading type with a resolution of 0.0001 g and a capacity of 150 g is needed for weighing the dry sediments.

10.6 *Laboratory Balance*, top-loading type with a resolution of 0.1 g and a capacity of about 4000 g is needed for weighing sample bottles containing water and sediment.

11. Procedure

11.1 After the sediment has settled, decant or vacuum away as much supernate as possible without disturbing the sediment. This can be accomplished by connecting a J-shaped plastic, copper, or glass tube to the vacuum line and lowering the tube until the curved section is near the bottom of the sample bottle. Supernate enters the upward-facing end of the tube and thereby flows away without creating currents and eddies in the sediment layer. Save the supernate for a dissolved-solids correction factor to be determined later.

11.2 After decanting, about 40 to 70 mL of water-sediment mixture should be left. To determine the exact volume, place the sample bottle on a level support then mark the liquid surface an the outside of the bottle. Use water to wash all of the sediment and supernate into an evaporating dish, then refill the sample bottle to the mark with water from a small graduate. Record the volume added to the sample bottle on the sample-data form.

11.3 Place the evaporating dish in the oven with the temperature set slightly below boiling. Maintain this temperature until all visible traces of water have evaporated. Then raise and hold the temperature at 105°C for about 2 h.

11.4 Transfer the dish from the oven to the desiccator; allow the sediment to cool to room temperature.

11.5 Weigh the dish to the nearest 0.0001 g as quickly an possible to minimize absorption of moisture from the air. Record the weight of the dish and its contents and also the tare weight of the dish on the laboratory form. Subtract the tare from the gross, then record the net weight on the form.

11.6 For nearly all sediment samples, a single drying cycle is sufficient to obtain stable weight; however, a few samples, principally those containing high concentrations of organic materials, may have to be dried a second time. If weight shifts occur, the specimens should be dried and weighed a third time to verify that the weights are stable.

11.7 Determine the dissolved-solids correction factor by using a volumetric pipet to transfer an aliquot (measured volume) of supernate into an evaporating dish. Record the aliquot volume in millilitres on the laboratory form.

11.8 Set the oven temperature slightly below the boiling point of water and evaporate the supernate to visible dryness. Then raise and maintain the oven temperature at 105°C for at least 2 h. After this, cool the dish in a desiccator. Then weigh the dish and its contents to the nearest 0.0001 g. Record this gross weight and also the tare weight of the dish on the form. Subtract the tare from the gross and record the net weight of dissolved solids in grams.

12. Calculation

12.1 Determine the dissolved-solids correction according to Eq 1:

$$DSc = (DS/Va) \times Vs \quad (1)$$

where:

DSc = dissolved-solids correction, g,
DS = net weight of dissolved solids determined in 11.7, g,
Va = aliquot volume taken for dissolved solids in 11.7, mL, and
Vs = volume of supernate remaining with the sediment in 11.2, mL.

In Eq 1, DS/Va is the concentration of dissolved solids in the supernate (see 11.7). This concentration is multiplied by Vs to obtain the dissolved-solids weight in the dry sediment (see 11.5). Enter the value of DSc on the laboratory form under the heading D. S. Corr.

12.2 Subtract the value of DSc in 12.1 from the net weight determined in 11.5. Record the difference on the laboratory form under the second heading labeled Weight of Sediment—Net. Notice each laboratory form has two rows with this heading.

12.3 Divide the Net Weight of Sediment (second entry) by the Net Weight of Sample. Both weights must be in the same units, preferably grams. Multiply the quotient by one million, then enter the result under the heading Conc. (ppm) on the laboratory form.

12.4 Modern practice calls for reporting sediment concentrations in milligrams per litre instead of ppm as determined in 12.3. Conversion can be made with the aid of Table 1. For example, consider a sediment concentration of 41 000 ppm. The multiplier obtained from Table 1 is 1.03; therefore, the concentration is 41 000 × 1.03 = 42 400 mg/L. The equation[8] immediately following Table 1 can be used instead of the multipliers. Equation 1 is easier to use in computer programs and is applicable to concentrations beyond the range in the table.

13. Precision and Bias for Test Method A (Evaporation)

13.1 These precision and bias data meet requirements of Practice D 2777.

13.2 Samples for collaborative testing were prepared by dispersing a specially prepared dry powder in approximately 350 mL of distilled water. Mixtures were shipped in sealed glass containers to the nine participating laboratories where three Youden pairs at each of three concentrations were tested.

13.3 Bias was influenced not only by analytical procedures such as decanting, drying, and weighing but also by failure to remove all sediment from the containers and by losing particles through dissolution.

13.4 The following table shows the precision and bias for Test Method A:

Concentration Added, mg/L	Concentration Recovered, mg/L	Standard Deviation of Test Method (St)	Standard Deviation of Single Operator (So)	Bias, %
10	9.4	2.5	2.3	−6
1000	976	36.8	15.9	−2.4
100 000	100 294	532	360	0.3

TEST METHOD B—FILTRATION

14. Scope

14.1 Test Method B can be used only on samples containing sand concentrations less than about 10 000 ppm and clay concentrations less than about 200 ppm. The sediment need not be settleable because filters are used to separate water from the sediment. Correction factors for dissolved solids are not required.

14.2 Even though a high-concentration sample may filter slowly, users should not divide the sample and use two or more filters. Instead, the entire sample should be filtered through one disk.

15. Summary of Test Method

15.1 The sample consisting of river water, sediment, and dissolved solids is weighed and then filtered through a glass-fiber disk. The disk and sediment are dried and weighed, then the sediment concentration is calculated in accordance with Section 18.

16. Apparatus

16.1 *Gooch Crucibles*—Porcelain or borosilicate glass crucibles with fritted glass bases are required for holding the filters. Capacities of the crucibles are optional; sizes in the 25 to 130-mL range work best with 1-L samples. Small crucibles have the advantage of requiring less oven space during drying and absorbing less moisture during weighing; large crucibles are needed if filtering proceeds slowly.

16.2 *Glass-fiber Filter Disks*—Filter diameter and filter retention rating, sometimes referred to as filter pore size, are critical to this analysis. The sediment that accumulates on a filter traps some particles that are smaller than the filter's retention rating. As filtration proceeds and the sediment layer thickens, the retention rating of the sediment and filter acting as a unit gradually decreases. Users should use filters with retention ratings of 1.5 µm to agree with practices in

[8] Williams, D. T., "The Relationship of Milligrams Per Liter to Parts per Million," *Sediment Transport Modeling*, Ed. by Sam S. Y. Wang, *Proceedings of the International Symposium*, American Society of Civil Engineers, August 1989, pp. 428–433.

many sediment laboratories.[9] Filter diameters should equal or exceed 24 mm. Filters as large as 42 mm may be required to avoid filter plugging at high concentrations. Record filter retention rating in micrometres and filter diameter in millimetres at a convenient place on the laboratory form.

16.3 *Vacuum System*—See 10.2.

16.4 *Drying Oven*—See 10.3.

16.5 *Desiccator*—See 10.4.

16.6 *Laboratory Balances*—See 10.5 and 10.6.

17. Procedure

17.1 Wash the filter with water to remove soluble compounds; then dry the filter and its crucible at 105°C for at least 1 h.

17.2 Transfer the crucible and filter to the desiccator, then, after the parts have cooled to room temperature, weigh them to the nearest 0.0001 g and record the reading on the laboratory form under the heading Weight of Sediment—Tare.

17.3 While a vacuum is being applied to the bottom of the crucible, decant supernate from the sample into the crucible. Flush the inner surfaces of the sample bottle with water to complete the transfer.

17.4 As filtering proceeds, inspect the filtrate. If it is turbid, pour the filtrate back through the filter a second and possibly a third time. If the filtrate is still turbid, the filter may be leaking. In this case, substitute a new filter and repeat the process. If the filtrate is transparent but discolored, a natural dye is present; refiltration is not necessary.

17.5 When filtration is complete, place the crucible and its contents in the drying oven set for 105°C.

17.6 When the crucible and its contents are dry, transfer to a desiccator. After the crucible has cooled, weigh to the nearest 0.0001 g and record the reading on the laboratory form under the heading Weight of Sediment—Gross.

17.7 Refer to 11.6 for a discussion of multiple drying and weighing cycles.

18. Calculation

18.1 Subtract Weight of Sediment—Tare from Weight of Sediment—Gross and record the difference under the heading Weight of Sediment—Net. No dissolved-solids correction is required.

18.2 Refer to 12.3 and 12.4 for computations.

19. Precision and Bias for Test Method B (Filtration)

19.1 These precision and bias data meet requirements of Practice D 2777.

19.2 Samples for collaborative testing were prepared by dispersing a specially prepared dry powder in approximately 350 mL of water. Mixtures were shipped in sealed glass containers to the nine participating laboratories where three Youden pairs at each of three concentrations were tested.

19.3 Bias was influenced not only by analytical procedures such as filtering, drying, and weighing but also by failure to remove all sediment from the containers and by losing particles through dissolution.

19.4 The following table shows precision and bias for Test Method B:

Concentration Added, mg/L	Concentration Recovered, mg/L	Standard Deviation of Test Method (St)	Standard Deviation of Single Operator (So)	Bias, %
10	8	2.6	2	−20
100	91	5.3	5.1	−9
1000	961	20.4	14.1	−3.9

TEST METHOD C—WET-SIEVING-FILTRATION

20. Scope

20.1 This test method covers concentration measurements of two particle-size fractions. The term fine fraction refers to particles small enough to pass through a sieve with 62 or 63-µm apertures; coarse fraction refers to particles large enough to be retained on the sieve. The fine fraction need not be settleable. This test method is useful when large samples must be collected in the field but only small subsamples, typically 300 to 500 mL, can be shipped back to the laboratory.

21. Summary of Test Method

21.1 The sample is poured onto a sieve with 62 or 63-µm openings. Analysis includes the entire coarse fraction but only a small, measured aliquot of the fine fraction. Sieving and aliquot extraction can be performed either at the sampling site or in the laboratory.

22. Apparatus

22.1 *Sieve*, fitted with a screen fabric having 62 or 63-µm square apertures. An 8-in. diameter sieve is recommended for samples larger than 3L; a 3-in. diameter sieve is recommended for all other samples. (See Specification E 11.)

22.2 *Splitter*, for extracting an aliquot of the fines.[10]

22.3 Additional apparatus are listed in Section 16.

23. Procedure

23.1 Measure the gross and tare weight of each sample and record the readings on the laboratory form. (See 6.2 and 6.3.) Hold the sieve over a beaker or large, shallow dish while pouring the sample through the sieve. Some sediments require vigorous rinsing with water to disaggregate clumps retained on the sieve. Use a minimum amount of water, and retain in the dish along with the fine fraction.

23.2 Wash the coarse fraction from the sieve into a preweighed evaporating dish. Dry, desiccate, and weigh the sediment in accordance with 11.3 through 11.5. Record the net weight of the coarse fraction on the laboratory form.

23.3 If possible, the sample received at the laboratory should be analyzed in its entirety, but if the sample volume is unwieldy, it may be reduced by splitting. Mix the fine fraction by vigorously shaking and stirring then, without pausing, pour the mixture through the splitter and into a

[9] The sole source of supply of the apparatus known to the committee at this time is Whatman type 934-AH, Whatman Lab Sales Inc., Hillsboro, OR. If you are aware of alternative suppliers, please provide this information to ASTM Headquarters. Your comments will receive careful consideration at a meeting of the responsible technical committee,[1] which you may attend.

[10] A Federal Interagency Sedimentation Project US72A or a Jones Ott splitter have been found to be satisfactory.

R0011821

clean tray. Several splitting passes are required if the aliquot is to consist of only a small fraction, typically 300 to 500 mL, of the original mixture.

23.4 Determine the net weight of the aliquot to the nearest 0.1 g and record the reading on the laboratory form.

23.5 The aliquot is usually analyzed by the filtration method, but it can be analyzed by the evaporation method. If filtration is used, follow the procedure in 17.1 through 17.6; if evaporation is used, follow the procedure in 11.1 through 12.4.

24. Calculation

24.1 Calculate the coarse-fraction concentration as:

$$C_{cf} = C \times 10^6/S \quad (2)$$

where:
C_{cf} = coarse fraction concentration, ppm,
C = mass of sediment in the coarse fraction, g, and
S = mass of entire sample, g.

24.2 Calculate the fine-fraction concentration as:

$$C_{ff} = F \times 10^6/W \quad (3)$$

where:
C_{ff} = fine-fraction concentration, ppm,
F = mass of sediment in the aliquot, g, and
W = mass of the aliquot, g.

24.3 Convert C_{cf} and C_{ff} from ppm to mg/L in accordance with 12.4.

25. Precision and Bias for Test Method C (Wet-Sieving-Filtration)

25.1 These precision and bias data meet requirements of Practice D 2777.

25.2 Samples for collaborative testing were prepared by dispersing a specially prepared dry powder in approximately 350 mL of distilled water. Mixtures were shipped in sealed glass containers to the nine participating laboratories where three Youden pairs at each of three concentrations were tested.

25.3 Bias was influenced not only by analytical procedures such as sieving, filtering, drying, and weighing but also by failure to remove all sediment from the containers and by losing particles through dissolution.

25.4 The following table shows precision and bias for Test Method C:

Mixture Number	Part Sieve Diameter, µm	Concentration Added, mg/L	Concentration Recovered, mg/L	Standard Deviation of Test Method (St)	Standard Deviation of Single Operator (So)	Bias, %
1	>62 (sand)	1	3.4	2.8	2.4	240
1	<62 (fines)	10	8.7	4.3	2.9	−13
2	>62 (sand)	9	5	5.9	1.9	−44
2	<62 (fines)	91	79	15.2	11	−13
3	>62 (sand)	91	107	12.3	5.9	18
3	<62 (fines)	909	832	87.2	61	−8

TABLE OF CONTENTS

1.1 INTRODUCTION

Los Angeles County (the County) is required to conduct a stormwater Critical Source Study. The objective of the study is to identify five industrial and/or commercial critical source types, and then monitor each source type for 2 years, the first year without controls, and the second year with controls. This report describes the methodology and results of the critical source selection process (Section 1) and describes the monitoring plan for testing the effectiveness of critical source BMPs (Section 2).

The County has previously conducted similar studies aimed at identifying critical sources of industrial stormwater pollution within the County as part of compliance with its National Pollutant Discharge Elimination System (NPDES) Municipal Stormwater Permit (Permit No. CA0061654). A planning study was conducted between March and December 1995 to identify the most common facility types and to select several key sites for conducting sampling. As a result of this work, three facilities (a trucking facility, a fabricated metal products facility, and a municipal corporation yard) were selected for study. The municipal yard has been monitored since the 1994-95 wet-weather season; the others were monitored in the 1995-95 wet-weather season. The work performed by the County provided considerable useful information for developing this Critical Source/BMP Monitoring Program.

A series of steps to be taken in conducting the Critical Source/BMP Monitoring Program has been outlined. These steps are as follows:

Step 1: The County first will develop an initial list of candidate critical sources, including industrial and commercial sources that are regulated under the General Industrial Activities Stormwater Permit (General Industrial Permit) and those which are not.

Step 2: The County next will develop a list of criteria for prioritizing the candidate critical sources developed pursuant to Step 1, including the following: runoff pollutants associated with each critical source; the impact of non-stormwater discharges associated with each source; whether or not the source is regulated under the General Industrial Permit; and ease of implementation of monitoring and BMPs.

Step 3: The County next will prioritize the candidate critical sources based on the selection criteria developed under Step 2.

Step 4: The County next will conduct a literature review and contact other municipal stormwater programs in California to identify what critical sources have been (or are planned in the next 5 years to be) studied elsewhere. Where studies have been conducted or are planned to be conducted elsewhere, such studies will be reviewed to assess whether the hydrologic conditions in the study area are representative of those in Los Angeles County, the quality of the study and any conclusions from already-conducted studies. This evaluation will be coordinated with the Stormwater Quality Task Force.

Step 5: The County next will take the list developed in Step 3 and refine and finalize it based upon the review conducted pursuant to Step 4.

As of July 1, 1996, the County has completed Steps 1 through 5. The following sections describe the County's approach and results from conducting each of these steps.

1.2 STEP 1 - DEVELOP INITIAL LIST OF CANDIDATE CRITICAL SOURCES

As part of their initial work on source monitoring, the County developed a list of candidate critical sources. These sources were selected based on prevalence in the County, regulation under the General Industrial Permit, and/or runoff pollutant potential. This initial list of candidate critical sources was deemed appropriate for the Critical Source/BMP Monitoring Program and is presented in Table 1-1.

1.3 STEP 2 - DEVELOP A LIST OF CRITERIA FOR RANKING INDUSTRIAL SOURCES

A ranking process was developed to prioritize the candidate critical sources in terms of the pollution potential of their stormwater runoff. The ranking scheme was based on five factors: **Q** (measure of pollutant unit loading, based on factors such as the type and number of industrial activities and the potential for non-stormwater discharges), **R** (measure of volume of runoff based on typical facility impervious area), **T** (additional measure affecting loading, based on types/toxicity of pollutants used at the facility), **E** (exposure factor, to account for the degree to which materials and activities are exposed to storm water), and **N** (number of facilities within Los Angeles County). The two factors affecting pollutant load, Q and T, were calculated using subfactors. Q was determined as a product of s (number of individual pollutant sources at a given facility, including various types of industrial activities and non-stormwater discharges) and l (likelihood of release). T was calculated as the product of n (amount of toxic pollutants) and I (inherent toxicity of the pollutants types present). In considering potential types of toxic pollutants, human viral contamination was not specifically considered. Such contamination is generally associated with feedlots, ranching, and cross-connections with sanitary sewers rather than with runoff from the industrial/commercial types of sites considered here. Each key factor and subfactor was assigned a value between 1 and 10, with the higher values representing a greater degree of significance. The pollutant potential, P, was then calculated as the product of the key factors:

$$P = Q \times R \times T \times E \times N$$

The data were normalized such that the value of P would fall between 0 and 100. The ranking scheme (along with instructions on how to use it) is presented in Table 1-2.

TABLE 1-1

INITIAL LIST OF CANDIDATE CRITICAL SOURCES

Rank (No. Facilities)	Industrial Category	SIC Code	No. Facilities
1	Automotive Repair/Parking	75	6,067
2	Machinery Manufacturing	35	4,223
3	Fabricated Metal Products	34	3,283
4	Automotive Dealers/Gas Stations	55	2,744
5	Personal Services (laundries)	72	2,515
6	Printing & Publishing	27	2,432
7	Electric/Gas/Sanitary	49	2,001
8	Apparel	23	1,900
9	Transportation Equipment	37	1,838
10	Electric/Electronic	36	1,636
11	Furniture & Fixtures	25	1,368
12	Food & Kindred Products (not including restaurant)	20	1,249
13	Miscellaneous Manufacturing	39	1,144
14	Chemicals/Allied Products	28	1,069
15	Rubbers/Miscellaneous Plastics	30	1,034
16	Instruments	38	1,029
17	Lumber/Wood Products	24	905
18	Motor Freight	42	872
19	Stone, Clay, Glass, Concrete	32	733
20	Primary Metals Products	33	703
21	Wholesale Trade	50	587
22	Paper & Allied Products	26	451
23	Textile Mills Products	22	440
24	Air Transportation	45	431
25	Local/Suburban Transit	41	336
26	Oil & Gas Extraction	13	327
27	Railroad Transportation	40	319
28	Petroleum Refining	29	231
29	Leather/Leather Products	31	163
30	Mining of Nonmetallic Minerals	14	39

Table 1-2
CRITICAL SOURCE RANKING SCHEME

P = Q x R x T x E x N

P = Pollution Potential	T = Toxicity of Pollutants at the Source
Q = Quantity of Pollutant	E = Exposure Factor (Extent of Contact with Rain)
R = Amount of Runoff	N = Number of Facilities in Los Angeles County

Q Q = s x l

Guidelines:

s = number of sources
"10" = >10 sources
"5" = 5 sources
"1" = <3 sources

l = likelihood of release
"10" = extremely likely to be released (>75% of the time)
"5" = likely to be released about 50% of the time
"1" = likely to be released <10% of the time

R R = relative size of paved area on a scale of 1-10, the higher the value, the more runoff

Guidelines:

"10" = >100 acres
"8" = about 10 acres
"6" = about 5 acres
"1" = less than ½ acre

T T = n x i

Guidelines:

n = number of toxic pollutants
"10" = if >5 types of toxic pollutants are usually present
"7" = if about 3 toxic pollutants are usually present
"5" = if about 2 types of toxic pollutants are usually present
"1" = if no toxic pollutants are usually present

i = inherent toxicity of the mix of pollutants that is generally present at the facility
"10" = extremely toxic
"7" = somewhat toxic
"1" = non-toxic

E E = Exposure factor

Guidelines:

"10" = if all industrial activities take place outdoors with significant exposure
"8" = if significant activities take place outdoors or are exposed to rainfall
"5" = if some activities take place outdoors or are exposed to rainfall
"1" = if most or all industrial activities take place indoors or are not exposed

N N = Number of Facilities in Los Angeles County

Guidelines:

"10" = >5,000 facilities	"5" = 300-400 facilities
"9" = 2-5,000 facilities	"4" = 200-300 facilities
"8" = 1-2,000 facilities	"3" = 100-200 facilities
"7" = 500-1,000 facilities	"2" = 50-100 facilities
"6" = 400-500 facilities	"1" = <50 facilities

1.4 STEP 3 - PRIORITIZE THE CANDIDATE CRITICAL SOURCES

Industrial and commercial facilities were evaluated based on their two-digit Standard Industrial Classification (SIC) Codes. There are over 50,000 industrial and commercial facilities within Los Angeles County. The study considered 36 different SIC code categories. Golf courses were not evaluated because they are not considered traditional industrial/commercial facilities, but rather, a type of recreational facility or land use type. Golf courses are being reviewed by the County as a land use type under the land use monitoring selection process. Thirty of these SIC code categories were analyzed for the purpose of this study (Table 1-1). Construction was excluded because it is transitory in nature, is covered by a separate General Permit, and has been extensively studied by others. Health Services (SIC 80) were excluded based on the assumption that most sites are probably storefront clinics and offices rather than large medical complexes. Agriculture was excluded from consideration, as it is currently exempt from the stormwater regulations and is not currently significant within the Los Angeles County. Metal mining and tobacco were excluded, based on the fact that there are very few facilities within the County. In addition, Water Transportation (SIC Code 44) was also excluded. The rationale for this exclusion is that the Port of Long Beach is currently conducting an extensive stormwater monitoring program at 21 locations at the Port. This monitoring effort began in wet-weather season 1995-96 and will be ongoing. Results from the first year of the monitoring effort will become part of the public record effective July 1, 1996 when the Port of Long Beach submits its Annual Report to the Regional Board. Given the extensive local effort underway at the Port of Long Beach, additional expenditure of effort to characterize storm water discharge from water transportation facilities appears unwarranted.

Values of the key factors and subfactors were determined on the basis of published data and the professional judgment of west coast stormwater experts. An Excel spreadsheet was then used to calculate the P value for each SIC code category to prioritize the candidate critical sources. The results of the ranking process are presented in Table 1-3.

