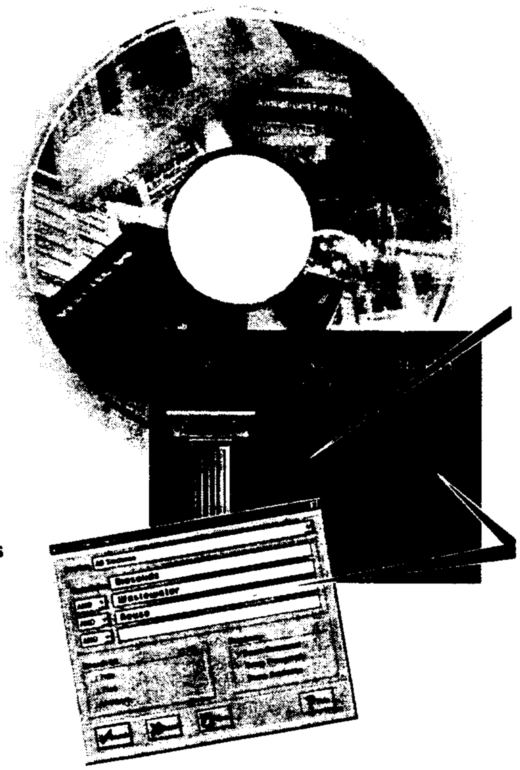
WEF TECHNICAL LIBRARY

ON CD-ROM

The newest solutions, freshest ideas, and latest research on one CD-ROM

The WEF Technical Library allows you to consult over 1,500 of the brightest and most respected minds in the water quality field. These are the people who write the WEF magazine articles you read and develop the technical presentations you attend at WEF conferences. You can now access their combined experiences, wisdom, and knowledge with a few clicks of your mouse.



Power and Flexibility

Searching Made Simple

Table of Contents
If you know exactly WHERE a paper was published or presented, click on Table of Contents and you are just a few mouse clicks away from the information you need!

Word Search
Type any word or string of words into the search screen. You get a listing of the articles that contain the words you were searching for in descending order of "hits". You can even find WHERE and HOW the words in your search appear within the relevant articles.

Direct Access to Every 1997 WEF Technical Publication — Manuals of Practice, Periodicals, WEF Specialty Conference Proceedings, and WEFTEC '97 Proceedings

ABSTRACT

The 12,000-foot long, 11-foot diameter North Dorchester Bay consolidation conduit will provide complete capture of overflows from seven combined sewer overflow (CSO) outfalls tributary to Dorchester Bay and the bathing beaches of South Boston (Figure 1). The conduit will be sized to capture the peak flow hydraulically feasible at the seven CSOs and convey the flow to a dedicated CSO facility at its downstream end. The CSO facility will provide coarse screening, effluent pumping, fine screening, disinfection, and dewatering for flows collected by the consolidation conduit. Flow up to the available storage capacity in the conduit will be pumped back to the interceptor system at the end of each storm, and flow above the storage capacity will be treated by the CSO facility prior to discharge into the Reserved Channel.

Even with the complete elimination of CSO discharges, water quality violations were still predicted along the South Boston bathing beaches. It was determined that the North Dorchester Bay consolidation conduit and the Reserved Channel CSO facility could be sized to capture separate stormwater tributary to the CSO outfalls downstream of the CSO regulators without significantly affecting the project cost. The capture of separate stormwater was determined to cost-effectively increase the water quality benefits of the project.

INTRODUCTION

In July 1997, the Massachusetts Water Resources Authority (MWRA) completed facilities planning for controlling CSOs in the Greater Boston area in accordance with state and federal CSO policies and in compliance with a federal court schedule. MWRA's CSO control plan consists of 25 projects, including the North Dorchester Bay consolidation conduit. This project will eliminate seven CSOs which currently discharge to North Dorchester Bay, along the most extensive bathing beaches in Boston. The North Dorchester Bay receiving water segment supports both swimming and shellfishing, which are considered critical uses under the Massachusetts Department of Environmental Protection (DEP) CSO control policy. This policy requires that CSOs be eliminated from critical use areas unless it is infeasible to do so. The North Dorchester Bay CSO relocation project will eliminate CSOs without creating the increase in stormwater discharge and the continued violations of bacterial water quality standards that would be associated with sewer separation. Instead, this project will also provide the means to control pollution from separate stormwater that is currently tributary to the CSO outfalls downstream of the CSO regulators without a substantial increase in project cost.