The County is required to conduct the Critical Source/BMP Monitoring Program at five high priority industry types. The five highest ranked facility types from Table 1-3 are:

1) Wholesale Trade (including scrap yards and auto dismantlers)

2) Automotive Repair/Parking

3) Fabricated Metal Products (including electroplating)

4) Motor Freight (including trucking)

5) Chemicals and Allied Products

In order to conduct the monitoring, the County will need to identify six facilities from each of the five industrial categories to participate in the study. These six facilities should be as similar in terms of size, practices, materials, and activities as is possible so as to ensure consistency within the monitoring study. Given that six participating facilities are required from each category, it is

1.4 STEP 3 - PRIORITIZE THE CANDIDATE CRITICAL SOURCES

Industrial and commercial facilities were evaluated based on their two-digit Standard Industrial Classification (SIC) Codes. There are over 50,000 industrial and commercial facilities within Los Angeles County. The study considered 36 different SIC code categories. Golf courses were not evaluated because they are not considered traditional industrial/commercial facilities, but rather, a type of recreational facility or land use type. Golf courses are being reviewed by the County as a land use type under the land use monitoring selection process. Thirty of these SIC code categories were analyzed for the purpose of this study (Table 1-1). Construction was excluded because it is transitory in nature, is covered by a separate General Permit, and has been extensively studied by others. Health Services (SIC 80) were excluded based on the assumption that most sites are probably storefront clinics and offices rather than large medical complexes. Agriculture was excluded from consideration, as it is currently exempt from the stormwater regulations and is not currently significant within the Los Angeles County. Metal mining and tobacco were excluded, based on the fact that there are very few facilities within the County. In addition, Water Transportation (SIC Code 44) was also excluded. The rationale for this exclusion is that the Port of Long Beach is currently conducting an extensive stormwater monitoring program at 21 locations at the Port. This monitoring effort began in wet-weather season 1995-96 and will be ongoing. Results from the first year of the monitoring effort will become part of the public record effective July 1, 1996 when the Port of Long Beach submits its Annual Report to the Regional Board. Given the extensive local effort underway at the Port of Long Beach, additional expenditure of effort to characterize storm water discharge from water transportation facilities appears unwarranted.

Values of the key factors and subfactors were determined on the basis of published data and the professional judgment of west coast stormwater experts. An Excel spreadsheet was then used to calculate the P value for each SIC code category to prioritize the candidate critical sources. The results of the ranking process are presented in Table 1-3.

The County is required to conduct the Critical Source/BMP Monitoring Program at five high priority industry types. The five highest ranked facility types from Table 1-3 are:

1) Wholesale Trade (including scrap yards and auto dismantlers)

2) Automotive Repair/Parking

3) Fabricated Metal Products (including electroplating)

4) Motor Freight (including trucking)

5) Chemicals and Allied Products

In order to conduct the monitoring, the County will need to identify six facilities from each of the five industrial categories to participate in the study. These six facilities should be as similar in terms of size, practices, materials, and activities as is possible so as to ensure consistency within the monitoring study. Given that six participating facilities are required from each category, it is

TABLE 1-3

RESULTS OF RANKING OF CANDIDATE CRITICAL SOURCES

Rank (Pollution Potential)	Rank (No. Facilities)	Industrial Category	SIC Code	No. Facilities
1	21	Wholesale Trade (scrap, auto dismantling)	50	587
2	1	Automotive Repair/Parking	75	6,067
3	3	Fabricated Metal Products	34	3,283
4	18	Motor Freight	42	872
5	14	Chemicals/Allied Products	28	1,069
6	4	Automotive Dealers/Gas Stations	55	2,744
7	20	Primary Metals Products	33	703
8	7	Electric/Gas/Sanitary	49	2,001
9	24	Air Transportation	45	431
10	15	Rubbers/Miscellaneous Plastics	30	1,034
11	25	Local/Suburban Transit	41	336
12	27	Railroad Transportation	40	319
13	26	Oil & Gas Extraction	13	327
14	17	Lumber/Wood Products	24	905
15	2	Machinery Manufacturing	35	4,223
16	9	Transportation Equipment	37	1,838
17	19	Stone, Clay, Glass, Concrete	32	733
18	29	Leather/Leather Products	31	163

21	28	Petroleum Refining	29	231
22	30	Mining of Nonmetallic Minerals	14	39
23	6	Printing & Publishing	27	2,432
24	10	Electric/Electronic	36	1,636
25	22	Paper & Allied Products	26	451
26	11	Furniture & Fixtures	25	1,368
27	5	Personal Services (laundries)	72	2,515
28	16	Instruments	38	1,029
29	23	Textile Mills Products	22	440
30	8	Apparel	23	1,900

possible that practical, non-technical considerations (e.g., lack of enough willing participants, inability to secure 24-hour/7-day access for sampling, etc.) may prevent the County from ensuring the participation of enough facilities from a given SIC category. As such, it may be necessary to select the next highest-ranking facility type for the study. In the event that this becomes necessary, the County will select facilities from the next highest ranking industrial categories. The next five highest-ranking facility categories are as follows:

6) Automotive Dealers/Gas Stations
7) Primary Metals
8) Electric/Gas/Sanitary Services
9) Air Transportation
10) Rubber/Miscellaneous Plastics

It is important to note that a numerical ranking scheme such as described above is designed as a semi-quantitative screening tool for a relative evaluation of critical sources. The values developed using the ranking scheme are not meant to be interpreted in any absolute sense.

1.5 STEP 4 - CONDUCT LITERATURE REVIEW

The objective of the literature review was to identify what critical sources have been (or are planned in the next five years to be) studied elsewhere (under conditions that are representative of Los Angeles County) so as not to duplicate efforts in the course of this study. Los Angeles County conducted an initial literature review and contacted various California municipal stormwater programs in order to identify which critical sources have been studied elsewhere. This search was conducted through a telephone survey and Internet data search. The survey was supplemented by conducting a computerized library search using DIALOG and Cambridge Scientific Abstracts Services to access specific data bases (e.g., Water Resources Abstracts, Water Net, NPIS, Enviroline, Pollution Abstracts, Aquatic Sciences and Fisheries Abstracts), as well as the EPA National Bibliographic Catalog. The focus of the computer data base searches was to identify published studies in technical and scientific journals conducted by universities, research groups, and practitioners (which were not targeted by the County's search). A summary of the studies that are pertinent to the Critical Source/BMP Monitoring Program is presented in Table 1-4.

The results of these searches indicated that much work on the runoff quality from specific industrial sites has yet to be done. Most of the studies, particularly those conducted by municipal stormwater management programs (e.g., Santa Clara Valley and Alameda County, California), monitored runoff from "industrial source areas" or "commercial catchments," rather than from specific industrial facilities. However, several studies were more specific. Pitt et al. (1995) looked at toxic pollutants in runoff from several industrial activity areas in Birmingham, AL, including parking lots and vehicle service areas. Stormwater samples from parking lots and vehicle service areas frequently contained organics and certain metals (notably, Ni in parking lots and Cd and Pb in possible that practical, non-technical considerations (e.g., lack of enough willing participants, inability to secure 24-hour/7-day access for sampling, etc.) may prevent the County from ensuring the participation of enough facilities from a given SIC category. As such, it may be necessary to select the next highest-ranking facility type for the study. In the event that this becomes necessary, the County will select facilities from the next highest ranking industrial categories. The next five highest-ranking facility categories are as follows:

6) Automotive Dealers/Gas Stations

7) Primary Metals

8) Electric/Gas/Sanitary Services

9) Air Transportation

10) Rubber/Miscellaneous Plastics

It is important to note that a numerical ranking scheme such as described above is designed as a semi-quantitative screening tool for a relative evaluation of critical sources. The values developed using the ranking scheme are not meant to be interpreted in any absolute sense.

1.5 STEP 4 - CONDUCT LITERATURE REVIEW

The objective of the literature review was to identify what critical sources have been (or are planned in the next five years to be) studied elsewhere (under conditions that are representative of Los Angeles County) so as not to duplicate efforts in the course of this study. Los Angeles County conducted an initial literature review and contacted various California municipal stormwater programs in order to identify which critical sources have been studied elsewhere. This search was conducted through a telephone survey and Internet data search. The survey was supplemented by conducting a computerized library search using DIALOG and Cambridge Scientific Abstracts Services to access specific data bases (e.g., Water Resources Abstracts, Water Net, NPIS, Enviroline, Pollution Abstracts, Aquatic Sciences and Fisheries Abstracts), as well as the EPA National Bibliographic Catalog. The focus of the computer data base searches was to identify published studies in technical and scientific journals conducted by universities, research groups, and practitioners (which were not targeted by the County's search). A summary of the studies that are pertinent to the Critical Source/BMP Monitoring Program is presented in Table 1-4.

The results of these searches indicated that much work on the runoff quality from specific industrial sites has yet to be done. Most of the studies, particularly those conducted by municipal stormwater management programs (e.g., Santa Clara Valley and Alameda County, California), monitored runoff from "industrial source areas" or "commercial catchments," rather than from specific industrial facilities. However, several studies were more specific. Pitt et al. (1995) looked at toxic pollutants in runoff from several industrial activity areas in Birmingham, AL, including parking lots and vehicle service areas. Stormwater samples from parking lots and vehicle service areas frequently contained organics and certain metals (notably, Ni in parking lots and Cd and Pb in

TABLE 1- 4

SUMMARY OF PERTINENT STUDIES FROM LITERATURE SEARCH

Authors	Name of Report	Publication	Subject of Study
M.A. Collins, K. Roller, G. Walton	"Managing Toxic Pollutants in Stormwater Runoff"	Water Environment and Technology, May 1992, p. 60-64	Monitored metals and ammonia in runoff from wood preserver, fertilizer mixer/packager, marine cargo handler, log home treating/packaging facility, and particle board manufacturer
E. Hoffman, J. Latimer, G. Mills, J. Quinn	"Petroleum Hydrocarbons in Urban Runoff from a Commercial Land Area"	Journal of the Water Pollution Control Federation, v. 54, no. 11, November 1982, p. 1517-25	Measured suspended solids and petroleum hydrocarbons in runoff from a commercial shopping mall
R. Pitt, R. Field, M. Lalor, M. Brown	"Urban Storm Water Toxic Pollutants: Assessment, Sources, and Treatability"	Water Environment Research, v. 67, no. 3, May-June 1995, p. 260-275	Monitored runoff quality from vehicle service areas and parking lots
Sacramento County	Special Study on Gas Station Runoff	Sacramento County	Conducted field screening monitoring at gasoline stations (the stations did not conduct vehicle repair)
Sacramento County	"Action Plan Demonstration Project at a Gas Station"	Sacramento County	Conducted wet and dry-weather monitoring at gas stations
Western States Petroleum Association	"Storm Water Best Management Practices for Retail Gasoline Outlets"	Western States Petroleum Association (WSPA)	Summarized runoff characterization studies conducted by WSPA and the American Petroleum Institute and described Best Management Practices for retail gasoline stations
Woodward-Clyde Consultants	1. Parking Lot Monitoring Report 2. Parking Lot Best Management Practices Manual	Santa Clara Valley Nonpoint Source Control Program	Conducted water quality monitoring and tested effectiveness of storm drain inlet inserts

vehicle service areas). The study indicated that organics were associated mainly with unfiltered samples, suggesting an association with particulates; metals were elevated in both the filtered and unfiltered samples, indicating that they are also present in the dissolved phase.

Hoffman et al. (1982) conducted a study to determine the relationship of hydrocarbon load to total rainfall and land use at a commercial shopping mall in Warwick, RI. Runoff was monitored for suspended solids and petroleum hydrocarbons only. Results suggested that suspended solids and hydrocarbons are present at elevated levels in the runoff (flow-weighted concentrations ranged from 20.5 to 112.7 mg/l for suspended solids, and from 0.69 to 2.15 mg/l petroleum hydrocarbons). The study did not differentiate between different types of hydrocarbons in the runoff, although gas chromatograms of the runoff samples from the site were similar to those for used crankcase oil, suggesting a probable source.

Collins et al. (1992) reported monitoring information for five industrial facilities for compliance with the Virginia Pollutant Discharge Elimination System (VPDES) stormwater permits. The facilities included a wood preserver, fertilizer mixing/packaging plant, marine cargo handling facility, log home treating/packaging facility, and a particle board manufacturer. Stormwater monitoring conducted at all five facilities indicated elevated metals and ammonia concentrations. Toxicity testing also revealed that the stormwater runoff was toxic for most of the samples. However, while this article contained some interesting information, the information presented was not adequate to justify exclusion of any of the facility types from the County's Critical Source/BMP Monitoring Program.

Sacramento County and the Western States Petroleum Association (WSPA) have conducted runoff characterization and control measure evaluations for retail gasoline service stations (SIC code 55). Since the studies were conducted in California, they may be considered representative of the conditions in Los Angeles County. However, SIC code 55 also includes motor vehicle dealerships and auto supply stores, both of which are common in Los Angeles County. Since neither of the studies addressed auto dealerships or supply stores, they do not appear to have adequately addressed runoff quality and control from this category of industry. Therefore, SIC code 55 should not be eliminated from consideration as a critical source.

Based on this review, the top five industry types developed through the ranking process are still good candidates for conducting the critical source monitoring program in Los Angeles County, as they do not appear to have been studied in detail in other areas, based on available published information.

1.6 STEP 5 - FINALIZE LIST OF FACILITY TYPES TO PARTICIPATE IN THE CRITICAL SOURCE/BMP MONITORING PROGRAM

Based on the prioritization developed in Step 3 and the literature review conducted in Step 4, the County has determined the top five facility categories to monitor in the Critical Source/BMP Monitoring Program. These categories are as follows:

1) Wholesale Trade (focusing specifically on scrap yards and auto dismantlers)

2) Automotive Repair/Parking (focusing on automotive repair service stations)

3) Fabricated Metal Products (including electroplating)

4) Motor Freight (including trucking)

5) Chemicals and Allied Products

As stated above, in the event that the County can not secure the participation of enough facilities within a given category, it may be necessary to select facility types from further down the list of priority industrial sites. Further, since critical source monitoring has already been initiated at a motor freight facility and a fabricated metals facility (beginning in wet-weather season 1995-96), the County may opt to continue monitoring at these facilities in future years to fulfill the requirements of the Critical Source/BMP Monitoring Program.

2.1 INTRODUCTION

Los Angeles County (County), is required to conduct a Critical Source/Best Management Practices (BMP) Stormwater Monitoring Program. The overall objective of the Program is to identify five industrial and/or commercial critical source types, and then monitor each source type for two years. The first year of monitoring will be performed without BMPs, and the second year with BMPs.

The following plan for the Critical Source/BMP Stormwater Monitoring Program presents the criteria for selection of stormwater monitoring methods, identifies the analytical methods to be used to detect pollutants in stormwater, describes the sampling methods, sampling locations, and frequency of monitoring, presents a quality assurance/quality control (QA/QC) program to ensure that all required elements of the monitoring program are conducted and that all monitoring is performed by trained personnel, and provides procedures and schedules for reviewing and evaluating the effectiveness of the monitoring program. This plan has been prepared as part of compliance with the Los Angeles County areawide National Pollutant Discharge Elimination System (NPDES) Municipal Stormwater Permit (Permit No. CAS614001).

As described in Section 1, the County tentatively plans to examine the following five critical source types over six rainy seasons, beginning during the 1996/97 rainy season.

1. Wholesale Trade (including scrap yards and auto dismantlers)
2. Automotive Repair/Parking
3. Fabricated Metal Products (including electroplating)
4. Motor Freight (including trucking)
5. Chemicals and Allied Products

During the 1996/97 rainy season, stormwater runoff from one of the top-ranking critical source types will be characterized. The County will make a good faith effort to obtain the participation of six facilities with similar characteristics (three control sites and three test sites) within each critical source type, so as to reduce the amount of variability inherent in sampling only a single facility. Selection of the six participating facilities will be based upon the following criteria:

- Willingness of the facility to participate in the program, including implementing BMPs, and provide written authorization attesting to such;
- 7-day, 24-hour access to the sampling point(s);
- Location within close proximity to other facilities within the test or control group (see below); and

- No confined space entry required.

Also, the number of sites may be less than three apiece if sites cannot be found in close enough proximity to be sampled by a single crew.

During the first year, stormwater runoff from all six sites will be sampled and analyzed during five targeted storm events. Stormwater runoff from the six sites will be split into two pools, reflecting the three control and the three test sites. Stormwater runoff from each pool will then be composited into a single sample for each storm event (compositing will be performed in the field). These samples will be neither time nor flow-weighted composite samples. The samples will be analyzed for those pollutants anticipated to be found in the critical source stormwater runoff, and such analytes will be partitioned, as appropriate, to measure the dissolved and undissolved portions (lists of analytical suites for each critical source type are provided in Table 2-1).

Based upon the first year of characterization data, appropriate BMPs will be selected and applied at the three test sites. (The same BMPs will be used at each site.) In the second year, ten storm events will be sampled and stormwater runoff quality from the control sources will be composited and analyzed, and the results compared to composited and analyzed samples from the test sites at which BMPs have been applied.

The process will be repeated, adding the second critical source in the second rainy season and so on, with the intent to complete two years of monitoring at each critical source type (with BMPs added during the second year each time) by the end of the sixth rainy season, which will be the rainy season of 2001/02.

Because of the semi-arid climate of Southern California and the inherent variability between storm events (both in terms of intensity/duration and geographic occurrence), it may not be possible to capture all of the targeted storm events at all stations within a given year. In particular, it may be difficult to capture ten storms in a given year, as there needs to be sufficient rainfall volume and intensity in order to collect the samples. The Critical Source/BMP Monitoring Program was designed to monitor each critical source type for two years only. Assuming the Program is conducted in good faith, sampling of a given critical source type will not extend beyond two years even if fewer than the targeted number of storm events are sampled.

2.2 PURPOSE OF CRITICAL SOURCE BMP MONITORING PLAN

The purpose of the Critical Source/BMP Monitoring Plan is as follows:

1. To provide procedures for conducting visual observations and collection of stormwater grab samples to ensure consistency over the six-year duration of the Critical Source/BMP Monitoring Plan.

TABLE 2-1
EXAMPLE ANALYTICAL SUITES FOR CRITICAL SOURCE MONITORING

Critical Source Type					Constituent	Sample Type	EPA Method	Detection Limit	Units	Holding Time	Container Type	Sample Volume
1. WT	2. ARP	3. FMP	4. MF	5. CAP								
X	X	X	X	X	pH	grab for comp	150.1	N/A	pH	immediate	plastic	25 ml
X	X	X	X	X	Electrical Conductivity	grab for comp	120.1	N/A	umhos/cm	28 days	plastic	100 ml

X	X	X	X	X	Semivolatile organics	grab	8270	var	µg/l	7 days	glass	1000 ml
	X		X		TPH (diesel& gasoline)	grab	8015M	var	µg/l	28 days	glass	1000 ml
X	X	X	X	X	TSS	composite	160.2	10	mg/l	7 days	plastic	200 ml
X	X	X	X	X	TDS	composite	160.1	10	mg/l	7 days	plastic	200 ml
X	X	X	X	X	TOC	composite	415.2	1	mg/l	7 days	plastic	25 ml
	X				MBAS (detergents)	composite	425.1	1	mg/l	48 hours	plastic	250 ml
		X		X	Other*							
					Metals (total and dissolved)							
X	X	X	X		Cadmium	composite	213.2	1	ug/l	48h/6 months**	plastic	300 ml for Total and Dissolved Metals
X	X	X	X		Chromium	composite	218.2	1	ug/l	48h/6 months	plastic	
X	X	X	X		Copper	composite	219.2	1	ug/l	48h/6 months	plastic	
X	X	X	X		Lead	composite	239.2	1	ug/l	48h/6 months	plastic	
X	X	X	X		Nickel	composite	249.2	1	ug/l	48h/6 months	plastic	
X	X	X	X		Zinc	composite	289.2	10	ug/l	48h/6 months	plastic	

* Additional organic or inorganic constituents may be added after facility selection, to test for specific chemicals handled in the selected facilities.
** Samples should be filtered and preserved in nitric acid within 48 hours, and subsequently held for up to six months.

1. WT Wholesale Trade
2. ARP Automotive Repair/Parking
3. FMP Fabricated Metal Products
4. MF Motor Freight
5. CAP Chemicals and Allied Products

R0011840

2. To ensure that appropriate BMPs for implementation at the test facilities are selected and evaluated in a timely and consistent manner.

3. To evaluate the effectiveness of the BMPs in reducing or removing pollutants in stormwater runoff by comparing the control and test facilities.

4. To ensure that data is obtained with field and laboratory QA/QC procedures that will result in a stormwater quality database adequate for characterizing stormwater runoff, selecting BMPs, and evaluating the effectiveness of BMPs.

2.3 PROGRAM DESIGN AND EQUIPMENT

Monitoring Program Design

During the 1996/97 rainy season, stormwater runoff from one of the five critical source types will be characterized. The Critical Source/BMP Monitoring Program requires collection of composite and grab samples of stormwater runoff. One set of samples shall be collected from each discharge point (also referred to as an outfall) of each facility beginning in 1996/97 during each of five storm events in the first year, and ten storm events in the second year of testing for each critical source.

A total of six similar facilities from each critical source type will be selected within a limited geographic area. Initially, the County will conduct reconnaissance visits to numerous sites within a given critical source type and apply site selection criteria to identify the six most suitable sites. Site selection criteria will include: representativeness of facility type (within the critical source category), accessibility of discharge points or outfalls, feasibility of installing a device that would enable stormwater sample collection in the absence of operators (e.g., sample collection bucket installed within a drop inlet, or other pre-fabricated passive stormwater collection device), and health and safety. The County will then seek permission from the facility operators to conduct the Critical Source/BMP Monitoring Program at their facilities. In the event that a given facility declines to participate, the next most suitable facility will be considered.

After the six most suitable sites have been selected, the County will perform secondary selection to divide the sites into two triads (groups of three facilities) for control and testing purposes. Samples from each triad will be composited together for analysis. The criteria for dividing the sites will include: feasibility of implementing BMPs during the summer following the first year of monitoring, and location within close proximity to the other two sites (preferably within approximately 15 minutes driving time, assuming typical local traffic patterns during a rain event).

Logistics

A minimum of two teams of two persons each will be needed to sample the six facilities for each critical source type. Each crew will be responsible for a composite triad of three adjacent sites (either from the control or test group). Starting in the second year (1997/98) when a second critical source type is added, a minimum of four teams of two persons will be required. Two complete sets of sampling equipment (described below) will be needed in rainy season 1996/97, and four sets will be needed beginning in 1997/98.

Prior to sampling, County personnel will visit each facility to identify the outfalls or sampling points to be monitored. In some cases, special or modified sampling equipment may be needed (such as a sampling bucket on a pole to access an outfall located within a manhole). At sites with difficult access or sites that would be difficult to get to in time to capture the first flush (concentrated pollutants in runoff from the early part of the storm event), a simple, low-cost sample device such as a passive stormwater collector may be useful. Such samplers have a container installed just below ground with the opening flush with the ground surface such that they can fill up with runoff even if sampling personnel are not present. The County may consider using such a device on a case-by-case basis, if certain criteria regarding their use are met. Criteria for determining whether such devices are appropriate for use at a given facility include:

- Outfalls or stormwater sampling points at which runoff consists of sheetflow;
- Outfalls or stormwater sampling points at locations that would preclude collection of the first flush (e.g., due to difficult access);
- Facilities that have more than two outfalls; and
- Facilities that grant permission to the County to install such device(s).

At facilities where automatic collection devices are determined to be feasible, County personnel shall install the samplers prior to the onset of the rainy season. If the County determines that such devices are not appropriate or feasible for use at the selected facilities, labor (e.g., additional sampling crews) may be substituted for automatic collection equipment in order to achieve the same results.

When rainfall is forecast, every effort will be made to collect the first flush at each site. The crew will collect a sample of sufficient volume to satisfy the analyses to be conducted (see Table 2-1 for test possibilities), fill out the observations sheet, and drive to the next site in the triad, performing the same actions there, and moving on again to the next site.

Once the first round is completed the crew will immediately begin a second round (i.e., drive to the first site, collect one sample, perform observations and measurements, etc.). The crew will keep moving between the three sites as long as the rain continues and flows are strong enough to fill the water collection devices between visits. For purposes of this monitoring program, a viable storm event is defined as a storm that is of sufficient volume and duration to enable collection of a minimum of three rounds of samples (the initial composite and grab samples and two additional rounds for composite samples) at all stations within each triad. However, sampling crews should collect as many samples as possible over the course of the entire storm event. The end of the storm event is defined by a break of at least three hours in rainfall. This means that the crews will have to remain near their sampling sites for three hours after the rain stops to ensure that the event is actually over. In the event that a given storm is of very long duration, sampling will be terminated 12 hours after the start of the rain event.

Sample Collection

In the first round each crew will need to collect several bottles of runoff for the initial grab sample, plus the first sample to be composited . The grab will consist of three or four liters, depending on what is being analyzed (see Table 2-1). In subsequent rounds, a smaller amount of sample volume will be needed in order to create a composite sample that is representative of the entire storm event at each group of 3 stations. The County may consider purchasing and installing several low-cost automatic sample collection devices (with a volume of 3-4 liters), or may examine the feasibility of installing sample collection buckets of a similar volume inside selected drop inlets.

Some water quality parameters such as oil and grease, total petroleum hydrocarbons, and semivolatile organics must be collected in glass jars and analyzed separately (cannot be composited), either because they stick to the container walls or because they are volatile. Grab samples for these parameters will be collected only once during the event, during the first round, and analyzed separately. For the other constituents, the crew will collect several samples in plastic bottles during the course of the event and they will be composited in the field to create one composite sample representative of the three facilities within each triad.

Equipment

Equipment needed for proper collection of samples include the following items:

- Communication devices
- Site maps
- Sample bottles with proper labels (provided by the contract laboratory);
- Collection vessel or scoop;
- Paper towels;
- Tool to retrieve passive sample collector, if needed;
- Clipboard with pencils; waterproof pens, observation forms; and data collection forms;
- Watch;
- Latex gloves;
- Rain gear;

- Hard hat (as needed);
- Flashlight (and spare batteries);
- Distilled water (supermarket grade; to rinse hands, collection equipment, etc.);
- Chain-of-custody forms;
- Sample cooler, packing tape, bubble wrap, ice, plastic bags to wrap samples in and pack for proper transport to the contract laboratory;
- Health and Safety Plan; and
- Traffic cones (if applicable).

In most cases, there will be no equipment to calibrate. If the County decides to use a portable pH and/or conductivity meter, the meters will need to be calibrated. However, use of field meters is not recommended, because field pH meters take a relatively long time to stabilize, and because both pH and conductivity will be measured at the laboratory.

Recordkeeping is an important part of this monitoring program. The Critical Source/BMP Monitoring Program requires that records be kept of all site inspections, visual observations, and analytical monitoring efforts.

There are several forms which may be used to record this information. The forms include:

- Form 1: Wet-Weather Visual Inspections Recording Form
- Form 2: Chain-of-Custody Form

Copies of these recording forms are included in Appendix A.

2.4 SAMPLING GUIDANCE

The following section provides step-by-step guidance for each sampling team in collecting stormwater samples.

PRE-SEASON PREPARATION

Step 1: Conduct pre-season preparation

Prepare for sampling before the rainy season:

1. Prior to the rainy season, call the laboratory and request that materials be sent for stormwater sampling.

2. Work with the laboratory to develop a simple labeling system to ensure that grab samples and discrete (composite) samples are collected and handled properly.

PRE-STORM PREPARATION

Step 2: Contact the laboratory.

Immediately before the storm event, call the contract laboratory and tell them you will be delivering samples for analysis.

1. State your name and explain that you are conducting critical source stormwater monitoring.
2. Depending on the critical source type being monitored, you will need to sample for a different suite of parameters. A list of example parameters for each critical source type is provided in Table 2-1. Based on the table, tell the laboratory what you will be sampling for, and when to expect the samples.
3. Request that the laboratory send a cooler with pre-labeled sampling bottles and blue ice for stormwater sampling.

Step 3: Prepare equipment

Use the sampling equipment checklist (Table 2-2) to select the equipment.

Prepare your equipment:

1. Familiarize yourself with the sampling bottles provided by the laboratory and make sure you have the correct type and number of bottles for the critical source type you will be sampling.
2. Check equipment that could fail to make sure it is ready for use (for example, flashlights, pens, etc.).
3. Place all the equipment in a container to carry to the sampling site.

Step 4: Pre-label the sample bottles

This section explains how to fill-in the right information on the bottle labels.

Label the sample bottles before you go out into the field.

1. Sample Identification. Record the critical source type, and whether sample is from the "control" or "test" group. List site location, identification number, and type of sample (either grab or composite).
2. Sampler. Record the name of the person who did the sampling.

TABLE 2-2
SAMPLING EQUIPMENT CHECKLIST
EQUIPMENT FOR OBTAINING WATER SAMPLES

CHECK	ITEM	COMMENTS
	Latex Gloves	To protect your hands against acid preservative.
	Collection Vessel	Recommend clean glass when feasible.
	Waterproof Ink Pens	Sanford's "Sharpie" recommended.
	Recordkeeping Forms	Included in the Appendix of Monitoring Program.
	Paper Towels	For wiping off water from labels and your hands.
	Tape	Electrical, fiber, or duct tape for shipping.
	Watch	Ordinary wristwatch.
	Plastic and Glass Bottles	pH, oil and grease (glass bottle), specific conductance, and total suspended solids.
	Ziploc Plastic Bags	For keeping forms and sheets dry during transport.
	Chain-of-Custody Forms	For recording the time, place, and your company name.
	Packing Material	Plastic bubble wrap, vermiculite or similar.
	Blue Ice	To be kept frozen until sampling begins.

3. Sampling Date and Time. Record the date and time you collected the samples on the chain-of-custody form. Include AM or PM to denote what time of day.

Step 5: Determine if a storm is acceptable for sampling

Storms to be considered for sampling should generate at least 0.25 inches of rain and should be preceded by at least 48 hours of dry weather.

1. Designate a Sampling Coordinator to monitor storm forecasts (radio, TV, weather channel, etc.) and make formal go/no go decisions as to whether to sample.

2. Be prepared when a storm is forecast (sampling equipment and sample personnel are ready).

3. Every effort will be made by the sampling crew to collect the storm's first flush.

4. Drive to the first designated sampling location.

5. Once water is flowing enough to collect a sample, begin timing the storm event.

6. Begin to sample.

7. If, at arriving at a site, there is not enough water flowing to take samples, then wait until stormwater runoff increases.

8. If the storm is not acceptable, then you must sample the next time a storm occurs.

Step 6: Collect the sample

This section explains how to collect stormwater samples.

1. Put on clean latex gloves and open a sample bottle from cooler.

2. If using a passive sample collector, remove the sample collection container. Shake vigorously to remove any material on the sides or bottom of the container, being careful not to spill sampler contents. If using a collection scoop or bucket, dip clean sampler into the center of flow. If there is adequate flow, wash the sampler three times in the flow prior to collecting the sample. Keep sample free from uncharacteristic floating debris and bottom sediments.

3. Carefully pour sample from the container or collection pitcher into sample bottle to the appropriate level.

4. Cap sample bottle tightly and place in cooler.

5. Rinse sampling equipment with distilled water to prevent cross-contamination with the following sample. For every tenth sample, rinse the sampling container once and

discard the rinsate. Then wash the container a second time and pour the rinsate into a clean sample bottle. This will constitute an equipment blank for field QA/QC purposes.

6. Repeat steps 2 and 3 for the remaining sample bottles. Note that you will have three or four sample bottles for the first round of sampling and one or two bottles for subsequent rounds.

7. At one of the stations within each of the test and control triads, collect one additional complete set of grab samples during the first round of sampling. These samples will be analyzed as duplicates for the purpose of field QA/QC.

8. Make visual observations at the outfall and record them on the proper form (Appendix A). Visual observations should be recorded in detail during the first round of sampling and updated during subsequent rounds to document any observed changes.

9. Find a relatively dry area and fill in the chain of-custody forms.

10. Proceed to the next facility and continue sampling.

Step 7: Prepare forms and pack the samples for the laboratory

This section explains how you will package your sample bottles, complete the forms, and transport the bottles and completed forms to the laboratory.

Complete the Chain-of-custody form as follows:

1. Facility Location. Record the name and address of the facility.

2. Sample Description. Record the sample identification number, what the sample is to be analyzed for, the type of sample (grab or composite), and the number of the sample (i.e., first, second, third, etc.).

3. Sampling Date and Time. Record the date and time that you collected the sample. Include AM or PM to denote what time of day.

Pack the sample bottles and forms as follows:

1. Place a plastic liner bag in the sample cooler.

2. Place blue ice (frozen) or regular ice in the cooler. If regular ice is used, place in zipper bags.

3. Wrap glass sample bottle in bubble wrap or similar protective material. Plastic bottles do not need to be wrapped. Make sure all bottle caps are tightened.

4. Place all sample bottles in the chests and tie off the plastic liners.

5. Keep one copy of all your forms for your files.

Transport the sample chest to the contract laboratory as follows:

1. Before sealing the cooler, make sure you have completed all steps, and have included everything in the cooler.

2. Seal the cooler with strong tape (fiber, package sealing or the like) making sure the top and the handle are secured to the bottom portion of the cooler.

3. Call the contract laboratory to tell them that your samples are on the way, and the anticipated time of arrival.

4. Take samples to the laboratory per sampling protocol.

2.5 QUALITY ASSURANCE / QUALITY CONTROL

Field Sampling Procedures. All County personnel responsible for collecting stormwater samples will be familiar with proper sample handling methods, field QA/QC, and reporting requirements.

Field QA/QC Procedures. County staff conducting the sampling will perform field QA/QC by collecting duplicate samples and through the use of blanks. One complete set of grab sample bottles collected during the first round of sampling at one station from each triad will be analyzed as a duplicate sample. In addition, equipment blanks will be collected for 10% of the samples and analyzed to check for cross-contamination introduced during the sampling process. Trip blanks will not be needed because volatile organic compounds (VOCs) will not be analyzed.

Chain-of-Custody. Chain-of-Custody forms track the handling of samples from the point where they are collected through the completion of laboratory analysis. Chain-of-Custody forms will be completed for every stormwater sample that is collected.

Laboratory QA/QC Procedures. Stormwater samples will be analyzed by the contract laboratory. When feasible (i.e., when there is adequate sample volume), the laboratory will split the composite sample in half and analyze both halves separately as a check on the consistency of laboratory analyses. In addition, the laboratory will assure internal quality of its data using commonly accepted methods approved by the State.

2.6 EVALUATION OF EFFECTIVENESS

General. The effectiveness of the Critical Source Monitoring Program will be assessed annually, based on the results of the visual inspections and analytical monitoring. In addition, this evaluation will assist in the evaluation of BMPs.

Use of Wet Season Visual Observations. Visual observations will be included in the determination of the effectiveness of implemented BMPs.

Use of Analytical Monitoring Data. Since chemical concentrations may vary widely during a given storm and between storms, it is unclear whether statistically significant data can be collected using this protocol. Consequently, levels of constituents observed in water quality should be used as *indicators* rather than definitive data on chemical loading.

2.7 HEALTH AND SAFETY

Stormwater sampling activities may occur when the sampling environment and/or stormwater discharges create hazardous conditions. Although the OSHA 40-hour HAZWOPER training is not required for individuals performing stormwater sampling, it is important that you know that hazards do exist when sampling. This section outlines general health and safety issues and concerns.

Safety Guidelines

- Watch out for traffic when sampling or making observations.
- Do NOT remain in open areas or stand under trees if lightning is occurring in the vicinity.
- Be alert to high water or flash flooding conditions.
- Always wear clean latex rubber gloves when sampling.
- Be extremely careful of the acid preservative in the sample bottles (if present); protect your eyes and skin against contact.

Safety Equipment

The following safety equipment is recommended for use during stormwater sampling:

- Wet weather clothing
- Safety glasses
- Latex gloves
- Waterproof flashlight

Hazardous Weather Conditions

Use common sense when deciding whether you should sample during adverse weather conditions. Do not sample during dangerous conditions such as high winds, lightning storms, or flooding conditions which might be unsafe.

Chemical Hazards

You can also be at risk of exposure to hazardous chemicals that have been placed in the sample collection bottles for sample preservation.

A preservative is included in the sample for oil and grease. The preservative is sulfuric acid. If contact is made with the skin and/or eyes burning and blindness may result. If the eye comes in contact with the acid, wash immediately with running tap water for at least 15 minutes. Have someone contact a doctor immediately and follow his/her instructions. If direct skin contact is made, also flush with tap water and remove any clothing that may be soaked with the acid.

Physical Hazards

Other hazards you might encounter are traffic hazards, sharp edges, falling objects and, slippery surfaces.

A STORMWATER/URBAN RUNOFF PROGRAM REPORT
FROM THE COUNTY OF LOS ANGELES

R0011857

Research Report on Issues, Pollutants and Materials

Table of Contents

Executive Summary & Situation Analysis

Purpose of Report

As the first step in the development of the County's Five-Year Stormwater/Urban Runoff Public Education Plan mandated by the NPDES Permit (see "Regulations' Role" section) and passed by the California Regional Water Quality Control Board/Los Angeles Region on July 15, 1996, the following *Issues, Pollutants and Materials* Report focuses on:

- The many and complex issues surrounding stormwater/urban runoff prevention efforts
- The prioritization of pollutants of concern, land uses and associated target audiences so that the education campaign is a focused, targeted effort and results in the highest pollutant reduction per-unit cost
- The specific materials and programs being implemented by municipalities, government agencies and environmental organizations throughout the country and abroad to reduce stormwater/urban runoff pollution
- Overall recommendations on how to proceed in developing the Five-Year Plan based on the information and research conducted by our team and insights provided by the 125 entities nationwide that are actively involved in stormwater/urban runoff pollution prevention programs -- including 58 stormwater managers within the County of Los Angeles

This report will serve as a resource for reviewing and assessing the individual and collective efforts of Los Angeles County, 85 Co-permittees and some of the nation's leading stormwater/urban runoff prevention programs. This analysis will be valuable in the development of the Five-Year Public Education Plan for a number of reasons:

- It will help identify those programs that may have applications in a broad, countywide effort
- It will present information and programs that can be used as springboards to new programs designed for countywide use
- It will provide valuable lessons on what to do and what not to do
- It will maximize resources by reducing the risk of "reinventing the wheel" or duplicating existing efforts

Background: Why Stormwater/Urban Runoff Is A Problem

Every day, millions of gallons of untreated water flow into the County's lakes, rivers and the Pacific Ocean from storm drains. On rainy days, up to 10 billion gallons make it through the drains. Because the County's storm drain system does not filter or treat any kind of contaminates or debris, stormwater/urban runoff has become the most significant source of water pollution in California.

Stormwater/urban runoff pollution is a year-round, continually threatening problem. While the enormous litter problem associated with stormwater and urban runoff pollution is highly visible in the County's communities and waterways -- polluted runoff is even more harmful in a number of other ways:

- It kills marine life
- It contaminates fish and seafood
- It causes illness in swimmers
- It causes storm drains to back up, contributing to flood conditions
- It harms the freshwater habitat
- It reduces residents' quality of life
- It affects the region's $2 billion annual tourism economy

Addressing the issue -- and significantly improving water quality -- poses great challenges because the activities most likely to cause pollution are conducted hundreds of times a day by millions of individuals and thousands of commercial businesses. Fertilizers, herbicides and pesticides, automobile exhaust and oil drips, improper clean-up after house maintenance projects, dumped restaurant grease and other waste, construction debris and runoff, litter, even yard trimmings swept into the street -- all contaminate runoff.

Regulation's Role in Stormwater/Urban Runoff Pollution Prevention

Stormwater/urban runoff was first actively addressed when the Clean Water Act of 1987 established requirements for stormwater discharges under the National Pollution Discharge Elimination System (NPDES) program. To ensure compliance, the California Regional Water Quality Control Board in 1990 issued a five-year permit to the County of Los Angeles for municipal stormwater discharges. Since the permit was very general, compliance varied from city to city. Thus, the level of compliance and any resulting reduction in stormwater/urban runoff pollution was difficult, if not impossible, to track.

To create a more specific standard of compliance, a new NPDES permit was issued by the Water Quality Control Board/Los Angeles Region on July 15, 1996. The Board approved a permit that relies on public education as the dominant means of reducing pollutants to coastal and inland waterways and communities. The Permit advocates a well-targeted program designed to reach those audiences most likely to be the biggest polluters and/or those audiences most likely to adopt behavioral changes that will prevent or reduce pollution.

Target Audiences Defined by the NPDES Permit

Commercial/Industrial Businesses
New Development/Construction
Residential/General Public
School Children
Public Agencies and Employees

In addition, the permit promotes a "Watershed Management Approach" to protect and enhance water resources. By working together, regulatory agencies, Co-permittees, environmental groups and other stakeholders can combine resources and efforts to achieve the greatest environmental improvements within their watershed. The County's six Watershed Management Areas (WMAs) are:

- Malibu Creek and Rural Santa Monica Bay
- Ballona Creek and Urban Santa Monica Bay
- Dominguez Channel/Los Angeles Harbor Drainage
- Los Angeles River
- San Gabriel River
- Santa Clara River

The [illegible] pollutants of concern re[illegible]tedly detected in the watersheds of Los Angeles County include: [illegible] polycyclic aro[illegible] hydrocarbons (PAHs) [illegible] and viruses, sediment, litter and [illegible] biochemical oxygen demand (B[illegible]), [illegible] and grease, nutrients and other toxic [illegible]ials [illegible] chlorinated biphenyls (PCBs) and tri-butyl tin (TBT). Some of [illegible] pollut[illegible] are potentially toxic [illegible] high concentrations, others are potent carcinogens and mut[illegible] [illegible] causing [illegible] growth. Sediments can sm[illegible] pools, while litter and debris are a blight on our water b[illegible].

Public Education's Role in Preventing Stormwater/Urban Runoff Pollution

Public education campaigns have been implemented as part of the NPDES permit enacted in 1990 and have shown success in increasing awareness about stormwater/urban runoff pollution. For example, after a year-long advertising campaign sponsored by the County of Los Angeles and the City of Los Angeles, research showed a 50 percent increase in the number of County residents who knew that stormwater and urban runoff leads directly to the ocean -- a change from 48 percent in 1995 to 76 percent in 1996.

Under the new permit, the Principal Permittee and Co-permittees are required to develop and implement a stormwater/urban runoff public education strategy that will raise the awareness level of even more of the County's 9 million residents about stormwater/urban runoff pollution -- *and motivate them to stop polluting.*

In fact, one of the goals of the County and many of the Co-permittees is to measure and demonstrate actual behavioral change that leads to pollution reduction. While behavioral change does not happen immediately, there is enough evidence from other environmental and social marketing campaigns -- such as recycling, seat belts, AIDS prevention, etc. -- that people can and will change their behaviors if they understand the need and are given convincing reasons and a "reward" to do so. Thus, the challenges will be to:

- educate target audiences about the problems and solutions;
- discover what will influence behavioral change in the target audiences; and
- document and prove that the education outreach effort resulted in a behavioral change that reduced pollution.

As the Principal Permittee, the County of Los Angeles is ultimately responsible for developing a Five-Year Public Education Program that serves the needs of the County and the 85 Co-permittee municipalities. This umbrella program will be developed in consultation with the Co-permittees and will address education outreach strategies countywide -- by pollutants, land use, watershed and targeted audiences outlined in the NPDES Permit. In addition, the Program will identify the Co-permittees' responsibilities for implementation, including specific objectives for changing knowledge and behavior.

♦ General Public

It is necessary to review and evaluate the most effective communication approaches the County can use as part of a broad-based campaign that can influence as many residents as possible. In that light, the following points must be considered:

- In surveys conducted by the County and throughout the country, the general public rates mass media (television, radio, print) as the number one source of information and education about environmental issues.[1] Mass media -- especially television and radio -- is a top-down approach and has the greatest potential to reach the largest number of people with broad-brush overarching messages.
- Using mass media in a countywide campaign is supported by interviews with managers of other stormwater public education programs in California. These managers stated that, given their experience, they would use the mass media and advertising much more heavily in the County program than they do in their own programs which are designed for smaller communities. Most of these smaller programs depend on grassroots programs (bottom-up approach), targeted outreach, school programs, brochures, flyers, posters and other collateral materials for their outreach.

[1] The Sierra Group (April 1995); Godbe Research and Analysis (1996)

R0011863

- The County program must address the issues of diversity -- ethnic, cultural and socio-economic -- to have any broad effect. For example, surveys conducted by the County of Los Angeles and the City of Los Angeles confirmed that foreign language media -- particularly radio and newspapers -- is a highly effective tool in reaching ethnic populations. Other studies indicate that low-income people who are struggling with daily economic survival put the health and well-being of their families over concerns for the environment -- a fact that needs to be considered when developing messages targeted to that audience.
- Given the varying financial resources of the 85 Co-permittees, the countywide program must be cost-effective and practical to implement.

♦ Business

For the business community, many of the salient points for the general public apply. However, there are some distinct considerations that must be incorporated in the development of Best Management Practice (BMP) education outreach programs:

- BMP information must provide very specific guidelines on how to execute tasks to ensure compliance -- there should be no room for misinterpretation.

- BMPs must not only improve the conditions in the storm drains, but must have a bottomline, cost-effectiveness benefit for businesses to comply. This is of critical importance to businesses in lower income or blighted areas that are in a "survival" mode of operation and are more apt to comply if it improves their profitability.

- More research must be done within business audiences to identify who should receive stormwater/urban runoff prevention information to ensure that education and retraining reaches those people who are doing the polluting. In a restaurant, for example, who should receive the pollution prevention training to make sure that busboys, cooks and janitorial staff comply with BMPs every day, all day long? The general manager? The head cook? Someone else?

- Attention must be paid to developing materials in several languages depending on the type of businesses and workers most likely to have polluting behaviors. In the restaurant example, management may learn BMPs if they are in English, but busboys may not. BMP information needs to be understood by both types of employees.

- Many small businesses -- particularly in the ethnic communities -- operate with very slim profit margins and have very little extra capital for improvements. An understanding of the economies of implementing BMPs must be paramount, as well as the cultural business values inherent in each ethnicity.

♦ Other Audiences

In addition to the general public and businesses, the NPDES Permit identifies school children and public agencies and employees as key audiences of the public education campaign. Based on discussions with Co-permittees, these targets are considered secondary to the general public and businesses in terms of broad campaign outreach. However, employee training is recognized by the Co-permittees as a highly important element of the Permit.

Generally, this is due to:

- the relatively lower levels of pollutants they generate;
- the fact that mass media efforts will reach them; and,
- because targeting them with specific messages can be costly and time consuming.

Having noted these issues, Co-permittees did agree that some level of targeted communications to these audiences should be developed and implemented at some point during the Five-Year Program.

Challenges and Opportunities That Lie Ahead

Although significant strides have been made in raising public awareness about storm drain pollution, the County and the 85 Co-permittees are embarking on uncharted waters in many ways:

- Never has a *coordinated* and *comprehensive* effort of this magnitude that is founded on research and evaluation, been developed and implemented between a Principal Permittee and so many Co-permittees.

- Of all the stormwater and urban runoff pollution prevention programs examined for this report, the largest was the Chesapeake Bay Program with more than 14 million people. The City of Los Angeles was next with half as many residents as Los Angeles County (9 million people). Other major West Coast stormwater public education programs have audiences between 750,000 and 1.5 million people -- between eight and 16 percent of the County's population.