Implementation of the MWRA's CSO control plan is currently underway, with projects now in design or in construction. Several smaller projects have already been completed. Design of the North Dorchester Bay consolidation conduit began in August, 1997. Construction is currently scheduled to begin in February, 2000, about seven months ahead of the court-mandated construction start date. Construction is scheduled to be completed in early 2003. The estimated capital cost of the North Dorchester Bay consolidation conduit, including the downstream CSO facility and other related features, is $140 million. The MWRA's financial commitment to this project and aggressive project schedule clearly demonstrate the Authority's dedication to fulfilling court-ordered requirements for CSO control in accordance with applicable regulatory requirements and in an environmentally responsible manner.

This paper presents pertinent project background, identifies the CSO control alternatives considered, and focuses on the development of the recommended alternative for elimination of CSO discharges from North Dorchester Bay.

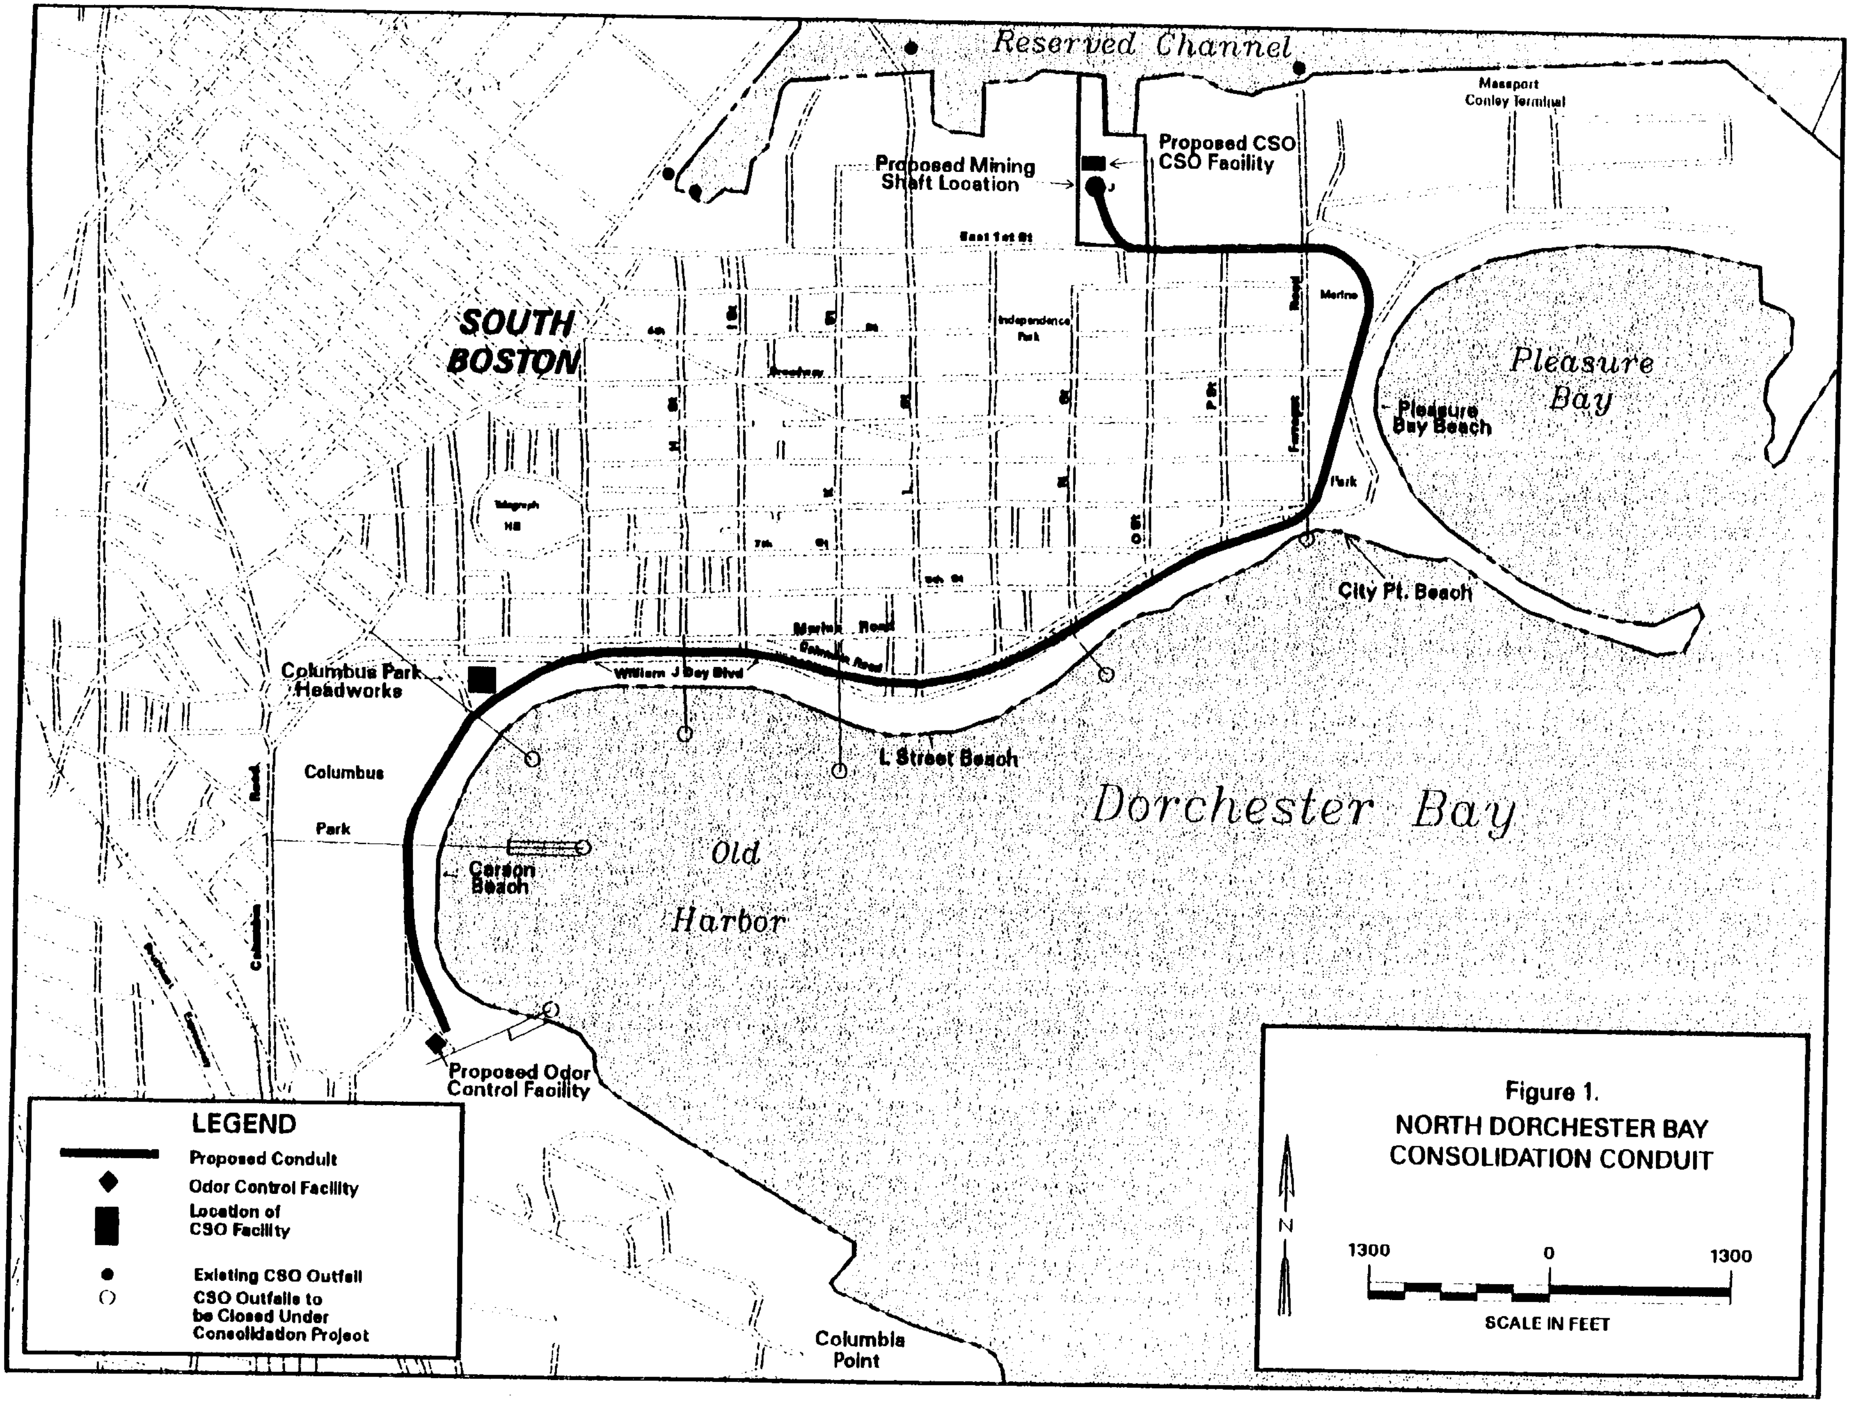

Figure 1.
NORTH DORCHESTER BAY
CONSOLIDATION CONDUIT

PROJECT BACKGROUND

The North Dorchester Bay CSO relocation project was developed based on an understanding of the features and uses of the receiving water segment, an in-depth understanding of the wet weather operation of the combined sewer system in the project area, and the regulatory framework established by the Massachusetts and national CSO control policies.