For the Five-Year Public Education Plan to be cost-effective and successful, an overarching theme must be developed that can:

- Be used throughout the County while still being adaptable for very localized use by Co-permittees
- Cross most regional, cultural and language barriers in the County
- Educate the public on how to prevent the problems of stormwater/urban runoff pollution in a succinct and memorable way, as "Reduce, Reuse, Recycle" does for the recycling movement
- Motivate the public and business to change their behaviors

Section 2: Issues & Program Considerations

Challenges to the Public Education Campaign

There are many challenges to producing a successful countywide stormwater pollution public education program, but challenge very often generates opportunity. Based on evaluation of materials and interviews with more than 100 cities and counties across the country[2], the County, in partnership with the Co-permittees, has the opportunity to produce the first coordinated, comprehensive program that can demonstrate it has changed behavior and reduced pollutants to the stormwater system.

This campaign also has the opportunity to address the largest audience to date of any stormwater program on the West Coast. While most other programs address smaller, largely homogeneous communities or cities/counties with approximately 1 million to 4 million in population, Los Angeles County's unincorporated areas and the Co-permittee cities encompass nearly 9 million people whose socio-economic levels vary from great wealth to welfare, and who collectively speak more than 50 languages/dialects.

While $5 million is a substantial commitment to fund a public education campaign, when it is spread over five years and needs to reach 9 million people, each dollar must be effectively spent and, whenever possible, leveraged to create additional resources.

Reaching these diverse audiences is a challenge. Reaching them successfully with a well-targeted, effective campaign has the potential to make our countywide program a national model for other large geographical areas. Achieving success is a challenge -- and a great opportunity. Achieving success requires a unified effort by the County, Co-Permittees and the consulting team and a creative, strategic plan of action.

Social Marketing -- Selling Behavioral Change[3]

Social marketing is the use of corporate marketing "technologies" (strategies and tactics) to influence a voluntary behavioral change in a target audience. While corporate marketing's bottomline is to influence the customer to "buy the product," social marketing's bottomline is to influence the customer to "buy-in to a behavioral change" that may be good for society, the environment and/or the individual.

[2] See Appendices for complete listing of cities.

[3] See Appendices for a social marketing program model.

R0011866

The definition and purpose of social marketing is quite different from that of traditional public education campaigns. In the past, public education programs were designed to raise awareness among the masses about a social issue or problem, with the ultimate hope that this awareness would encourage people to analyze their behavior and change it.

Social marketing takes a more strategic, aggressive and scientific approach. Using research, it identifies target audiences, appropriate messages, and the best vehicles to deliver those messages. In targeting audiences, social marketing strives to reach those segments of the population most affected by/or most likely to affect a certain situation. And by using behavioral and attitudinal research, social marketing programs look to reach these targeted audiences in a way that is highly personal and offer specific suggestions for behavioral changes. Given this highly personal approach, social marketing can motivate individuals to take action, if executed with sensitivity and care.

By using research ... social marketing identifies target audiences, appropriate messages, and the best vehicles to deliver those messages.

Communicating the Message

Communicating effectively to the program's diverse target audiences is one of the program's major challenges. As a first step in the research process and to obtain a thorough understanding of the programs already in place, interviews were conducted with 58 stormwater program managers in Co-permittee cities.

♦ Need for an Overarching Theme/Look

A majority of the stormwater program managers interviewed expressed a need for simplified concepts and "everyday" terminology to bring the stormwater/urban runoff issue home to the public. Communications research shows that the most memorable and effective themes or "sayings" are simple and relate to everyday life. Co-permittees are aware of and understand their demographics, and toward that end, have asked for concise, memorable "reader-friendly" messages that can be understood by all.

The initial step in the campaign process should be to develop an umbrella theme -- such as "Buckle Up" or "Reduce, Reuse, Recycle" -- to tie the campaign together. These themes have produced positive results because they do more than describe an issue, they tell people what they can do to solve it in simple, easy-to-remember language.

Developing an overall campaign theme will address another concern expressed by the cities: the need for unified messages and uniform quality of materials. While there is at least some degree of stormwater/urban runoff public education in every Co-permittee city, there is great variation in audiences targeted, materials used and the level of effort expended. In addition, city stormwater managers have expressed concern that their materials are not being picked up or noticed by the public, defeating their public education purpose.

In addressing this concern, one of the campaign's strategies is to produce materials that are uniform in look, with an identifiable theme and logo and messages that apply countywide. The cities must also be able to customize, produce and distribute these materials cost effectively.

For example, one Co-permittee suggested supplying copy and format for collateral materials on computer disk, allowing cities to communicate under the "countywide umbrella," and still customize the materials with their phone numbers and relevant city information. Another direction that has been discussed is to produce countywide materials centrally, listing the names and phone numbers of all 85 Co-Permittees -- a proposal with obvious cost advantages for the cities.

♦ Addressing Diversity

City stormwater program managers expressed opinions and insights on appropriate ways to address the County's cultural, ethnic and socio-economic issues to effectively reach the County's diverse population. Interviews with various cities and counties nationwide revealed that while many programs are written for non-English speaking audiences, most are simply translations from English and do not address differing cultural issues. The cities of Los Angeles and San Francisco are two of the few that have materials specifically tailored to various cultures. Producing such materials is another opportunity for Los Angeles County and the Co-Permittees to develop effective communication materials that fulfill a specialized and often overlooked need -- and more importantly, motivate the target audiences.

Approaching certain materials from a cultural point of view rather than a simple translation from the English language is important. Research shows that messages that ethnic audiences value most differ significantly by places of origin, and from traditional English-speaking audiences. For example, some cultures are highly influenced by role models and will change behavior based on what these models say; others are very family-oriented and will make changes to protect their family's welfare -- protecting the environment will not rank as high in their priorities.

♦ Broadening the Messages

In addition to cultural issues, there is the challenge of geography: While organizations such as Heal the Bay and the Santa Monica Bay Restoration Project have initiated highly effective education campaigns in beachside communities, messages and efforts now need to be broadened to include the Co-permittee cities whose watersheds drain into harbors and waterways other than the Santa Monica Bay, and inland cities whose watersheds drain into rivers, creeks and other waterways and who may have little or no physical or psychological connection to the ocean. In addition, care must be given to target messages to inland communities with a priority to clean up their own city that supersedes, but is complementary to, the mandated effort to reduce ocean pollution from the storm drain system. For countywide public education materials to be applicable to all communities, reference will be made to "oceans, waterways and communities" rather than to the ocean or Santa Monica Bay alone.

By the same token, the program needs to broaden its base of spokespeople beyond those known primarily for their association with the Santa Monica Bay. Program spokespeople also need to reflect the diversity of the County's geography as well as the target audiences and include the leadership models that research has identified as most believable: professors, doctors and environmental organizations.[4]

Finally, whenever possible, the communications program should work in conjunction with other relevant environmental public education programs in the region, including household hazardous waste and recycling efforts.

Co-permittee City Concerns

Given the regulatory environment under which the Permit was formulated, it is understandable that several cities have expressed concerns during the process. The Permit focuses on public education as a means of accomplishing a reduction in stormwater/urban runoff pollution. Final terms were negotiated and approval was reached after 18 months of negotiation, with the resulting permit a product of compromise between the Regional Water Board, the County, the Co-permittee cities, environmental groups and the trade associations of targeted industries.

A major sticking point in the negotiations was the original Permit provision that the targeted industries should be subjected to formal inspections. To reach consensus, educational site visits -- with no penalties for noncompliance -- were substituted for these inspections. Because the Permit went from a compliance-based approach to an educational approach, it is even more critical that educational site visit materials and tools be persuasive in order to achieve the desired results.

[4] The Sierra Group, April 1995 Stormwater/Urban Runoff Public Opinion Poll. County of Los Angeles.

Despite the challenges in reaching agreement on the Permit, most cities interviewed want to have a successful program. In general, the cities support a unified countywide effort as the most viable way to achieve success, but have expressed a need to have materials allowing them to retain their autonomy.

The cities vary in size and financial resources and have varying levels of financial support available for the countywide public education effort. In fact, the very diversity that makes the countywide program unique also poses the challenge of developing a Plan that accounts for the resources of all Co-Permittees. In developing the Five-Year Plan, individual cities' financial resources will be considered with an eye to producing a program that is both easy to implement and affordable.

Regional Considerations

With many issues being regional in nature, the Permit defines six Watershed Management Areas (WMA)[5] and calls for the cities within these WMAs to work collaboratively to implement a public information program within their watershed. Currently, many cities are looking only to their own jurisdictions rather than the entire watershed, a point that was highlighted during the Co-permittee interviews by the few program managers who discussed issues regional in nature.

In addition, stormwater public education program managers in other parts of California have stated that it has been extremely challenging to forge the cooperative partnerships that are necessary for Co-permittees to work beyond their jurisdictions for the benefit of the entire watershed. A similarly challenging situation is anticipated in Los Angeles County with 85 Co-permittees, the County as the Principal Permittee and six WMAs.

During the research phases of the Public Education Program, it will be determined how and when communications-by-watershed will be specifically addressed. While it is clear that the public needs to understand how and what they are contributing to stormwater pollution, other public education efforts -- including the State of California AIDS Prevention Campaign -- have learned that using technical terms usually leads to confusion and lack of understanding. The term "Watershed Management Area" is not part of the general public vocabulary and the team needs to ask the question -- Is it important to spend money educating about WMAs, or is it more important to motivate them to change their actions like not throwing litter in the gutters?

Given the need to change specific behaviors in order to improve water quality, it is likely that initial materials will not address watersheds per se, but that messages will be targeted to address pollution concerns and actions within the WMAs. This strategy is based on other social marketing campaigns where the value of first educating the public with simple, overarching messages that are relevant to their lives has been demonstrated.

[5] See Section 3 for a listing of cities within each WMA.

♦ Land Use Issues Within the Region

The difference in land use within the region must be understood to maximize the effectiveness of the campaign.

Areas with expanses of open land are particularly sensitive to erosion and pollution by sediment loads. Land where development is taking place on a large scale, where fires have removed protective vegetation from slopes, or other things have occurred to expose dirt to rainwater will require a concentrated educational effort with developers, builders, architects, and engineers.

To help target and track the outreach to this audience and as part of the research effort, a database of all construction projects in Los Angeles with current building permits has been -- acquired. The database includes not only the location of the proposed or ongoing project, but also the builders and designers involved.

Areas with a higher concentration of septic tanks are more sensitive to pollution by pathogens released from leaking tanks. In Los Angeles County, the highest concentration of septic tanks is in the Malibu area and in foothill communities. Maps of areas with varying concentrations of septic tanks have been produced by the City of Los Angeles Department of Public Works for a septage-related environmental impact study.

Groundwater quality is a major concern in areas that have suffered contamination from past business and agricultural practices. This includes the San Gabriel Valley which has had communitywide involvement in Superfund projects for more than a decade. Residents and business leaders in this Valley have a heightened awareness of the relationship between regional economic well-being and water quality. Education about pollution prevention to benefit drinking water supplies, local economics and regional surface water resources is both timely and relevant.

Economic revival is clearly evident in the Long Beach area with the massive Gateway Project. Sediment and trash flowing into the harbor from the Los Angeles River are consistent and serious problems for the Cities of Long Beach and Los Angeles, which have invested substantially in coastal resources. Targeting litter and erosion control upstream is essential not only for the quality of coastal waters, but also to help coastal communities that have to dredge accumulated sediments to unblock shipping channels and remove floatables that blight the surf.

Program Development Considerations

In developing the Five-Year Public Education Program, there are components that *must* be included, and a second tier of strong recommendations that *should* be included based on information collected thus far:

The program must:

- Provide an umbrella concept for Countywide stormwater outreach
- Gain participation by all Co-permittees
- Maintain Co-permittee involvement and allow for tailoring to Co-permittee specific needs; and be easily implemented and economically feasible

The program should:

- Build upon strong stormwater programs already underway in Los Angeles County and what other regions have done well
- Develop simple concepts that motivate behavioral change
- Focus on individual responsibility and actions to achieve results
- Educate the public that household and small business waste are now the major sources of pollutants to the storm drain system rather than waste treatment plants and large industries
- Target major sources of stormwater/urban runoff pollution within each WMA
- Provide efficient, cost-effective communication materials
- Coordinate and integrate with other existing programs countywide, including household hazardous waste, used oil recycling, solid waste recycling, and environmentally-oriented school programs

Summary -- The Five-Year Public Education Program Should Be:

- Broad-based, with an overarching theme
- Appropriately targeted
- Flexible
- Cohesive
- Results-oriented

Program Evaluation

The NPDES Permit (Section VII.C.1) requires the Principal Permittee to evaluate the general success of the Five-Year Public Education Plan. While it may take years of water quality monitoring to see measurable changes resulting from public education efforts, this public education program must plan for and be able to show research indicating attitudinal change, shifts in behavioral intent and actual behavioral changes after the program is implemented.

This type of public education research can be conducted in a formalized, scientific manner (e.g., focus groups, telephone or intercept surveys) or through informal data collection (e.g., number of incoming phone calls). Regardless of the method utilized, the goal of research is to validate and fine-tune program components and outreach efforts; and, to adjust and enhance the Five-Year Plan on a regular basis in relation to what is working and what isn't in the various communities and target audiences.

♦ The Role of Evaluation

Marketing experts agree that research plays a vital role in both the development and measurement of any public education campaign. To ensure that campaign messages are focused in a manner that is meaningful and compelling to the target audiences, research during the development phase of the process should seek answers to key questions, such as:

- What messages are most likely to draw attention, be understood and resonate with residents and business owners?
- What messages carry a sense of importance and urgency?
- What information delivery medium, amount of repetition and combination of resources will produce the greatest influence on intended behavioral change?
- Countywide, what combination of messages and information will affect the greatest level of behavioral change?

Steps Involved in Changing Behavior

- Build Awareness
- Change Attitudes/ Generate Concern
- Change Intentions
- Change Behavior

♦ Laddering -- Putting Effort Where It Counts

Understanding where the messages will have the greatest impact and where they will have little or no impact is also critical to creating a cost-effective campaign. This can be achieved by conducting segmentation -- or laddering -- research. This type of research assesses the degree to which various groups of people are part of the problem, their susceptibility and suitability to different messages, and their willingness or lack of willingness to try new behaviors.

This type of knowledge paints a clearer and more concise picture of the audiences who are the most realistic targets for changing behavior. Those groups of people who test as "not willing to try" should not be targeted, as the expense involved would not be justified or results realized.

♦ Baseline Research

There are two existing pieces of comprehensive research that address measurement of stormwater education.

- ♦ *County of Los Angeles Stormwater/Urban Runoff Quality Management Program Initial Public Opinion Poll* (April 1995), The Sierra Group
- ♦ *City of Los Angeles Storm Drain Public Education Program Knowledge and Awareness Survey* (October 1993, February 1996), Fairbank, Maslin, Maullin & Associates

The County of Los Angeles research was a point-in-time assessment of awareness of the storm drain system, attitudes about environmental pollution and awareness of previous stormwater education efforts. It encompassed the County's English- and Spanish-speaking residents who were 18 years old and older, and had a sampling error of 2 percent.

The City research contained pre- and post-methodology and was designed to measure changes in public knowledge of basic storm drain facts. It included English- and Spanish-speaking residents who were 16 years and older and who lived within the Los Angeles City limits. This research has a sampling error of 4.4 percent.

Overview of Findings -- Existing County and City of Los Angeles Research

Overall, the two studies are similar in their approaches and in the questions used to assess levels of awareness and concern about stormwater issues.

The City study provides an interesting benchmark in that it includes 16 and 17 year olds -- a potentially important segment -- however, the sample is limited to residents within the City limits, not countywide. The County research also provides a good benchmark because, although it does not include the 16 and 17 year olds, it draws its sample from residents countywide.

Taken together, the surveys include many questions that can serve as benchmarks for tracking the progress of the Five-Year Plan. They also serve as a springboard for further research necessary for the Plan.

R0011874

We recommend the following issues be formed as questions and be added to the mix:

- Perceived importance of issues facing the community
- Belief that the waterways in Los Angeles County are polluted
- Awareness and recall of information about the storm drain system
- Sources of information on storm drains
- Stencil awareness
- Do-it-yourself activities
- Awareness of stormwater slogan
- Willingness to change behaviors
- Attitudes toward various pollutants

Recommendations Based on Existing County and City Research

We recommend that the following modifications be made to the existing surveys and implemented with respect to the Five-Year Plan evaluation:

- A meaningful baseline measure of behaviors targeted for change is absent from both studies. Neither of these studies ask direct questions about the actual behaviors we want changed. This team recommends future survey questions not be focused on awareness, but on actions that will be a measure levels of activities that threaten the quality of the County's stormwater.

- The idea of asking a question about whose responsibility it is to clean up pollution is a good one (City of Los Angeles); however, for the purposes of the Five-Year Plan, the question should focus on whose responsibility it is to make sure that trash and other materials don't go down the storm drains -- instead of whose responsibility residents think it is to clean up pollution in Santa Monica Bay or the Los Angeles River.

- Media (radio, television, newspapers) usage questions are better addressed through MRI data (standard advertising/advertiser data) rather than tracking survey data.

- Many of the questions included in both surveys deal with behaviors which some participants will likely not want to admit. The order in which questions are asked in this type of survey is critical to collecting accurate data. We recommend organizing the questionnaire so that the content of previous questions do not "clue" the interviewee as to bad or good answers on preceding questions or "lead" them into answering a certain way.

- For open-ended questions we would "group" responses into meaningful categories of information instead of reporting only individual responses.

- Additionally, information will be more meaningful if the data is segmented into groups of respondents who are more and less important to the campaign efforts (e.g., weekly beach goers -- those most likely to change their behavior -- as opposed to non-beach goers). These breakouts can be determined through the laddering research.

– The coding needs to be consistent between wave one and wave two. If the County uses one of the two previous studies as a benchmark, the team needs to obtain the coding structure in order for data to be comparable.

– During the City survey, participants were told the following facts: "In the City of Los Angeles, the storm drain system is separate from the sewer system. The storm drain system empties into the Santa Monica and San Pedro Bays. The water, which carries other substances through the storm drain system, is not treated or filtered before it reaches the bays. What flows through the storm drains can pollute the beaches and the ocean." The County may wish to give respondents this information at the end of the survey as education. However we do not recommend giving them this information prior to asking survey questions because it would clearly influence responses. Costs associated with reading the statement would be minimal.

– Business owners are an important target group for the upcoming campaign and need to be addressed in the evaluation research.

♦ Formalized, Scientific Methods of Evaluation

Marketers and educators know that the best laid plans are useless if they do not "speak to" those whose behavior they are intended to change. Using focus groups and/or one-on-one interview techniques give the target audiences an opportunity to react to preliminary ideas in terms of their motivational power. To the extent that some of the ideas are found to be ineffective, the *reason for* their ineffectiveness can be identified by the research and alternative approaches can be developed.

Methods of measuring the effectiveness of the campaign will also be tied to assumptions about the steps involved in behavioral change efforts:

- Are residents and business owners more aware of the problems related to stormwater/urban runoff after the campaign, e.g., four or five years following the launch in early 1997?
- Do residents and business owners believe that certain pollution-causing practices are improper after exposure to the campaign?
- Are residents and business owners implementing stormwater-safe behaviors/best management practices that will ultimately improve the water quality in the County's storm drain system?

Measurement Tools	What Is Measured
Focus Groups	Concept testing Strategy exploration
In-Depth Interviews	Materials assessment
Laddering	Values exploration Target audience segmentation
Shopping Mall Intercepts/One-on-One Interviews	Copy testing Communications refinement
Public opinion surveys	Campaign awareness Changes in attitudes and levels of concern with key issues Intention to change behavior Behavioral change

♦ Informal Methods of Evaluation

During the interviews with stormwater education program managers in other areas, it was found that several informal methods of evaluation have been used. While these interviews do not provide in-depth information, and in many cases, may not have a high degree of accuracy, they do provide some valuable insight.

The following summarizes the evaluation methods discussed:

- Tracking and counting the number of incoming phone calls on a published telephone number; noting differences in call volume after the phone number has been advertised or printed in a brochure
- Changes in the number of participants in community household hazardous waste round-ups
- Results of citizen volunteer water quality monitoring (typically a creek or local waterway)
- Citizen participation in stewardship grant efforts; requiring grant recipients to provide an evaluation of effectiveness at the conclusion of the grant work
- Documenting the attendance at events
- Changes in the results of inspections of businesses (a reduction in the number of violations would indicate better implementation of pollution prevention BMPs)
- Teacher's evaluations of school programs and results of students' tests or activities after participating in an education program
- Results of examinations taken by contractors and trade professionals that have taken BMP training

The County and Co-permittees must create a measurement and evaluation instrument that can demonstrate that the education program meets a requirement far beyond public awareness -- actual behavioral change.

While the challenges are formidable, the County and Co-permittees show great promise in having what it takes to develop and implement a public education campaign that not only achieves its goal of behavioral change, but can serve as a national model for successful public education programs in large geographic areas. First, everyone understands and believes in the need for public education; and second, the County and a number of municipalities, including the City of Los Angeles have already executed award-winning public education campaigns that have heightened awareness among media, influential business and political leaders, and segments of the general public.

The Five-Year Public Education Program Should Be:

Broad-based
with an overarching theme
Flexible
Coordinated
Results-oriented

All these reasons and resources provide the information and the incentive needed to build a public education program that is based on a solid communications strategy. But, ultimately, it will take the County's leadership and a strong partnership with the Co-permittees to create and implement a campaign that has enough impact to change human behavior so stormwater/urban runoff pollution *can* be reduced.

The key to developing a Five-Year Plan for a coordinated, comprehensive stormwater public education program is an understanding of the big picture in Los Angeles County --

its large and diverse population,
its history of water and land use issues,
the issues within and across the boundaries of
Watershed Management Areas,
and the NPDES Permit requirements.

- Assessing the value of "in-kind" or financial donations received from grants and/or corporate sponsors

- The number of businesses that participate in "Ocean Safe Coalitions" or take training to get involved in other BMP-related programs

- Number of positive stories placed in newspapers, television, radio

- The number of ordinances sponsored by the public to require stormwater/urban runoff pollution prevention measures (i.e., picking up dog waste)

Section 3: Summary of Pollutants by Watershed Management Area Within Los Angeles County

A well-targeted stormwater/urban runoff public education campaign prioritizes pollutants of concern, land uses and associated target audiences so that the education program results in the highest pollutant reduction per unit cost. According to the 1996 NPDES Permit issued by the California Regional Water Quality Control Board/Los Angeles Region, pollutants of concern in stormwater/urban runoff vary considerably throughout the County, depending upon hydrology, geology, land uses, weather patterns, and storm events. Chapter V of the Permit recommends that the Five-Year Public Education Plan target pollutants and the audiences that typically create them. Therefore, this report examines the many sources of information about pollutants in Los Angeles County stormwater/urban runoff including the following:

Pollutants Most Frequently Associated With Stormwater (Source: 1993 *California Stormwater Best Management Practices Handbook*)	Pollutants Found in Every County WMA (Source: L.A. County Dept. Of Public Works water monitoring records)	Pollutants Found in the County's Water Bodies (Source: RWQCB, 1996 *Draft Findings of Assessment*)
♦ sediment ♦ nutrients ♦ bacteria ♦ oxygen demanding substances, ♦ oil and grease ♦ heavy metals ♦ other toxic chemicals ♦ floatables including litter and debris	♦ heavy metals ♦ polycyclic aromatic hydrocarbons (PAHs) ♦ bacteria/coliform ♦ sediment ♦ litter/debris ♦ biochemical oxygen demand (BOD) ♦ oil and grease ♦ nutrients ♦ other toxic materials (pesticides, chlorine, etc.)	♦ heavy metals ♦ coliform ♦ enteric viruses ♦ pesticides ♦ nutrients ♦ PAHs ♦ polychlorinated biphenyls (PCBs) ♦ organic solvents ♦ sediments ♦ trash and debris ♦ algae and scum ♦ odor

Several studies have been conducted locally and nationally to identify potential sources of the pollutants detailed above. The following table describes the activities that typically generate the stormwater pollutants discussed above.

Residential Activities	Commercial/Industrial Businesses	New Development/ Construction Activities
♦ automobile use and maintenance ♦ do-it-yourself home improvements and maintenance ♦ landscaping and gardening ♦ pet waste ♦ septic tanks or sewer leaking ♦ littering	♦ automobile services ♦ food service industry ♦ fabricators and manufacturing ♦ building maintenance ♦ landscaping/landscape maintenance ♦ operation/maintenance of fuel burning equipment ♦ dumpster ♦ littering	♦ construction trades: painting, plumbing, electrical, etc. ♦ operation/maintenance of fuel burning equipment ♦ clearing/grubbing, earthwork, and grading ♦ landscaping/landscape maintenance ♦ portable toilets and dumpsters ♦ storage of materials ♦ littering

R0011880

Pollutants by Watershed Management Area (WMA)

The 1996 NPDES Permit approved by the Regional Water Quality Control Board/Los Angeles Region promotes a "Watershed Management Approach" to protect and enhance water resources. By working together, regulatory agencies, Co-permittees, environmental groups, and other stakeholders may achieve the greatest environmental improvements within each watershed and the entire County with the resources available to all participants.

Los Angeles County Watershed Management Areas (WMA)

Malibu Creek	Ballona Creek	Los Angeles River	Dominguez Channel/Los Angeles Harbor	San Gabriel River	Santa Clara River
Agoura Hills Calabasas Malibu Westlake Village Los Angeles County	Beverly Hills Culver City El Segundo Hermosa Beach Los Angeles Manhattan Beach Palos Verdes Estates Rancho Palos Verdes Redondo Beach Rolling Hills Rolling Hills Estates Santa Monica West Hollywood Los Angeles County	Alhambra Arcadia Bell Bell Gardens Burbank Commerce Compton Cudahy El Monte Glendale Hidden Hills Huntington Park La Canada-Flintridge Long Beach Lynwood Maywood Monrovia Montebello Monterey Park Paramount Pasadena Rosemead San Fernando San Gabriel San Marino Sierra Madre Signal Hill South El Monte South Gate South Pasadena Temple City Vernon Los Angeles County	Carson Gardena Hawthorne Inglewood Lawndale Lomita Torrance Los Angeles County	Artesia Azusa Baldwin Park Bellflower Bradbury Cerritos Claremont Covina Diamond Bar Downey Duarte Glendora Hawaiian Gardens Industry Irwindale La Habra Heights La Mirada La Puente La Verne Lakewood Norwalk Pomona Pico Rivera San Dimas Santa Fe Springs Walnut West Covina Whittier Los Angeles County	Santa Clarita Los Angeles County

Based on the Water Quality Assessment, combined with the County's historic monitoring record and past work conducted by Santa Monica Bay Restoration Project, specific groups of pollutants in each WMA can be targeted for focused public education and outreach.

The table below indicates in broad terms pollutants of concern for each of the WMAs and is based on the 1996 *Draft Water Quality Assessment* by the RWQCB. The data that currently exists only tells if a particular pollutant has been detected -- not how much or how little of it is present, or if the quantity of that pollutant is harmful to the environment. Monitoring data that will be available in approximately two years will enable pollutant loads to be calculated for each WMA. The pollutant load projections will allow for a more accurate method of identifying and quantifying the most problematic pollutants.

Overview: Pollutants of Concern Found in Water Bodies in Each Watershed Management Area[6]

	Malibu Creek WMA	Ballona Creek WMA	Los Angeles River WMA	San Gabriel River WMA	Dominguez Channel WMA	Santa Clara River WMA
Heavy Metals	x	x	x	x	x	x
PAHs		x	x	x	x	
Bacteria/Pathogens	x	x	x	x	x	x
Sediment/TSS, TDS	x	x	x	x	x	x
BOD	x	x	x	x	x	x
Nutrients	x		x	x		x
Oil and Grease		x	x			
Litter/debris	x	x	x	x		
Other Toxic Material		x	x	x	x	x

Listed on the following pages are the pollutants of concern historically detected in the watersheds of Los Angeles County. This information was published in the *Report of Stormwater Monitoring -- Winter 1994 - 1995* (Los Angeles County Department of Public Works, Environmental Programs Division, March 1996). Also listed are the pollutants of concern that were detected in major bodies of water in Los Angeles County. The Regional Water Quality Control Board/Los Angeles Region included this information in the draft *Water Quality Assessment 1996* which was prepared for the Basin Plan.

Samples in the County's earlier monitoring program were not analyzed for the presence of pesticides; therefore, they are not included in the historic record. However, as a result of the July 1996 NPDES Permit, monitoring and laboratory work have been expanded substantially, and it is anticipated that additional pollutants, including pesticides, will be detected in the future.

R0011884

Typical Sources of Pollutants

There are certain everyday activities that residents, business people and the construction industry do that generate the types of pollutants detected in the County's stormwater and urban runoff. The following table indicates the activities and commonly used products and materials that contain the pollutants that enter the storm drain system.

	Residential	Commercial/ Industrial	New Development/ Construction	Other
Heavy Metals				
Chromium	♦ Exterior paints and stains ♦ Auto use	♦ Paint ♦ Metal corrosion	♦ Cleaning products ♦ Exterior paints and stains	--
Copper	♦ Gardening products ♦ Root killers ♦ Auto use	♦ Auto services ♦ Metal fabricators ♦ Anti-fouling paints ♦ Manufacturing (e.g., electroplating) ♦ Fertilizers	♦ Cleaning products ♦ Plumbing materials ♦ Electrical wiring materials ♦ Wood preservatives	♦ Water supply
Lead	♦ Paint ♦ Batteries ♦ Auto use	♦ Auto Services ♦ Paint	♦ Plumbing materials ♦ Electrical wiring materials ♦ Paint	♦ Water supply
Nickel	♦ Auto use	♦ Metal plating ♦ Industrial uses		♦ Water supply
Zinc	♦ Roof runoff (galvanized) ♦ Paint ♦ Auto use	♦ Galvanizing ♦ Auto repair ♦ Paint ♦ Metal corrosion	♦ Plumbing materials ♦ Galvanized metals ♦ Venting systems ♦ Paint and pigments ♦ Wood preservatives	♦ Water supply
PAHs	♦ Motor oil dumping ♦ Oil leaks and spills ♦ Auto use	♦ Oil leaks and spills ♦ Fuel and oil combustion	♦ Oil leaks and spills ♦ Fuel and oil combustion	♦ Natural oil seeps ♦ Brush fires
Bacteria	♦ Pet waste ♦ Septic tank or sewer leaks ♦ Illegal connections ♦ Organic waste (from landscaping, etc.)	♦ Food waste ♦ Organic waste	♦ Portable toilets	♦ Wildlife

	Residential	Commercial/ Industrial	New Development/ Construction	Other
Sediment/Total Suspended Solids	♦ Erosion, landscaping ♦ Pavement wear	♦ Dust and dirt	♦ Grading, earth work ♦ Materials storage	♦ Natural erosion
Biochemical Oxygen Demand (BOD) Debris	♦ Landscaping, plant debris ♦ Pet waste ♦ Litter ♦ Other organic matter	♦ Landscaping, plant debris ♦ Litter ♦ Dumpsters	♦ Clearing and grubbing ♦ Landscaping, plant debris ♦ Litter ♦ Portable toilets ♦ Dumpsters	♦ Natural Vegetation
Nutrients	♦ Detergents ♦ Fertilizers ♦ Organic matter, lawn clippings and leaves ♦ Auto exhaust ♦ Manure	♦ Detergents ♦ Facility cleaning ♦ Fertilizers	♦ Landscaping graded areas, fertilizing	♦ Natural erosion ♦ Air depletion
Oil and Grease	♦ Waste oil dumping	♦ Auto services ♦ Restaurants ♦ Vehicle and machinery maintenance, oil leaks and spills	♦ Vehicle and machinery maintenance, oil leaks and spills ♦ Exposed materials storage	
Other Toxics	♦ Household toxic products ♦ Auto use and maintenance ♦ Paint ♦ Gardening and landscaping (pesticides and herbicides)	♦ Manufacturing ♦ Landscape maintenance (pesticides and herbicides)	♦ Adhesives ♦ Paint ♦ Fuels, equipment use and maintenance ♦ Materials storage ♦ Landscaping (pesticides and herbicides)

Conclusions

There is not enough monitoring data currently available to narrow the list of pollutants for a public education program that targets specific contaminants by watershed management area. However, the recent work of the County, Regional Water Quality Control Board and Santa Monica Bay Restoration Project indicates that the following pollutant groups should be included in targeted public education:

- Heavy metals
- Oil and Grease/PAHs
- Sediment
- Oxygen Demanding Substances
- Litter/Trash/Debris
- Nutrients
- Other Toxic Materials, such as pesticides

Additionally, the activities that generate these pollutants should be the focus of targeted public education. Until more detailed monitoring data is available, and stormwater pollutant loads can be calculated for each watershed management area, the following everyday activities should be targeted.

Residential Activities	Commercial/Industrial Businesses	New Development/ Construction Activities
♦ automobile use and maintenance ♦ do-it-yourself home improvements and maintenance ♦ landscaping and gardening ♦ pet waste ♦ septic tanks or sewer leaking ♦ littering	♦ automobile services ♦ food service industry ♦ fabricators and manufacturing ♦ building maintenance ♦ landscaping/landscape maintenance ♦ operation/maintenance of fuel burning equipment ♦ dumpster ♦ littering	♦ construction trades: painting, plumbing, electrical, etc. ♦ operation/maintenance of fuel burning equipment ♦ clearing/grubbing, earthwork and grading ♦ landscaping/landscape maintenance ♦ portable toilets and dumpsters ♦ storage of materials ♦ littering

School education should emphasize stormwater/urban runoff public education in ways that facilitate students' passing along better habits to their parents/caregivers and that provide the foundation for nonpolluting habits as children grow into adulthood. Student education should focus primarily on BMPs associated with residential activities.

Lastly, municipal employees should incorporate BMPs associated with both commercial/industrial and new development/construction activities to their everyday work habits. This enables the County and Co-permittees to:

- reduce their own contributions to stormwater/urban runoff pollution;
- serve as role models for others in the county; and,
- empower municipal employees to pass along their own experiences/successes with BMPs to the public they encounter during work.

Section 4: Analysis of Co-permittee Programs

Interviews With Co-permittees

Telephone interviews were conducted in July, August and September 1996 with 58 of the 85 Co-permittees to solicit the following information:

- What individual cities have been doing to date to educate constituents about stormwater/urban runoff issues
- The unique needs of the cities as they apply to stormwater public education (e.g., multiple language materials)
- Local issues and insights for the Five-Year Plan

Each interviewee was asked the same six questions. These questions formed the core of the interview and were used as a starting point for an open dialogue. Interviewees were encouraged to elaborate on their responses to the questions and to freely offer all information they felt important to share. The core six questions were:

1) Who are the appropriate target audiences for stormwater/urban runoff public education in your city?

2) What stormwater pollution prevention public education resources/materials and programs are already available and being used in your city? How are they distributed/implemented? How long have they been out? Do you consider them effective?

3) Are there existing city newsletters, local access TV, or other methods of communications that could include stormwater messages?

4) What materials/programs would you like to see developed in the Five-Year Plan that would be particularly helpful to your city?

5) With respect to the public education element of the NPDES Permit, what will pose the most difficult challenge(s) to you as the stormwater program manager?

6) Are there any specific stormwater-related issues in your city that you would like the County and the stormwater team to keep in mind as the Five-Year Public Education Plan is developed?

Overall there is strong support among the Co-permittees for the public education component of the NPDES Permit. In addition, there is interest in unifying the public education messages and materials on a countywide basis to ensure continual and consistent reinforcement of positive pollution prevention behaviors regardless of the recipient's geographic location. In varying degrees of concern and importance, the public education managers discussed (1) lack of funding; (2) limited staff resources; (3) ethnic diversity of residents; (4) community geographic location and its bearing on the receptivity to messages; (5) success or lack of success of existing programs; (6) "wish list" programs; and, (7) and evaluation methods.

The following findings and comments came from the interviews and are applicable to current situations within each city and hold implications for the Five-Year Plan.

♦ Target Audiences

Target audiences cannot always be contained within a specific city or Watershed Management Area. On a daily basis, people travel from area to area, city to city, even county to county, for business, recreation and home.

Eighty-one percent (81%) of the Co-permittees identified the ***general public*** among their most important target audiences because they are the largest contributors to the countywide pollution problem. Eighty-three percent (83%) said that ***commercial businesses/industries*** were equally important. There is a strong interest in protecting the interests of businesses; making certain that stormwater pollution management does not cause loss of business or jobs, or weaken an already tenuous business climate.

School children were identified by 55 percent (55%) of the Co-permittees as important targets because of the ability to incorporate messages into existing school curriculums, children's natural interest in their surroundings, and the fact that children are a source of education when they carry information and questions home to their parents.

Schools are overwhelmed with requests for teachers to educate students about many different environmental and social issues. In order to compete with other programs trying to get into schools, stormwater school education materials and activities must be what teachers really need -- broad environmental information without agendas or partisan approaches, application to specific age groups, integration into several subjects, strong supporting activities and easy resources for additional information.

Countywide, Co-permittees indicated little interest in ***municipal employees*** and ***new development/construction*** target audiences for stormwater public education despite the fact that the Permit requires targeting these audiences. However, some Co-permittees recognized that municipal employee training was key to "having our house in order" and providing a model for the rest of the County's population. It should be noted that when the Alameda County public education program was kicked off, it did not have a municipal employee BMP training program. This omission created an initial negative impression that had to later be corrected in order to regain credibility.

With regard to the new development/construction target audiences, some Co-permittees were more concerned about their smaller remodeling and in-fill projects than about the larger construction jobs planned for the communities. The primary reason is that BMPs are well-developed for the larger jobs, and stormwater pollution prevention design measures are available for projects that have ample acreage. But smaller projects, which are often confined to sites as small as a single city lot, have significantly fewer BMPs and fewer design options to help them comply with stormwater/urban runoff prevention regulations. BMP development for situations such as this should be addressed with Co-permittees, contractors and the development field countywide.

Special needs audiences within some of the broader categories that have unique needs include landscape maintenance businesses, low-income and illiterate residents, and livestock owners. Co-permittees expressed an interest in having programs that target these special groups and other small businesses.

♦ Unified, "Corporate" Look

There also was consistent support for developing public education materials with a unified, corporate appearance. Approximately one-third of all Co-permittees interviewed mentioned their interest in this component of the Five-Year Plan.

A unified look will identify any stormwater/urban runoff materials and their own special entity and will set the tone and feel for the entire communications program. Once established, the unified look will become the way all targeted audiences instantly can identify the program and know that the information contained within relates specifically to solutions for stormwater pollution. Many of the Co-permittees also commented stormwater/urban runoff messages would be reinforced if the public saw a unified program on a countywide basis.

♦ Cost-Effective, Easy Production and Implementation

There is strong interest in a program that is "turn-key," considering limited staffing and funds available to many Co-permittees. There should be opportunities for cities to individualize materials that are prepared and distributed on a countywide partnership basis. For example, computer disks of artwork could be provided so that Co-permittees can incorporate their own contact names and telephone numbers.

Co-permittees discussed the viability of pooling information, vendor and funding resources to produce professional videos and advertising to get their umbrella theme and messages across to the public. Collaboration between existing stormwater public education programs is necessary to avoid duplication of efforts and to take advantage of good, existing materials while working jointly on future materials.

Integration of stormwater public education with other environmental and pollution prevention programs that already are in place (e.g., solid waste and waste oil recycling programs) is a logical step and an economical use of cities' resources in several departments.

In some communities, the Chambers of Commerce have joined efforts to help. Specifically, one chamber facilitated input from local businesses (e.g., architects and developers) as stormwater public education materials targeted to those businesses were being developed. In another, the Chamber hosted presentations given by the County Department of Public Works. Many opportunities exist throughout the County to utilize more organizations (e.g., business and trade associations, networking groups) as avenues of distribution with systems and audiences already in place.

♦ Information Distribution Methods

Sixty percent (60%) of the interviewed Co-permittees currently distribute brochures and/or posters originally prepared by the County or City of Los Angeles. Most distribution is accomplished by placing materials on public counters for easy pick up. However, as noted in Section 2, concern was expressed that the materials generally were not being picked up and when they were, there was no way to know if they were read or used.

Several Co-permittees felt that too many different brochures are being printed, utilizing too many natural resources for the return in public education value. Further discussion should be held on whether collateral materials are the best means of communications, or whether other, more efficient methods should be used to reach the Los Angeles County audiences.

More than 75 percent (75%) of the cities have newsletters and a cable access television channel, but an average of less than half have used either of these media for stormwater public education.

Co-permittees believe the obstacle with cable access television is that it is viewed by a very small portion of the overall community population and therefore is not an efficient use of limited funds. However, several interviewees suggested running a scrolled message about stormwater pollution on all the community cable stations across the County -- the same message, simple graphics, no video pictures, no/low production cost, wide distribution.

Several Co-permittees expressed an interest in a catchy Internet homepage that would be applicable to school children in the classroom and the growing portion of residents who "surf the Internet." According to a national report published in the September 23, 1996 *Los Angeles Business Journal*, the greater Los Angeles area is one of the most active users of the Internet. "Los Angeles is an Internet city. It's on the information superhighway," said Sky Dayton, chairman and chief executive officer of EarthLink Network, Inc.

R0011891

Co-permittees in some cities have recruited students and Eagle Scouts to distribute materials with varying degrees of success. They found that high school students are good peer educators because they find meaning in the work and, as their peers, other students are more willing to listen to and believe them.

Other methods of distribution utilized by the Co-permitees in varying degrees and with varying successes include school programs, community and environmental events, media relations and advertising.

Finally, the Co-permittees wanted the telephone hotline number to be restructured so that the countywide public need only to call one phone number.

♦ Cultural Diversity and Languages

There was a consistent recognition of the need for public education materials and strategies that accommodate non-English speaking audiences. Approximately one-third of all of the Co-permittees mentioned that their constituents spoke languages other than English.

While Los Angeles County has a widely diverse population, public education materials and strategies should avoid using cultural stereotypes that may not be appropriate or appreciated by the ethnic community[9].

♦ Best Management Practices

Best Management Practices brochures should be developed that can be used countywide. These need to be industry-specific and give enough information for audiences to implement changes that are logical and simple, yet significant. The specific targets of BMP materials should be carefully assessed. For example, in a restaurant, who actually has the greatest potential to dump oil and grease improperly? Is the appropriate target the kitchen workers, their supervisors, the restaurant manager or owner, or the property owner?

When talking about targeting and distribution of BMPs for "do-it-yourself" oil changes, an example of a weak target is residents of financially upscale communities who generally do not change their own oil. This is a function performed by automobile service businesses and these businesses, not the residents, should be the primary target of this type of education in certain communities.

In most cases, businesses need financial incentives to comply with Stormwater Best Management Practices. A possible incentive is to offer reduced business license fees for implementation of BMPs. While there currently are few working models of this incentive program, it has been discussed by several cities in California and other states. One example is Santa Clara County, which has reduced industrial permit fees for attending workshops conducted by the County, and then conducting self-audits.

[9] See Section 5, Cultural Issues.

R0011892

In another example, Manhattan Beach businesses are rewarded for their "Ocean Safe" plans with recognition by the City Council and identification stickers for their store windows.

Landscape workers were noted as an important group to include in Best Management Practices training. However, their clients should also be included in the training to ensure that they understand the workers' efforts and that environmental practices are correct and according to appropriate policy; and not mistaken as doing the job wrong.

♦ Inland Communities

Inland communities said that the Five-Year Public Education Plan and the printed materials should reflect not only the County's bays and beaches, but also rivers and creeks upstream. In fact, some of these communities said that materials that focused only on beaches and bays would alienate their constituents who rarely go to the beach. One of the messages used in the inland communities is neighborhood or city beautification.

By the same token, the Five-Year Plan should take into consideration the fact that stormwater pollution occurring upstream adds to the challenges for communities downstream. These communities not only have to provide public education related to the stormwater pollutants that are generated in their city limits, but also have to deal with the problems that flow from sources upstream.

An example of upstream pollution floating down is the City of Long Beach which continually deals with litter and sediments that blight the shipping channel from up-river pollution.

Public education materials need to be universal in consideration of the other water bodies involved. In Los Angeles County, there are rivers, creeks, lakes, harbors, beaches and bays -- not just beaches and bays.

♦ Needs and Issues by Watershed Management Areas

During the interviews, Co-permittees provided many insights based on personal experience with the target audiences, needs and issues within Watershed Management Areas.

WMA	Target Audiences	Needs	Issues
Malibu Creek	33% said materials in languages other than English are needed 33% said there were special needs in the city (e.g., landscape maintenance services) 33% many restaurants and/or automobile-related businesses	33% needed technical assistance related to training	33% concerned about being able to measure effectiveness 33% short on staffing and want easy implementation 66% stressed interest in school programs
Ballona Creek	11% ethnicity is important consideration 11% materials in other languages are needed 44% special needs (e.g., horse owners, low income, illiteracy, landscape maintenance)	11% needed technical assistance re: BMPs 22% needed technical assistance re: training 11% want to combine environmental issues (e.g., recycling, waste oil) 33% unified countywide approach 11% want polished looking materials 11% want easy-to-understand and to practice materials 22% need more information re: educational visits	44% concerned about measuring effectiveness 33% short on staffing and want easy implementation 11% short on funding 11% worried about alienating local businesses

Note: Percentages reflect the frequency that select comments were received. They do not necessarily add up to 100%.

WMA	Target Audiences	Needs	Issues
Los Angeles River	38% ethnicity is important consideration 24% materials in languages other than English are needed 24% special needs (e.g., horse owners, low income, illiteracy, landscape maintenance)	19% beach/ocean focus in materials will turn-off residents 5% need technical assistance re: BMPs 14% need technical assistance re: training 14% want to combine environmental issues (e.g., recycling, waste oil) 5% unified countywide approach 5% want ability to insert city's name/logo on materials 5% want polished looking materials 10% want videos 14% want easy-to-understand and to practice materials	10% concerned about being able to measure effectiveness 19% short on staffing and want easy implementation 14% short on funding
San Gabriel River	30% ethnicity is important consideration 40% materials in languages other than English are needed 10% special needs (e.g., gangs)	20% beach/ocean focus in materials will turn-off residents 10% need technical assistance re: BMPs 20% need technical assistance re: training 30% want to combine environmental issues (e.g., recycling, waste oil) 40% unified countywide approach 10% want ability to insert city's name/logo on materials 20% want polished looking materials 10% want videos 20% need more information about educational visits 10% want a business incentive program	10% concerned about being able to measure effectiveness 10% short on staffing and want easy implementation 20% short on funding 30% worried about alienating local businesses 10% suggested pursuing funding grants for the Five-Year Plan 10% expressed strong interest in school programs

WMA	Target Audiences	Needs	Issues
Santa Clara River		Beach/ocean focus in campaign materials will turn-off residents Need technical assistance re: training	Concerned about being able to measure effectiveness Is short on staffing and want easy implementation
Dominguez Channel/Los Angeles Harbor		10% need technical assistance re: BMPs 10% need technical assistance re: training 10% want to combine environmental issues (e.g., recycling, waste oil)	10% concerned about measuring effectiveness

♦ Program Evaluation

While most Co-permittees do not have an effective method for measuring the results of their public education campaigns, they are interested in knowing what can be done to measure their success or lack of success. Of the 58 Co-permittees interviewed, 18 felt -- without being able to conclusively prove -- that their programs were effective. They based these "feelings" on informal information like the number of brochures/information picked up, the increased number of telephone calls to a specific number and increased participation in household hazardous waste roundups. One program tried a more formalized method to evaluate success and distributed materials to residents with tear-off response cards to complete and mail back. The number of cards returned has been very low -- 25 completed cards from a mailing of 1000. This represents a two percent (2%) response rate which is considered by direct mail experts as the lowest acceptable response level. This may not, however, reflect the effectiveness of the communications effort.

Target Audiences by Watershed Management Area

The following table details the level of interest expressed by the Co-permittees in each WMA[10] for information by target audience.

Co-permittee Priorities For Materials By Targec Audience

Malibu Creek	Ballona Creek	Los Angeles River	Dominguez Channel/Los Angeles Harbor	San Gabriel River	Santa Clara River
100% Gen. Pub. 66% Comm. Bus./Industries 0% New Dev./ Construct. 33% Schools 33% Municipal Employees	89% Gen. Pub. 78% Comm. Bus./Industries 22% New Dev./ Construct. 33% Schools 22% Municipal Employees	86% Gen. Pub. 95% Comm. Bus./Industries 38% New Dev./ Construct. 57% Schools 19% Municipal Employees	100% Gen. Pub. 33% Comm. Bus./Industries 0% New Dev./ Construct. 33% Schools 0% Municipal Employees	70% Gen. Pub. 70% Comm. Bus./Industries 0% New Dev./ Construct. 50% Schools 10% Municipal Employees	General Public Commercial Businesses/ Industries Schools

Gen. Pub. = General Public
Com. Bus./Industries = Commercial Business/Industries
New Dev./Construct. = New Development/Construction

[10] See Section 3 for complete listing of cities within each WMA

Materials, Distribution Methods and Effectiveness by WMA

The following table represents a summary of responses from the Co-permittees regarding their methods and successes with materials and information distribution avenues. The numbers in parenthesis are the number of Co-permittees in the Watershed. When reviewing the percentages reflected in this table, please note the total cities counted. For example, 25% of a watershed with four cities equals only (1) one city.

	Malibu Creek (4)	Ballona Creek (13)	Los Angeles River (32)	San Gabriel River (28)	Dominguez Channel/ LA Harbor (7)	Santa Clara River (1)

R0011898

Section 5: Cultural Issues

Defining the Populations

Los Angeles County's population is evolving at a rapid pace, with a marked pattern of increased racial and cultural diversity that will continue through the next five years -- and into the next century. For example, the County's Latino population, already well past 2 million, is growing rapidly as evidenced by the school population: currently, more than 65 percent of Los Angeles County kindergartners and 58 percent of all County school children are Latino. And according to the latest U.S. Census, Latinos and Asian/Pacific Islanders (APIs) are the fastest-growing populations in the County, with the growth rate in each group increasing at a rate of 50 to 100 percent per year.

Clearly, these diverse populations will be on the receiving end of stormwater/urban runoff education. Their increasing population alone, and their participation in target businesses such as restaurants, automotive services and landscaping validates further research into cultural nuances and possible messages that may need to be communicated these groups.

♦ County Demographics (18 years and older)

According to the 1990 U.S. Census, the adult population of Los Angeles County is:

African American	677,767
Latino	2,346,893
White	2,864,306
Other	88,075
Total	**5,977,041**

Note: the above numbers reflect the vast undercount of Asian Pacific Islanders in the Census. This is largely attributed to lack of participation because of language and cultural barriers, and lack of understanding of the importance of Census participation. The U.S. Census was used instead of the California Department of Finance because, until 1996, the Department of Finance did not include Asian Pacific Islanders in their projections.

The 1990 U.S. Census shows the County's total API population (all ages) at nearly more 1 million people, or 10 percent of the total population. Subgroups[11] of the larger API population include:

Chinese	25.7%	Japanese	13.6%
Filipino	23.0%	Vietnamese	6.6%
Korean	15.2%		

[11] These percentages reflect only the larger API subgroups

Communicating to Ethnic Audiences

The following section summarizes existing issues and conditions in Los Angeles County that are crucial to public education and outreach to diverse ethnic groups. Specifically, this section:

- Identifies issues that are important to the County's various ethnic communities

- Identifies key community leadership/messenger positions that must play a major role in any public education and outreach efforts to ethnic groups

- Identifies L.A. economic conditions that have affected minority residents and have caused a strong emphasis on survival issues among the County's minority communities. These conditions make it even harder for businesses to be concerned with environmental issues

- Contains information about the importance of interpretation and adaptation -- rather than mere translation -- to non-English speaking groups, and the importance of messages that are relevant to specific cultures

- Summarizes public awareness surveys conducted for the Los Angeles County Department of Public Works in 1995 and 1996 that relate how environmental information is received by various ethnic groups and preferred methods for outreach

Developing Program Messages

♦ Key Messages, Communication Vehicles & Special Issues

Stormwater public education messages will be effective to the degree that research is conducted and baseline information is used to identify key messages and messengers. To be successful, any messages targeting these groups need the endorsement and active involvement of local ethnic leaders who are critical models for Latino, African American and Asian/Pacific Islanders individuals and businesses. Our focus should include:

- Local business and community leaders
- Community-based organizations
- Local news media, including foreign language media
- Local elected and appointed officials

Moreover, further research is warranted regarding the way messages are delivered so they are meaningful to these target audiences. For example, program messages may include "neighborhood pride" for residents, "good-for-business/better business environment" for small businesses and "stewardship of resources" for church-based organizations. These messages may be better received in Latino, African American and Asian/Pacific Islander communities than traditional environmental approaches.

Some studies show that recent Latino and API immigrants tend to bring a weak environmental ethic from their former homes and may require education that is properly aimed at their needs and values. Conversely, acculturated immigrants and first and second generation populations may gain as much or more from a general public campaign than one targeted to their ethnic community.

Non-English language research is necessary to ensure that non-English language messages are received as they are intended and are most appropriate for the audiences. From all indications, clear, concise messages that consider idiomatic differences in language may also be crucial for ethnic groups. For example, when Kentucky Fried Chicken tried to translate its slogan "Finger Lickin' Good" for advertising in Taiwan, it came out "Bite Your Fingers Off."

In another example, the term "environment" for many minority communities may be understood as "environmental justice" -- a highly sensitive connotation to these audiences. Vice President Al Gore discussed environmental justice as follows: "...environmental burdens are disproportionately placed on disadvantaged and minority communities." For this reason, environmental issues will need to be positioned with sensitivity to communities that have been or will be the focus of construction-oriented outreach. For example, communities that have become sensitized regarding "environmental justice" are those affected by the construction of the Blue Line Light Rail, Pacific Pipeline, the Alameda Corridor Project, and in the San Gabriel Valley, the presence of Superfund groundwater sites.

In all materials, words and visuals must be culturally sensitive. During interviews with Co-permittee stormwater managers conducted for this study, one Co-permittee commented that, even though research has shown many Latinos are "do-it-yourselfers," presenting this scenario in public education materials has often been interpreted by the Latino community as a negative.

In addition, for APIs, the campaign must consider the language and cultural differences among the various subgroups if multiple language materials and outreach are to be developed -- this is not a homogenous group.

♦ Businesses

Minority-owned small business and their operational practices represent a full range of environmental protection measures -- from the best to the less than successful. Because the County and City of Los Angeles consistently rank first in the number of small businesses owned by Latinos, African Americans and Asian Pacific Islanders, these business owners are important targets to receive stormwater/urban runoff campaign messages.

In many cases, employment -- and sheer survival -- are the urgent issues for these businesses. These businesses may be poorly capitalized and their profit margins quite slim. This and other data indicates that environmental messages will be best received when they are directed at the positive affects on the economy of individual businesses.

Current Level of Stormwater/Urban Runoff Awareness

The Sierra Group conducted a public awareness survey of stormwater/urban runoff issues for the County of Los Angeles. The research included the ways various groups receive information.

	Overall	Asian/ Pacific Islanders	African American	Latino	White	Other
Newspapers	63%	68%	59%	55%	73%	64%
Broadcast T.V.	63%	66%	65%	72%	55%	61%
Radio	24%	23%	18%	27%	22%	24%
Cable T.V.	15%	14%	18%	13%	15%	19%
Magazines	12%	11%	10%	10%	14%	12%
Brochures	6%	5%	9%	6%	5%	7%
Newsletters	6%	5%	6%	5%	6%	6%
Billboards	5%	6%	8%	5%	4%	8%
School Child	4%	2%	4%	4%	3%	5%
Other	4%	7%	4%	3%	5%	5%
Don't know/NA	0%	0%	0%	0%	0%	0%

Ethnic language newspapers, television and radio are key to reaching large culturally and linguistically isolated segments of the County's population. The City of Los Angeles has a recent experience to prove the point -- recent success in a public service announcement program prepared for Spanish-language radio stations was a significant success.

Spanish radio stations also have been shown to be an effective medium to communicate information related to BMPs on automobile maintenance to this population segment. For example, the Marketing Research Survey of "Do-it-Yourselfers" conducted by The Sierra Group with Godbe Research and Analysis indicates that almost 75 percent of Spanish-speaking males in the survey changed their own oil. It also concluded that this audience listens to Spanish radio stations.

R0011903

Section 6: Review of Public Education Materials and Programs Conducted In Other Parts of The Country

Background

Stormwater and pollution prevention public education materials were requested for this research report from agencies and organizations located throughout the United States. Nearly 500 brochures, flyers, door-hangers, videotapes, school programs, posters, bumper stickers, and various guides and manuals were received from 25 states. Discussions in this section focus on materials received from the San Francisco Bay, Puget Sound, the Great Lakes, Massachusetts Bay, Narragansett Bay, Chesapeake Bay, the Florida coastline, and the Gulf of Mexico. Materials were also received from non-coastal communities in Arizona, Colorado, Iowa, and Texas. More detailed information about programs within the Southern California region is included in Section 4.

The audiences for the major programs that were examined varied between 500,000 and 14.2 million. Only Chesapeake Bay's program involves more people than the County of Los Angeles' 9 million residents.

	Population
♦ Chesapeake Bay Area	14,200,000
♦ Los Angeles County	9,000,000
♦ Los Angeles, California	3,500,000
♦ Dade County, Florida	2,000,000+
♦ Santa Clara County, California	1,700,000
♦ King County, Washington	1,600,000
♦ Alameda County, California	1,350,000
♦ Seattle, Washington	500,000
♦ San Francisco, California	750,000
♦ Milwaukee County, Wisconsin	650,000
♦ Greenville, Texas	18,000

Internet, Chesapeake Bay Program

Summary of Observations: Overall Programs

There is an abundance of materials being disseminated by programs throughout the United States, some of which are outstanding and will be very useful to the Los Angeles County program. However, many of the materials are too regionally oriented or too technical to fit the countywide program. Additionally, this team's evaluation found the programs and strategies from other programs extremely interesting; but the individual materials were not as strong as some of those we found in California. Specifically, we felt the graphics and text could have been stronger for the adult populations. Our exception to this observation was the materials for children, which were very good. Following are specific observations:

- Multiple jurisdictions are involved in most major stormwater programs and while the Chesapeake Bay program targets a larger population, none have as many Co-permittees or partnerships as the Los Angeles County program. For example: The Chesapeake Bay program involves three states, Washington D.C. and four agencies; the Milwaukee (Great Lakes) program targets 27 cities; the Alameda Countywide program has 14 Co-permittees; the Puget Sound is the focus of at least five public education programs conducted by King County, the Puget Sound Water Quality Authority, and the Cities of Seattle, Bellevue and Olympia.

- No stormwater/urban runoff program has yet to discover the message/concept that is equivalent to the "3Rs of Recycling -- Reduce, Reuse, Recycle."

- Several programs are producing quality products being adapted for use by others. Among them are: City and County of Los Angeles; Heal the Bay; Santa Clara Valley Nonpoint Source Pollution Prevention Program; Alameda County Urban Runoff Clean Water Program; San Francisco Pollution Prevention Program; Bellevue Washington; and Milwaukee.

- There is much "reinventing the wheel." The apparent reasons are:

  - Education materials produced by most programs are designed for specific audiences and use text and graphics that highlight local characteristics (e.g., the creeks of Northern California vs. the Great Lakes). While there will always be a need to customize materials, consistent themes can unify the overall campaign.

  - Few regions coordinate their education efforts. The statewide California Stormwater Task Force, Public Information and Involvement Program subcommittee is an exception to this, as it is also a vehicle for coordination. Yet materials being produced throughout the State have widely varying appearances and programs that are tailored to their local audiences, because the task force coordination is meant to assist the various programs rather than unify them under a common look or strategy.

- The messages conveyed in the educational materials reviewed have focused on raising awareness and understanding -- that the public, as individuals, are the nonpoint sources contributing everyday to the most significant water pollution problem still persisting in the United States. As a motivator to change behavior, the materials stressed the fact that the protection and future enjoyment of bodies of water depend upon each individual's efforts to make the changes necessary to reduce their portion of the pollutant load. Most of the materials included lists of activities that people could do to reduce pollution, to give concrete examples of individual actions that can be taken.

- Early stormwater public education programs focused on grassroots strategies, such as community participation in events, use of advisory committees, demonstration projects, workshops, and distribution of educational materials. Some of these programs have been in place for more than a decade -- and cleaner water quality has been measured as a result. One example is the Puget Sound, where, according to the public education manager for the Puget Sound Water Quality Authority, improvements in water quality have been accomplished. The manager attributed this measurable success to a comprehensive stormwater management plan, of which public education is a significant part.

Summary of Observations: Print Materials

- Most materials do not have a unified appearance and no stormwater/urban runoff program has yet created a representative graphic symbol on *how to* prevent stormwater pollution (e.g., "Reduce, Reuse, Recycle" or the chasing arrows of recycling.)

- The best materials were concise, used good illustrations and provided information that is practical and easy for the average person to understand and incorporate into his/her daily life. Materials that have been adapted for use by other programs tend to be very strong in both graphics and text.

- As it is relevant to Los Angeles County, preliminary research shows that California audiences respond best to materials aimed at specific target audiences, by ethnicity as well as age, and at common activities that produce pollutants. Examples[12] of stormwater programs that have effectively used these aspects of a targeted approach for large populations include: City of Los Angeles, Santa Clara Valley Nonpoint Source Program; Alameda County Urban Runoff Clean Water Program; and San Francisco Pollution Prevention Program.

[12] Does not reflect an all inclusive list.

Summary of Observations: Media Programs and Advertising

When publicity reinforces public education/outreach activities, greater success has been measured.

- In Greenville, Texas, a public education program was launched to reduce the levels of pesticides being detected in wastewater treatment plant effluent (after-treatment) and violations were issued by regulators on a regular basis. No treatment methods were available to reduce the specific pesticide, diazinon. The only option to achieve regulatory compliance was for the public to reduce diazinon usage. Greenville's public education program employed a wide range of grassroots strategies, but most important, it publicized every activity in local newspapers, magazines and radio. The end result was overwhelming public cooperation; levels of diazinon in effluent dropped and the regularly issued violations stopped.

- In the Puget Sound area, water quality is measurably better today than a decade ago, when several stormwater/urban runoff education programs were just getting underway. One element of the program has been broad print media coverage, and most recently, television advertising.

- In Los Angeles County, Heal the Bay has worked extremely well with the media to effectively gain awareness of stormwater issues, including the 1996 NPDES Permit. Annual media coverage is given to Heal the Bay's annual beach report card. As noted in Section 7, the organization was the number one source for technical information in newspaper articles.

Advertising, particularly billboards, has successfully raised awareness in several programs, including:

- The County and City of Los Angeles partnered to produce a billboard and bus shelter campaign in 1996. These messages are highly visual, and by joining forces, the City and County were able to reinforce stormwater messages over a broad region. This campaign was nominated for the 1995-96 Productivity Award, given annually by the County Productivity Commission.

- A billboard and bus shelter advertising campaign is underway in San Mateo County with the theme message, "A drop of oil goes a long way." The graphic that accompanies this message is a stylized upside-down fish.

- According to its "Pure Water" newsletter, the Alameda Countywide Urban Runoff Clean Water Program conducted surveys that documented a 34 percent increase in awareness of stormwater issues that resulted from a billboard campaign in 1994. The survey determined that 29 percent of the population had changed their behaviors as a result of this campaign.

Summary of Observations: Storm Drain Stenciling

- Nearly every community surveyed in the United States has some kind of storm drain stenciling program. In fact, public awareness polls in Santa Clara County determined that storm drain stencils are the number one medium for the public to become aware of stormwater pollution issues.

- The City of Oakland has not only recognized the effectiveness of storm drain stenciling, but also tried to reach more of its diverse population by stenciling in English, Spanish and Chinese.

Summary of Observations: Partnerships With Businesses

- Point-of-purchase campaigns have not been used to their full potential, but the oil recycling campaign conducted jointly by San Mateo County and Pennzoil demonstrates how effective they can be. Highly attractive stormwater/waste oil educational materials, a free oil funnel, and a display stand were distributed in automotive shops that carry Pennzoil products. The campaign resulted in a 12 percent increase in waste oil received at San Mateo's recycling centers.

- Clean business recognitions -- such as the Ocean Safe Coalition -- have been developed in several areas, including Southern California. Case studies in the area of pollution prevention have shown that businesses have actually saved money by following pollution prevention practices (many of which are similar to stormwater/urban runoff BMPs). This financial aspect will be crucially important to many of the County's smaller businesses. Businesses that have participated in these types of programs have received recognition and publicity for their efforts.

- Donated services by businesses are common in many stormwater programs. The City of Los Angeles reports that it has received more than $1 million in donated billboard advertising space, and more than $1 million in television, radio and theater advertising time for its public service announcement (PSA) and $250,000 in donated services related to making the PSA. These donations equaled more than the City's total budget for two years of stormwater public education.

Summary of Observations: School Outreach

- Some of the printed materials for children were excellent; others were not age-appropriate. The latter group used illustrations for grade-school children but the text was so technical that it would be more appropriate for junior or senior high school students. Literacy levels must be taken into consideration for school-aged audiences *and* adults.

- Most school education programs placed higher emphasis on activities associated with stormwater education than on printed materials. The school programs that appear to be most successful feature activities such as field trips, classroom experiments, creek monitoring and interactive theatrical presentations.

Summary of Observations: Collective and Cooperative Efforts

The following are summaries of the best education materials from cities/communities most applicable to the Los Angeles County program. In general, they meet the following criteria: (1) contain good information; (2) visually interesting; and, (3) easy to understand.

The materials described below originated outside Los Angeles County. The team searched for good materials being used elsewhere in order to borrow their best ideas that are applicable for the County. It is important to note that there are many excellent materials being produced within Los Angeles County. These are not included here because they already are familiar to stormwater public information managers countywide.

- **Alameda Countywide** Urban Runoff Clean Water Program and the **Santa Clara Valley** Nonpoint Source Program

  - These two programs have shared in the development of many of the publications described below. The materials were prepared in a way that only one printed panel needed to be customized for each of the separate programs -- all other parts of the brochures were identical.

  - These programs found that the cooperative efforts saved money in terms of design, production and printing, and unified the messages regionwide.

- **San Francisco Bay Area** Programs Collectively

  - The appearance of the Alameda, Santa Clara and other San Francisco Bay Area programs is uniform and corporate in appearance. Water-color graphics illustrate most materials for general public audiences. Illustrations show people of different ethnicities.

  - General public materials -- many in English and Spanish include:

    The Bay Begins at Your Front Door! -- general information. This brochure has been adapted for use by Los Angeles County.

    Home Maintenance Tips for a Cleaner Bay -- focuses on main activities that the residential public can do to prevent stormwater pollution.

    Bugged and *Pests Bugging You?* -- safer pest control strategies and products.

    Keeping It All in Tune -- car repair and pollution prevention tips.

  - Materials for businesses are thorough, and target the automotive industry, and industrial companies/construction and restaurants.

    Guidelines for Vehicle Service Facilities is a series of BMPs prepared and produced by Bay Area wastewater treatment plants and stormwater management agencies including the counties of Santa Clara, Alameda, San Mateo and San Francisco.

    Good Cleaning Practices to Protect Our Creeks and Bay is a restaurant package for the food industry that includes a thorough brochure (somewhat similar to a menu in appearance) of BMPs; a four-color, two-sided poster of good illustrations of BMPs (can be displayed vertically or horizontally, depending upon the space available); and wipes clean, multi-language checklists of BMPs to hand out to employees.

    Blue Print for a Clean Bay. Best Management Practices to Prevent Stormwater Pollution from Construction-related Activities is a BMP booklet for all construction activities. Research of existing materials found that this booklet has been adapted by several other programs. The booklet refers to additional resources for more detailed design information, and includes guidance in complying with the Construction General Permit.

Summary of Observations: San Francisco Bay Pollution Prevention Programs

- San Francisco's materials have been targeted at specific activities; and research has tested whether or not the campaigns using these materials have been effective. Two types of surveys were used in 1996 to measure effectiveness -- written and telephone questionnaires. The telephone survey indicated that 15 percent of city residents were aware of a home maintenance-targeted campaign called *Clean It!*. Results are still being determined from the written survey.

- *Clean It!* includes a wheel/fan of home maintenance BMPs for the residential target audience. This piece is highly visual, practical to use, includes numerous important telephone numbers and references to recycling centers, offers safe alternatives to toxic products, and succinctly explains how certain activities harm the San Francisco Bay. This has been translated to Spanish and Chinese. Similar wheel/fans are available for gardening and automobile maintenance.

- *Shop Information Package of Automotive Repair Businesses* is a good ready-reference package of BMPs for small auto businesses. It provides not only the applicable BMPs, the binder also includes a case study of a local success story and a list of vendors that provide supplies and services needed to comply with stormwater and pollution prevention requirements.

- The San Francisco Water Pollution Prevention Program prepared a binder of materials for automotive repair facilities. These materials included a *Green Wrench Guide* which has pollution prevention tips for auto repair and body shops; a checklist to help these businesses document hazardous materials and wastes; locations and phone numbers for recycling centers that take solvents, paint thinners, some solid wastes, and other auto services products; a case study of a business that saved money following the suggested BMPs; and a guide to vendors and services related to the industry. The materials also include a *Regulatory Agency Matrix for Automotive Repair Facilities*. The purpose of the binder of is to give enough information to overcome hurdles that might prevent auto shop managers and owners from following through with measures that prevent pollution.

- *Tips for Painting Contractors* is a comprehensive guide that describes BMPs for proper handling and disposing of paint waste. Options and phone numbers for more information are provided. The layout of the BMP brochure is attractive and easy for painters to follow.

- The city of San Francisco, which has a population of approximately 750,000, conducts one of the more multifaceted programs for targeting ethnic communities. This program has tried innovative ways of reaching the ethnic population. One of these was a series of workshops for Latina housecleaners that focused on messages that were secondary to the stormwater program but primary to the target audience. Because pre-workshop research showed that Latina housecleaners were more concerned about their health than the environment, the workshop taught stormwater BMPs in the framework of protecting the workers' health and well-being. The Los Angeles County Five-Year Public Education Plan may also need to present stormwater BMPs in terms of issues of primary importance to target audiences, such as protection of the health of families, neighborhood beautification, and cost savings.

- The San Francisco program created fan-style brochures for the Do-It-Yourselfers in the areas of pest control, home cleaning and maintenance, and automobile maintenance. These are extremely attractive and handy for users in the process of any of these activities.

- This program has also done a good job of documenting before and after public awareness. Public awareness surveys have been conducted to confirm the effectiveness of campaigns targeted at home and car BMPs.

Summary of Observations -- Bay Area Stormwater Management Agencies Association (BASMAA)

- *Pollution From Surface Cleaning*, produced in 1996 for mobile cleaners (steam and high pressure cleaners/wash the outsides of buildings, parking lots and sidewalks). This is an eye-catching brochure that first explains the pollutants of concern to mobile surface cleaners and the effects of improper disposal of wash water. The remainder of the brochure uses tables and easy to read bulleted summaries to demonstrate proper cleaning and disposal methods. The brochure was used in combination with training workshops that included a self-graded examination. Approximately 125 mobile cleaners were trained and certified in the first workshop.

- *Vehicle Service* brochure provides a set of comprehensive BMPs for vehicle service and maintenance facilities. It includes referral phone numbers for local agencies and an explanation of why pollutants from vehicle service facilities are a problem. This attractive brochure is easy to follow.

Summary of Observations -- Riverside County Flood Control and Water Conservation District

- Several materials including giveaways have been prepared by the District. Of particular interest is a videotape targeting new development and construction, which is suitable for most Southern California cities.

- This is the only video received for the research task that targeted a specific business; it is very good in that it is thorough and clearly communicates new development issues, construction BMPs, and long-term maintenance. It mentions Riverside, but subtly enough so that the video could be used by other stormwater public education programs.

Summary of Observations -- Sacramento Stormwater Management Program

- Overall, there were excellent materials and interactive displays for children.

- Posters are in Spanish and English.

- The program has a portable game that allows children to toss a ball into a "storm drain," it rolls through pipes and lands in clean water. This builds the connection between storm drains and nearby rivers. One potential drawback of the game is that children may think it is fun to drop balls down the storm drains and do it "for real."

Southern California Programs[13]

The City of Los Angeles began its stormwater public education program in 1993. It represented a departure from the earlier grassroots programs because of "unparalleled diversity of the population [that] creates a unique environment that poses as many challenges as it does opportunities."[14] According to the Public Information Director, the City has achieved its greatest successes with educational methods that reach large numbers of people with each effort -- such as radio programs for Spanish-speaking residents, a co-op outdoor advertising campaign with Los Angeles County which used billboards and bus shelter posters, and a bilingual school program that reaches hundreds of children at a time. The cost-effectiveness of each educational effort is essential in a market the size of Los Angeles.

[13] See Section 4 for a detailed discussion of Southern California/Co-permittee programs.
[14] City of Los Angeles, 1996 EPA Excellence Awards application

Managers[15] of other stormwater public education programs in California stated in interviews that, if they had to develop a program for Los Angeles County, they would use the media and advertising much more than they do in their own programs designed for smaller populations. Reasons cited were the size of the population and that, because Los Angeles County is a world center for the entertainment and advertising industries, residents are already conditioned to receiving messages via the media.

Heal the Bay, a major environmental organization in Los Angeles County, has an 11-year history of activism and accomplishment in cleaning up Santa Monica Bay. Its active stormwater/urban runoff public education program has:

- Effectively used the media to increase public awareness of the issue
- Established the organization as a credible source for the news media about stormwater issues
- Recruited visible spokespersons to communicate stormwater issues to the public and the media
- Effectively used political pressure to build support for regulatory decisions
- Produced creative, recognizable print and PSA materials
- Conducted a successful storm drain stenciling program, called the "Gutter Patrol"
- Provided authoritative technical expertise on scientific issues
- Effectively used the "carrot and stick" approach with agencies to promote water quality improvements

The Los Angeles County Department of Public Works has joined resources with both the City of Los Angeles and Heal the Bay in advertising, public education materials, and storm drain stenciling programs. While these united efforts were short-term (lasting up to six months) their positive results reinforce what can be achieved with messages delivered on a large scale.

[15]Managers of the Alameda County and Santa Clara Valley stormwater programs, August 1996.

Summary of Observations: State and National Programs

Chesapeake Bay (Maryland, Virginia, West Virginia, Pennsylvania, Delaware, Washington DC)

- Multi-jurisdictional, grassroots, highly targeted public education program for stormwater and pollution prevention issues.

- Materials were received from several agencies that focus on improving water quality of the Chesapeake Bay. The materials focused primarily on erosion control, nutrients and toxics as these are the three primary pollutants of concern. Some of the materials borrowed images created by the stormwater public education programs in Milwaukee, Wisconsin, and Bellevue, Washington.

- In addition to the print materials distributed by the Chesapeake Bay Trust and the four states in the watershed, public education has a strong grassroots emphasis. Storm drain stenciling, stream cleanups, and volunteer monitoring are major elements of the Chesapeake Bay program.

- Storm drain stenciling is similar to the programs in Los Angeles County.

- Stream cleanups organized and conducted by volunteers include education about urban stream ecology to emphasize ownership and understanding of the watershed.

- Volunteer waterway monitoring involves sampling specific water bodies for a range of characteristics. This program involves students, primarily in middle and high schools, but also elementary- and college-age volunteers.

- School outreach materials emphasize understanding of watersheds and are targeted to middle school students. Activities include interpreting topographic maps, building models and testing drainage under various conditions, solving a watershed puzzle, holding watershed races, planning and conducting a volunteer monitoring program, field trips and actual monitoring.

- The Bay is cleaner and marine life is rejuvenating; however, much public awareness must still be accomplished in the Chesapeake Bay area. A public awareness survey conducted in 1994 by the University of Maryland indicated that only seven percent of the population was aware that individuals caused water pollution.

- The state of Maryland has "Treasure the Bay" slogan on its license plates.

Southern Florida; Dade County

- Dade County, Florida, has a strong pollution prevention program that includes stormwater public education. The program is driven by the fact that Southeast Florida's only source of drinking water is the Biscayne Aquifer which lies three to 10 feet below the ground surface.

- The program combines several environmental issues: solid waste, wastewater, air pollution, energy conservation, household hazardous wastes, and stormwater/urban runoff. Support is provided to local businesses and industries because enforcement alone was not solving local pollution problems.

- Pollution prevention and BMPs were initiated at county facilities, which sent the message to the community that these actions were important to protect local environmental resources.

- Key elements of the overall strategy were workshops, printed educational materials, on-site technical assistance for county employees and local businesses, and integrating pollution prevention into enforcement agreements. One example of the outreach program is a "Solvent Alternatives Exposition" that brought together government and industry experts for a full day of workshops and featured vendor table-top displays.

- Success for this program is measured by participation in events. The program was reviewed by the National Association of Counties and was considered very successful in meeting its goals. The problems encountered by the program were related to availability of staff and the public's reluctance to make major changes.[16]

[16] "Preventing Pollution in our Cities and Counties," National Association of Counties, Fall 1995.

Great Lakes, Milwaukee, Wisconsin

- Wisconsin spent billions of dollars in the 1970s and 1980s on treatment plants and industries to clean up flows discharged to Lake Michigan and the Milwaukee River. To clean up stormwater runoff, a five-year public education strategy was prepared in 1994 by the University of Wisconsin with funding from the U.S. EPA.

- The public education program targets urban residents, local governments, and businesses/industry, and was well-documented in *"Spreading the Word on Storm Water -- A Strategy for the Milwaukee Area"*[17]

- Pollutant loads were calculated for the urban Milwaukee area. The calculations focused on sediments, nutrients, oxygen demanding material, bacteria, toxic pollutants, metals, pesticides, and other chemicals (e.g., PAHs, PCBs). While this technical information was documented, the report did not disclose how the information was ultimately used in the public education program.

- Research of existing pollution prevention practices and sources of information on water quality clearly helped shape the five-year public education strategy. A public awareness survey conducted in 1989 indicated a strong willingness to recycle oil, separate household hazardous wastes from trash, limit use of chemical fertilizers and weed killers, support ordinances requiring dog owners to clean up pet waste, and to route roof water to lawns rather than driveways.

- Elements of Milwaukee's five-year public education strategy built upon the willingness to implement these BMPs. The report stated that the public education strategy is intended to guide activities but should also be flexible in order to respond to new information and conditions.

- Evaluation of effectiveness is one of the major elements of the five-year plan. Evaluation methods include telephone surveys, focus groups, teacher evaluation forms, student test results, interviews with advisory committees, and business programs needs assessments.

[17] Southwest Area Water Quality Education, University of Wisconsin -- Extension, March 1994.

Puget Sound Water Quality Authority and King County, Washington

- The King County Surface Water Management Program has used many different strategies to build awareness and cooperation to protect local water resources, which include Puget Sound, local creeks and lakes. The Puget Sound Water Quality Authority implements a number of grassroots programs, including a Public Involvement and Education Grants Program that builds public stewardship of water quality.

- The King County Surface Water Management Program conducts a well-known stormwater public education program that focuses on one of the counties that borders Puget Sound.. The theme message is "Everyone lives downstream." The public education program follows the philosophy of empowering the public to act in the stewardship of water resources. The materials and outreach program targets a wide range of public interests and needs.

- The King County program includes:

  - Community Stewardship Grant-funded projects
  - Volunteer projects, including storm drain stenciling and volunteer monitoring
  - Citizen advisory committees
  - Public meetings
  - Student education for K-12 and college presentations
  - Public education using workshops and presentations
  - Targeted mailings
  - Stream signage
  - Public event displays
  - Media outreach

- The materials provided by King County included information about a business outreach program, encouraging the implementation of BMPs. They also included a newsletter that indicated an even broader public education program.

- The Community Stewardship program, active since 1988, has funded 88 projects and involved more than 2,700 citizens. In 1996, grant projects will remove invasive weeds from local creeks; create and install interpretive signage along one creek; create a Web page; create a volunteer monitoring program; distribute a watershed bike tour pamphlet and develop new educational watershed bike tour routes; coordinate monitoring and teacher training; create a watershed atlas; create and distribute a student-made brochure on community watershed stewardship; plant native species in a meadow; recruit and train urban youth in restoration projects; create a video on wetland birds; and build and maintain a native plant nursery.

- A local youth career center participated a "Businesses for Clean Water Program." The students' various language skills helped in promoting the program in the community: among them they spoke Cambodian, Vietnamese, Spanish, Samoan, and Russian. Businesses for Clean Water provides free publicity, window decals, and other incentives to businesses that implement BMPs related to stormwater and urban runoff.

- The King County program produced the best videotape for students of any reviewed in this research project. It was reinforced with an excellent teachers guide. The school materials support an activities-oriented program, rather than introduce new curriculum to the area's classrooms.

- A variety of teachers workshops are offered by the North Cascades Institute. Session titles include *Watershed Week for Educators, Where the Forest Meets the Stream, Aquatic Insects: Riparian Habitats and Stream Ecology*. The Internet is among the ways that teachers can find out about these workshops.

- Television advertising showed a man walking a fertilizer dispenser along the water's edge of a lake. The caption read: "When you're fertilizing the lawn, remember you're not just fertilizing the lawn." This advertising campaign was reinforced by programs sponsored by park rangers at the lakes targeted for protection.

- Developers and organizations such as the Boy Scouts and Girl Scouts joined forces to salvage native plants that would have been destroyed at sites slated for construction. Plants were replanted to stream banks and lakeshores that needed additional vegetative protection.

- Volunteers who monitor local water resources are trained in wetlands characteristics, hydrology, soils, wildlife, vegetation and the impacts of various land uses.

- Videotapes prepared for the general public combine groundwater protection and stormwater/urban runoff education.

- Puget Sound Water Quality Authority also has a diverse public education program, but the most outstanding effort is the Public Information and Education (PIE) Grants program that strives to involve community-based organizations, businesses, local and tribal governments, and schools:

  - The program has been an overwhelming success -- in the last nine years, the Authority provided more than $4 million in funding for 230 projects. The projects spread the word about clean water to at least 2 million people.

  - All applications for project funding must include a method of measuring success. The intent of this requirement is two-fold: there must be some tangible measurement of effectiveness for public funding and support for the program to continue; and by including this task along with the implementation of the project, the applicant learns important project management skills. In this way, the grants program gains from the community and gives back to the community.

  - The Authority found early in its creation that a variety of organizations and groups were asking for funding for their special projects. The Authority saw that many good ideas were being suggested by the public, and wanted to provide the funding. The grants program enabled this process to become formalized and well-organized.

- The PIE Grants program has evolved so that partnerships and alliances among groups with different missions are becoming commonplace. Projects aimed at involving a variety of ethnic groups, particularly non-English speaking people, have grown, and as a result language and cultural barriers are being bridged.

- The criteria for a PIE project are:
  - Move beyond "us versus them" attitudes and emphasize that good water quality is in everyone's best interest.
  - Emphasize interesting, innovative activities that involve people; put them in charge of decisions that lead to local action.
  - Be well-designed and clearly articulate effective methods for reaching identified target audiences.
  - Support cleanup and protection of Puget Sound waters.
  - Be carried out by groups which have demonstrated their abilities to implement the project they propose.
  - Clearly justify the expenditures.
  - Be guided by an advisory group that includes a cross-section of affected people (for example, a mixture of business people, local and government staff, citizen group representatives, and technical experts) as needed for the particular projects.

San Francisco Bay
Alameda Countywide Urban Runoff Clean Water Program

- The Alameda Countywide program has three main objectives: (1) to educate the public about non-point source pollution to eliminate illicit discharges, (2) monitor the quality of water in the storm drain system, and (3) to reduce urban runoff pollution by promoting BMPs.

- The program has developed partnerships among Co-permittees. In its newsletter, the County includes "City Spotlight," a regular feature that focuses on the efforts of local cities.

- Storm drain stenciling in Oakland, one of the participants in this countywide program, has been done in Chinese, Spanish and English.

- The countywide program manager suggests that first outreach efforts focus on those who most readily support stormwater/urban runoff pollution prevention: teachers who are enthusiastic about environmental issues and business leaders who are similarly positive about environmental responsibility. These people will carry the educational messages to many others and give the program momentum.

- The county program began by teaching basic BMPs, but has lately included a watershed focus. Groups are being formed to focus on the watershed of particular local creeks -- such as "Friends of San Leandro Creek." This aspect of watershed emphasis is highly localized and of a manageable scale; it is not equivalent to creating a WMA in Los Angeles County such as "Friends of the Entire Malibu Creek Watershed Management Area."

- The Alameda program received a second place award from the EPA for outstanding municipal stormwater program in 1994 for public education -- depth, creativity and effectiveness of the efforts were the judging criteria.

San Francisco Bay
Santa Clara Valley Nonpoint Source Pollution Control Program

- The Santa Clara Valley program has produced attractive, well-targeted public education materials that are used by many other stormwater public education programs. Research has shown that the most effective tool for communicating awareness of stormwater/urban runoff pollution prevention has been storm drain stenciling.

- The Santa Clara Valley program prepared focused pieces that explained BMPs for inspectors to use during visits to local businesses. As more public employees became aware of needs in the community for education about stormwater BMPs, they informed the Santa Clara Valley program manager and the necessary materials were developed.

- There are certain umbrella activities that are undertaken by the Santa Clara Valley program. Others that are more localized and hands-on are managed by the Co-permittees, such as taking an active role in school education programs in their individual communities.

- The program is restructuring its committee hierarchy. Since there were more subcommittees than were manageable, the organization is moving toward being staff-driven with a management committee that oversees decision-making.

- A community stewardship grants program will start up in Fall 1996. The budget will be $60,000.

- Measurement of effectiveness has not been easy. Surveys have been used to indicate public awareness, along with embedding a telephone number in newsletters monitoring response and tracking the number of people who sign in at events.

- This program is undertaking large scale advertising. Little advertising has been done to date, but advertising is considered important for the future to reach the large general public audience.

- Watershed educational materials are being created. Among the initial tools will be watershed maps.

- A fresh, crisp, unified corporate appearance is used in most Santa Clara Valley program materials. This clean overall "look" helps people remember the messages.

Section 7: Survey of Newspaper Coverage of L.A. County Stormwater/Urban Runoff Pollution and Related Environmental Issues

"All I know is what I see in the newspaper." That observation, made many years ago by humorist Will Rogers, could have been said today about stormwater/urban runoff pollution. In fact, surveys conducted in Los Angeles County and nationwide confirm that the media -- television, radio, advertising, magazines and newspapers -- are rated highest of all sources for the general public to learn about environmental issues (see Section 2). Because of their complexity, the deeper issues surrounding stormwater pollution have largely been covered by the press -- metropolitan, regional and local newspapers.

Los Angeles County-based newspapers -- especially the *Los Angeles Times* -- have reported on stormwater pollution for more than a decade. Press coverage increased in the 1980s, when organizations such as the Santa Monica Restoration Project (SMBRP) and Heal the Bay were formed and began drawing attention to the dangers of stormwater/urban runoff in the Santa Monica Bay. More recently, efforts such as Heal the Bay's annual water quality-based beach safety report card; annual Coastal Cleanup Day (September); and Gutter Patrol stenciling program have been featured on local television and covered in greater depth in the metropolitan and local press.

A review of recent newspaper coverage of stormwater/urban runoff pollution provides a baseline of the type and level of information County residents have already received. For the Five-Year Public Education Plan, this information will help form the basis of research and program strategies such as the direction of County resident and business-owner focus groups, the best times of the year to release information, and the development of key messages for collateral materials, advertising and general media outreach.

As a first step, a review of more than 200 articles covering stormwater/urban runoff in L.A. County-based newspapers[18] from 1994 to 1996 has been conducted. Preliminary results show approximately how many people have received information via newspapers; where they live and the papers they read; how much they may already know about stormwater pollution; reporters who write about the environment and/or who have shown continued interest in stormwater/urban runoff; authorities quoted or cited; and the general attitude of the press toward stormwater/urban runoff pollution.

[18] Articles from files of the Los Angeles County Department of Public Works and Heal the Bay.

Newspapers Surveyed: June 1994 -- September 1996

More than 20 newspapers carried stormwater/environmental articles in Los Angeles County communities from the far-northwest San Fernando Valley, to the Inland Empire, to the South Bay from June 1994 to December 1996. As anticipated, the greatest concentration was in the Los Angeles metropolitan area and coastal cities.

Following is a breakdown of the percentage of stormwater-related stories by each newspaper, each paper's average 1994-96 circulation and the number of impressions, which accounts for subscribers and "pass-along" newspaper readers such as subscriber-family members, business-subscriber employees and customers, and news-stand readers.

Newspaper	City/Area	Percentage	Circulation	Impressions
Los Angeles Times	L.A. Metro	50%	1.1 million 1.5 million	2.7 million (M-F) 3.7 million (Sun.)
The Outlook	Santa Monica	18%	26 thousand	65 thousand
Daily Breeze	Torrance/S. Bay	10%	82 thousand 122 thousand	200 thousand (M-F) 300 thousand (Sun.)
Daily News	S.F. Valley	5%	207 thousand 223 thousand	518 thousand (M-F) 559 thousand (Sun.)
S. Gabriel Valley Tribune	S. Gabriel Valley	3%	60 thousand 115 thousand	158 thousand (M-F) 288 thousand (Sun.)
Long Beach Press Telegram	Long Beach	2%	124 thousand 138 thousand	309 thousand (M-F) 345 thousand (Sun.)
Misc. Newspapers[19]	Los Angeles County	12%	50 thousand or less[20]

Stormwater/Urban Runoff Issues Identified in the Press

The following summarizes the people, pollutants and issues that have been identified in the media over the past two years. While the public is somewhat familiar with this information, it is useful in identifying advocates and possible spokespeople and in formulating program messages for the Five-Year Plan.

♦ Major Focus and Most Coverage: Swimmer Health

By far, the major focus and greatest amount of coverage was given to Santa Monica Bay storm drain pollution and to Heal the Bay's cleanup efforts. The greatest concentration of articles[21] was the May-July 1996 announcement of Heal the Bay's monthly beach report card which gives grades "A-F" to County beaches for water quality/swimmer safety, alerts the public to unsafe beaches and highlights major stormwater/urban runoff issues. Typically, report card results are published near the end of May, to coincide with Memorial Day -- and the beginning of swimming season.

This year, these articles also tied in with the May 1996 release of the Santa Monica Bay Restoration Project's (SMBRP) landmark study which for the first time scientifically links storm drain runoff to illness. Several articles also combined this information with reporting on the July NPDES Permit hearings by the Regional Water Quality Control Board. It is noteworthy, however, that stormwater/urban runoff was identified as the number one pollutant fouling beaches and threatening marine life in only one of the articles reviewed, an editorial in the *San Gabriel Valley Tribune*.

[21] Nearly 10% of all articles reviewed.

R0011924

Concentration was in the *Los Angeles Times*, *The Outlook* and the *Daily Breeze* with additional articles, editorials and letters to the editor in the *Daily News, L.A. Weekly, La Opinion, San Gabriel Valley Tribune, Long Beach Post Telegram, Malibu Times, San Pedro News Pilot, Beach Reporter, Palisadian Post* and *The Argonaut*.

♦ Illnesses Identified:

Newspapers have published that storm drain-polluted seawater leads to a variety of symptoms and illnesses including:

- Sore throat
- Skin rashes
- Fever
- Chills
- Stomach flu
- Nausea
- Headache
- Viruses
- Bacterial infections

Importantly, several articles noted that swimming less than 100 yards from a storm drain poses the greatest health risk -- and in fact makes people sick -- and that risks are dramatically reduced the farther away swimmers are from storm drains. This is critical information -- and the first time anecdotal swimmer reports spanning more than a decade have been scientifically validated.

In a vital implication for the Five-Year Plan, it was also noted that swimmers tend to have cavalier attitudes about "dirty water" and often swim/surf in spite of the County's posted "No Swimming" signs. Given this attitude, it is possible that publishing the idea that swimming more than 100 yards from a storm drain is "OK" could possibly lead to reduced caution among swimmers, who generally lose distance perception while in the ocean. In addition, several articles quoted County Lifeguards as saying swimmers are more concerned about riptides than they are about the chances of getting sick.

As this applies to the Five-Year Plan, it would seem that health risks should be a component of messages to the public, particularly those in beach communities, despite the relatively widespread newspaper exposure given the link between storm drain runoff and illness. To determine the extent of the need for health risk-related messages, public awareness and attitudes will be further explored in focus groups and other research as the Five-Year Plan is developed.

R0011925

♦ Stormwater/Urban Runoff as Distinct From Sewage

Stormwater/urban runoff as a pollution source separate and apart from sewage was a running thread throughout the newspaper articles reviewed. Yet in proportion to other issues, this information was scanty, with approximately two percent of the articles covering it as a major issue. Most of the articles defining storm drains -- and their intended use as flood control -- were not directed at public education about the risks associated with pollution. In these articles, issues such as public health, community beautification and/or behavioral change were generally not mentioned or only mentioned as an aside.

Typical among these was a series of articles in July 1996 detailing L.A. Mayor Richard Riordan's $15 million plan to divert runoff from 14 storm drains to the Hyperion treatment plant to demonstrate support of the Permit. Rather than the risks to public health and communities, these stories focused on the City Council debates triggered by the Mayor's proposal.

There were also articles published in 1995 that covered the County's construction of the Hollyhills Storm drain. In fact, this latter article -- which focused on the inconvenience to nearby residents caused by the storm drain's construction -- was the only negative storm drain-related story of all the articles reviewed. Storm drains as flood-control mechanisms were also defined in articles written in 1995-96 which report on the debate over the County Department of Public Works' proposal to construct cement flood-control barriers adjacent to the Los Angeles River.

Given the relatively small amount of published information defining storm drains, it is likely that segments of the County population -- especially in inland communities -- are unaware that what goes into storm drains comes out untreated at the other end. As with the health issue, it is likely that measuring the level of public awareness will be part of the countywide baseline research that will be conducted during development of the Five-Year Plan.

♦ Regional Economic Concerns

Several sources, most notably those from the American Oceans Campaign, cited threats to the region's economy, to our $2 billion a year tourist business and more than 600,000 tourist-related jobs as a reason to address stormwater/urban runoff pollution. In one article, a County lifeguard is quoted as asking, "What messages do closed beaches give tourists?" In most articles, however, this concern was either ignored or not mentioned as a major focus. Again, research will tell us the extent of the larger business community's concern and resulting messages that need to be developed.

Level of Public and Business-Community Awareness

As reported in the media, the level of public awareness of stormwater/urban runoff pollution is low. In general, the public remains ignorant about the issues and indifferent about cleanup. A possible reason lies in the concentration of many efforts and outreach materials to beachside communities. The same observation holds true for small businesses, where it was noted several times that businesses responded only when organizations such as Heal the Bay and the watchdog group BayWatch contacted individuals, pointed out violations and compelled corrective action. Businesses identified in the press are restaurants, auto repair shops, gas stations, transportation facilities, freeways, streets, parking lots and construction sites, which are already targeted as major education campaign audiences. Overall, cost of corrective action was cited as a major concern of small business owners.

Advantages to the Program Generated by Media Coverage

There are several reporters, most notably James Rainey of the *Los Angeles Times* and *The Outlook's* Susan Woodward, who have covered the issue for several years and demonstrated extensive knowledge. These and other reporters have a generally positive attitude regarding the need to "clean up the act" countywide, their information is scientifically accurate and their articles strongly support corrective action.

That health risks of stormwater pollution have been reported in the media -- and that results of the SMBRP study have been published -- will add credibility to the campaign's messages. Again, determining how much information the public has read and/or retained will be explored during the program's developmental research phase. The same observation is true for the several examples of cleanup methods that appeared in the press and are listed below. How much information does the public know and retain?

Challenges to the Program Generated by Media Coverage

While newspaper exposure could raise public awareness of stormwater pollution as an issue, its concentration on beachfront areas could pose a challenge in developing the Five-Year Plan. As noted earlier in this report, inland residents and businesses have received far less information than those adjacent to the Pacific Ocean. The majority of articles reviewed focused on -- or emanated from -- communities adjacent to the Santa Monica Bay and other oceanside cities, with little or no attention to the inland rivers and creeks that have the same levels of pollution and that bring those pollutants downstream to the beaches and bays. Further research will determine how much people outside the communities near the ocean know about stormwater pollution, and in turn the level and type of education they will need.

And while newspaper stories make the public aware of the problem and the danger to health and the environment, these same stories indicate general apathy toward cleanup on a day-to-day basis. In fact, the most recent articles stressed one of the program's greatest challenges: solving the stormwater pollution problem depends on the everyday actions of hundreds of thousands of individuals.[22] To succeed, the public education program must reach the source of many people's motivations to change behavior -- and elicit that change. Following is a summary of the stormwater/urban runoff information published in the press that will be useful in achieving program goals:

Representative Sherwood Rohlert (R-NY)

♦ Pollutants Identified

Restaurant food waste, grease and litter
Auto shops: Motor oil, radiator coolant & grease
Santa Monica Canyon horse corrals
Chemicals
Golf courses
Residential septic tanks
Fertilizer
Pesticides
Construction debris
Manufacturing solvents
Human and animal waste
Yard trimmings
Solvents
Metals, with lead and copper specified

♦ Cleanup Methods Cited

"Good housekeeping" practices in general
Restaurants constructing special drainage systems leading to treatment plants
Autoshops using solvents to neutralize oil-saturated runoff
Periodic Street sweeping
Watering lawns less often
Not dumping septic tanks into the storm drain system
Properly maintaining septic tanks
Heal the Bay Gutter Patrol
Catch basin stenciling
Controlling litter
Cleaning up oil leaks in driveways
Recycling used motor oil
Repairing broken sprinklers
Cleaning up after pets

Conclusions & Implications For The Five-Year Plan

The breadth of knowledge gathered in the "Issues, Pollutants and Materials" Report illustrates how much the stormwater/urban runoff prevention education movement has grown in the past several years. In addition, analysis of the information leads to some important conclusions that will serve as guideposts during the development of the County's Five-Year Stormwater/Urban Runoff Public Education Plan.

The County and the Co-permittees have discussed and acknowledge that a *coordinated* countywide education program must be implemented because of:

- The synergy the coordinated campaign will create -- and the potentially greater impact it will have on the region's highly mobile residents
- The need for simplified messages/concepts that tell people HOW to prevent stormwater pollution and influence them to act
- The research-based approach that should help the program to be strategic -- and increase its effectiveness and results
- The high-quality materials that can be created for a lower unit cost than if done individually by each Co-permittee
- Its flexibility in providing an overarching, consistent theme while allowing Co-permittees to retain their identity
- The limited resources (time, staff and funds) of most Co-permittees

Additionally, other stormwater pollution program managers interviewed from across the country recognize that stormwater/urban runoff pollution prevention campaigns are evolving beyond their grassroots outreach "roots." Program managers are looking for more in-depth research on target audiences to help ascertain motivational factors that will encourage behavioral change. And they know that not everyone can be converted to non-polluter status. They want to narrow the field so they can focus on those who *can* be converted -- and they want to reach those audiences in ways most likely to trigger response.

To this end, managers are wanting to implement more strategic social marketing programs, expanding beyond the traditional brochures and collateral materials to encompass mass media tools such as TV and radio advertising. For example, the Puget Sound, San Francisco Bay, Alameda County and the City of Los Angeles have all built research-based programs that utilize new and innovative media outreach approaches while still retaining important grassroots outreach efforts like brochures, "adopt-a-creek" programs and displays at community fairs.

Research shows, and managers agree, that stormwater public education has increased awareness. In fact, a recent study by the City of Los Angeles indicates that people recognize the difference between stormwater and sewage systems -- but they don't necessarily realize that stormwater is untreated when it reaches receiving waters. Therefore, it is time to expand and bolster the movement toward not only increasing awareness, but teaching people *how* to prevent pollution. For example, the stormwater/urban runoff prevention movement needs a meaningful and concise slogan or call-to-action that everyone can use with most any audience and get results. A slogan that does for the stormwater pollution prevention movement what "reduce, reuse, recycle" did for the recycling movement.

Moreover, as education outreach efforts are coordinated and expanded, it is necessary to clearly identify for the general public *why* stormwater/urban runoff pollution is so harmful -- so it becomes relevant, important and worth doing something about.

To better identify why stormwater pollution is harmful, more conclusive information about stormwater/urban runoff pollution must be obtained. This data will not only make the case to media, lawmakers and other influentials, but can be compelling to certain segments of the population just as concern for the rapid filling of landfills made a salable case for recycling with the general public.

For example, Santa Monica Bay Restoration Project's highly publicized, landmark research study offered the first conclusive evidence that there was a direct link between stormwater pollution and illness in swimmers. In addition, public agencies have continually monitored affected receiving waters and Heal the Bay has interpreted and publicized the meaning of the data to protect public health. However, additional research must be done to indicate not only which pollutants are found in receiving waters, but at what levels these pollutants are dangerous, and the specific ill affects they cause so that the public can be better educated.

For the countywide Public Education Program to succeed, it will take:

Research
Strategy
Creativity
Leadership
Teamwork
Vision
Commitment

In closing, while significant strides have been made in educating the public, the County and Co-permittees are taking on a challenging program -- the nation's second largest metropolitan area conducting a research-based, targeted outreach program to change the behaviors of a richly diverse population, and partnering with the largest number of Co-permittees known to ever be involved in a stormwater/urban runoff public education effort.

Aside from the expected program challenges of addressing ethnic, cultural, geographical and socio-economic diversity, there will be three greater challenges:

- discovering exactly what will influence behavioral change in the target audiences;
- measuring and documenting behavioral change; and
- demonstrating that the education outreach effort has indeed helped to reduce stormwater/urban runoff pollution.

Appendices: Glossary of Terms

Ammonium - Ionized ammonia found in human and animal wastes. Ammonium may be toxic to aquatic life depending upon pH, temperature and ionic strength of the water.

API - Asian Pacific Islander; representing Chinese, Vietnamese, Japanese, Korean and others who have come from countries in Asia and the Pacific Islands.

Best Management Practice (BMP) - The most effective and practical ways to control nonpoint sources of pollution from stormwater/urban runoff. Guidelines are usually provided to businesses to incorporate into their facility operation protocol.

Biochemical oxygen demand (BOD) - The amount of oxygen consumed in the biological process that breaks down organic matter in water. The greater the degree of pollution by organic matter, the higher the BOD. This pollutant depletes available oxygen in water for marine life.

Bottom-up approach - In public relations, this approach relies upon working with many groups of people to build support from "the bottom up." Also referred to as grassroots outreach.

Chlorides - Compounds of chlorine with another element or chemical group. The level of chlorides can affect the amount of dissolved solids/salts in water.

Circulation - Related to newspapers, magazines and other publications, this is the number of people who receive the paper directly through subscriptions..

Collateral - The variety of materials produced to support a marketing, outreach or public education program, such as videos, give-aways, brochures, newsletters, etc.

Community beautification - Cleaning up a community, especially litter control.

Corporate sponsorship - Funding provided by a corporate business to support a public education effort, usually in return for publicity.

Enteric virus - Disease-causing organisms that poses potential health risk to swimmers and waders exposed to polluted stormwater/urban runoff. Sources include leaking septic tanks, sewer lines, outdoor campers.

Environmental ethic - The willingness to protect the environment.

Environmental justice - The disproportionate burden of environmental impact on one group within a large community or region.

Evaluation instrument - The research tool used to evaluate, or measure, effectiveness or awareness; e.g., a survey or questionnaire.

Focus groups - A research method whereby small groups of people who have been pre-selected for specific characteristics such as where they live, their age or ethnicity, are convened to answer carefully focused questions. Their answers usually provide information on attitudes and behaviors to help guide a public education campaign.

Gatekeeper - Leadership role or allowing or disallowing information to pass from one group to another.

Heavy metals - This is a group of metals typically used in a variety of industrial applications, and associated with fuel combustion and automobile use. They are potentially toxic in high concentrations.

Impressions - Related to newspapers, this is the number of people who read the paper; it includes not only those who subscribe and purchase it, but also those who share the copies.

Interpretation - Translating not only the words written in English to another language, but also adapting materials to reflect cultural differences to ensure that the translation reflects what was actually meant. Not all words and phrases translate directly to another language without some means of interpretive correction.

Laddering - A research method designed to reveal a more complete and personal view of the public than is possible through traditional qualitative and quantitative techniques.

Land use - Activities that dominate an area, such as residential housing, commercial businesses, etc.

MRI data - Demographic collection of people who utilize a certain brand or product (e.g., fertilizer users or who buy Pennzoil motor oil). This demographic data group is then cross-referenced with the type of mass media that they normally use - newspaper, TV, radio, etc. In this manner, if a campaign is targeting homeowners who normally change their own oil, the type of people who buy motor oil can be categorized and then a media buy can be specifically targeted to the publications, TV, radio most likely to reach them.

New development - Planning and design of developing raw land into a new land use.

Nitrate - A form of nitrogen used by algae. Excessive concentrations result in nutrient enrichment and algae blooms.

Nitrite - A form of nitrogen that is toxic to aquatic life. Nitrites and nitrates are common by-products; bacterial breakdowns of organic matter. This process is called mineralization.

Nitrogen - Typical nutrient.

Nutrient - Includes fertilizers, runoff from livestock (e.g., horse corrals), detergents, etc. Excessive nutrients can cause algae growth. Algae can compete with other marine life for oxygen.

Organic solvents - Products used for heavy, industrial-strength cleaning. These can impair the health of aquatic habitat.

Overarching theme - A major theme that provides the "look," slogan graphics, etc. for a public education campaign.

Oxygen demanding substances - Materials that consume oxygen in water and will deplete oxygen content of receiving waters. They typically come from plant debris, animal waste, street litter and organic matter. These substances reduce the amount of oxygen available to aquatic life.

Pathogenic bacteria - Disease-causing organisms that pose potential health risks to swimmers and waders exposed to polluted stormwater/urban runoff. Sources include leaking sewer lines, illegal sewer connections or dumping, malfunctioning septic tanks, outdoor campers. Carried to beaches via storm drain runoff.

Phosphorus - A typical nutrient. Commonly found in fertilizers and detergents. It can cause excessive vegetation or algae growth, resulting in impaired use of water.

Pollutant load - A calculation of the volume of specific types of pollutants on an area of land.

Pollutant of concern - A pollutant that is known or believed to cause environmental harm.

Polychlorinated biphenyls (PCBs) - A group of 209 compounds, commonly used in electrical insulation and heating/cooling equipment. PCBs have been banned since 1979. Among the most persistent and toxic of organic compounds; biomagnifies. Accumulated in sediments, the most persistent and toxic of organic compounds; causes contamination of seafood.

Polycyclic aromatic hydrocarbon (PAH) - Results from incomplete combustion of organic compounds because of insufficient oxygen. PAHs are associated with oil and grease and other petroleum products, and are potent carcinogens and mutagens.

Sediment - Results from erosion, land grading activities. Soil particles suspended in and carried by water. Sediments can smother tidepools and artificial reefs, resulting in sedimentation of coastal lagoons. Can be a problem in some areas with limited circulation.

Segmentation research - Understanding where the messages will have the greatest impact and where they will have little or no impact can be achieved by conducting segmentation -- or laddering -- research. This type of research assesses the degree to which various groups of people are part of the problem, their susceptibility and suitability to different messages, and their willingness or lack of willingness to try new behaviors.

Social marketing - The use of corporate marketing strategies and tactics to influence voluntary behavioral changes in target audiences.

Stakeholder - Person who have a vested interest in something, such as a watershed. A stakeholder can be a land owner, resident, business interest, public agency, environmental organization, etc.

Stewardship - The act of taking responsibility for something, such as trying to improve the water quality in a creek, watershed, or storm drain system.

Sulfates - A salt of sulfuric acid.

Survival issue - Refers to status of a business, particularly one that is struggling to keep its doors open.

Target audience - The group of people targeted for public education, e.g., residents, small business owners.

TBT (Tri-butyl tin) - Very toxic pollutant found in anti-fouling paint; restricted in 1987. Bioaccumulates in all organisms.

Top-down approach - In marketing/communications, this involves using a mass-media strategy (TV, radio, outdoor advertising, print) for public education.

Total dissolved solids (TDS) - The volume of solids that are dissolved in water and carried through the storm drain system. The source is both erosion and organic matter; excessive TDS can interfere with aquatic life functions.

Total suspended solids (TSS) - The volume of solids that are suspended (not necessarily dissolved) in water and carried through the storm drain system. The source is erosion, organic matter and litter/debris. Excessive TSS can impair natural aquatic life functions.

Toxic material - Pollutants that can poison the environment.

Volatiles - Substances that evaporate at low temperatures. Examples are solvents and dry cleaning fluids. Some can cause toxicity in the environment.

WMA - Watershed Management Area.

Water Quality Assessment - An assessment of the condition of water bodies, including an identification of the particular pollutants of concern measured in them. This is a requirement of the Basin Plan.

Watershed - The land area that drains into a river, lake, or ocean.

Appendices: Databases

Comprehensive databases of (1) events, (2) VIPs, and (3) media are being developed in conjunction with the Five-Year Plan. The databases will enable continual tracking and response to implementation of scheduled events, outreach to key opinion leaders and media coverage.

♦ Event Database

This database will provide a complete listing of Los Angeles County events, from the L.A. County Fair to community grassroots festivals, and from trade shows to symposiums and seminars. This database will be coded by target audience/industry, attendance, geographic locale, date and frequency, with an emphasis on annual events. Utilization of existing events will provide maximum cost-effectiveness while bringing the stormwater pollution prevention message to a great number of people at one time.

The event database will be updated throughout the program, making it a "living document" that will enable strategic targeting of events for Program outreach and materials distribution. In addition, the database is structured so it facilitates tracking/monitoring of attendance, materials and benchmark Program response.

Event database sample categories:

Art festivals
Auto shows and races
Boating shows and races
Commercial construction
Craft shows
Dog shows and races
Engineering/architectural shows
Entertainment/performances
Environmental expos
Fairs, carnivals
Health and fitness
Home and garden, decorating and remodeling
Parades
Restaurant trade shows
Sporting events

◆ VIP Database

The VIP database will identify key environmental authorities, researchers, scientists, national, state and local political leaders, and key city staff/managers of the Co-permittees and other cities with notable stormwater programs. The database will be designed to sort by title, category (e.g., politician, expert, city staff) geographical location, and field of expertise.

These types of detailed lists will facilitate tracking and continuing relationships with spokespeople, movers/shakers and potential public/private partners. It will also allow near-immediate action on key events, breaking news, crises and emerging issues.

VIP database sample categories:
Local, state and national elected officials
Key city employees (mayors, city councilmembers, city managers, directors of public works, stormwater program managers)
Environmental experts, scientists, marine biologists and researchers
Construction/developers, restaurant, automotive and other industry leaders
Trade associations
Community activists
Special interest group leaders
Celebrities

◆ Media Database

The media database will be a comprehensive listing of Southern California electronic and print media outlets and the key media reporting on the environment, business and economy as it relates to the environment and lifestyle.

The media list will facilitate tracking coverage and County responses in the form of letters to the editor and opinion pieces. It will be sortable by reporter name and publication/outlet, geographic location, and reporter interest/expertise.

Media database sample categories:
Major Los Angeles County daily newspapers
Weekly community newspapers
Trade and special interest publications
Network and independent television stations
Cable television stations
Radio stations and specific talk shows/hosts

Appendices: Cities with Public Education Materials and BMPs Related to Stormwater

Public education materials and BMPs related to stormwater/urban runoff issues and pollution prevention were collected from 125 jurisdictions, agencies, organizations and individuals in the United States and Australia:

Alameda Co. Urban Runoff Clean Water Prog.
Albuquerque, New Mexico
Ashville, North Carolina
Assoc. for Environmental & Outdoor Education
Bay Area Stormwater Mgmt. Agencies Assoc.
Bellevue, Washington
Bellflower
Benicia
Boulder, Colorado
Calabasas
California Chamber of Commerce
California Coastal Commission
California Coastal Conservancy
California Conservation Corps
California Dept. Of Toxic Substances Control
California Dept. Of Water Resources
California Integrated Waste Management Board
California Lifeguard Program
California Museum of Science and Industry
Caltrans
Carson
Cedar Falls, Iowa
Center for Environmental Education
Center for Marine Conservation
Center for Marine Studies
Center for Urban Ed. About Sustainable Agric.
Central Contra Costa Sanitary District
Central Marin Sanitation Agency
Chesapeake Bay, Maryland
Common Ground for Environment
Concrete Products Industries
Covina
Culver City
Davis
Earthspirit
East Bay Municipal Utility District
EPA -- California
EPA -- U.S.
Gardena
Glendale
Greenville, Texas
Gold Ridge Resource Cons. Dist.
Sen. Tom Hayden
Hermosa Beach
Highlands, New Jersey
Hydrosphere Ocean Opportunities
Inland Empire West Resource Cons. Dist.
King County (Seattle) Washington
Lake Michigan Federation
Lee Co. Div. Of Natural Resources
Lindsay Museum
Livermore
Long Beach
Los Angeles, City of
Los Angeles, County Public Works
Los Angeles Conservation Corps
Louisiana Dept. of Env. Quality
Lower Colorado River Authority
Madison, Wisconsin
Malibu
Manhattan Beach
Mendocino County Resource Cons.
Metropolitan Washington COG
Metropolitan Water District of So. Calif.
Miami, Florida
Mississippi River Basin Alliance
Montana Watercourse
National Park Service
National Project Water Ed. For Teachers

National Oceanic & Atmosph. Admin.
New Bedford, Massachusetts
New York State
Northeastern Illinois Planning Comm.
Olympia, Washington
Seattle, Washington
Sunnyvale
Surfrider Foundation
Orange County
Palo Alto
Phoenix, Arizona
Portland, Oregon
Providence, Rhode Island
Puget Sound Water Quality Auth., Washington
Pomona
Rancho Cucamonga
Redondo Beach
Renew America
Reynolds Metals Co.
River Voices/River Network
Riverside Co. Flood Control & Water Conser.
Sacramento, City & County
San Bernardino
San Diego
San Francisco
San Francisco Estuary Institute
San Jose
Santa Catalina Island Conservancy
Santa Clara Valley Nonpoint Source Pollution Control Program
Santa Monica
Sarasota, Florida
Sierra Club
Surfers' Environmental Alliance
Sydney, Australia - Clean Up the World
Tallahassee, Florida
Terrene Institute, Virginia
TreePeople
Trenton, New Jersey
U.C. Santa Barbara
U.S. Coastal Guardian Campaign
U.S. Navy
Vallejo
Ventura County
Video Project, The (Oakland)
Washington Environmental Council
Washington Toxics Coalition
Water Education Foundation
Water Environment Federation
West Hollywood
Western Lake Superior San. District
Wisconsin Dept. of Natural Resources
Worchester, Massachusetts

Selling Behavioral Change

One of the best ways of explaining the difference between traditional public education and social marketing can be found in the article *"Selling Good Behavior"* from the November 1995 issue of *American Demographics* magazine. In it, Fred Kroger, a communications specialist at the Centers for Disease Control, explains a problem with some public health outreach efforts: "We pass out the truth and expect everyone to recognize it."

He goes on to illustrate his point by highlighting the publicity efforts surrounding the Surgeon General's 1964 report on the ill effects of smoking. Publicizing that report did persuade millions of Americans to quit smoking. However, today, one in four adults still smokes. Now, social marketing programs are in place throughout the country to target segments of the smoking population with messages that will influence them to quit. In addition, highly-focused campaigns are being executed to persuade segments of the youth population most at risk of smoking to never start.

♦ Conducting Social Marketing Programs

A good model for creating a social marketing program comes from an article in the *Journal of Public Policy & Marketing,* April 1994.

- Program managers understand the target audience's needs, wants, perceptions, and present behavior patterns before acting, in many cases through the use of specific formative research. Managers do not make assumptions about these characteristics.
- Program managers segment target markets wherever politically feasible and devise budgets and strategies that are specifically adapted to the characteristics of each defined segment.
- Whenever economically feasible, all major elements of program strategy and tactics are pre-tested with members of the target audience.
- Program managers conceive of the decision process by which target consumers come to undertake a target behavior as comprising the following steps.

  1) Acquire the necessary knowledge to be aware of the option

  2) Embrace the values that permit the behavior to be considered for adoption

  3) Perceive the behavior as potentially relevant to their own circumstances, those of a member of their family or those of the broader society

4) Conclude that the positive consequences of the behavior exceed the negative consequences to a degree that is superior to realistic alternatives

5) Believe that they have the ability to carry out the action

6) Believe that others who are important to them support their action

- The program explicitly recognizes that it faces direct or indirect competition for the target consumer's behavioral choices.

- Strategies designed to effect behavioral change always comprise all four elements of the marketing mix (The Four Ps = **P**roduct, **P**lace, **P**rice, and **P**romotion)

Product -- Design of a product (i.e., the behavior to be promoted) that is fully responsive to the target consumers' needs and wants, in other words, that is easy and satisfying

Place -- Making the place at which the behavior can be carried out convenient and accessible

Price -- Minimizing to the extent possible the economic, social and psychological price of the behavioral change

Promotion -- Seeking to promote the behavior with messages through personal or impersonal media appropriate to the target audiences lifestyle patterns and preferences