Receiving Water Segment

The North Dorchester Bay receiving water segment extends from the mouth of the Reserved Channel to Columbia Point in Dorchester. This area is classified as SB-Fishable/Swimmable with restricted shellfishing in approved areas. Massachusetts DEP-designated critical uses for this receiving water segment include swimming and shellfishing. Existing water-based uses within this area are primarily recreational and include power boating and sailboarding, swimming, and fishing. Although the Division of Marine Fisheries has identified a significant shellfish resource in the Carson Beach area, shellfishing is currently prohibited due to the fecal coliform levels in the overlying waters and the proximity of the CSOs. Pleasure Bay also contains shellfish beds, which are currently closed for management reasons.

Many of the land uses along the shore of this receiving water segment support water-based recreational uses. The Metropolitan District Commission, a state agency, controls much of the waterfront in this area, although certain parcels are controlled by the city of Boston or by private water-based interests. Much of the waterfront is used for passive recreation, and a number of separate beach areas, some including bathhouse facilities, are located in this area. Immediately inland is the densely developed residential neighborhood of South Boston.

The seven CSOs which currently discharge to North Dorchester Bay are the predominant source of fecal coliform bacteria during larger storms, such as the 1-year, 24-hour storm event. Although the average concentration of fecal coliform bacteria in stormwater is substantially less than the concentration in CSO, the total annual volume of stormwater discharged to North Dorchester Bay is substantially greater than the annual volume of CSO. Approximately 85 percent of the storms that occur in a typical year do not cause CSO discharges to North Dorchester Bay, but do generate stormwater discharges. In terms of other pollutants, such as biochemical oxygen demand (BOD), total suspended solids (TSS), nutrients, and toxics, pollutant loadings from stormwater appear to be substantially greater than the loads from CSOs.

System Understanding

Several methods were applied to gain an understanding of the configuration and performance of the combined sewer system. These included a careful review of system plans and record drawings, field inspections, flow monitoring, and detailed sewer system modeling. For this project, the EXTRAN block of the U.S. EPA Stormwater Management Model (SWMM) was used to predict system response to specific design storm events and to assess a range of CSO control alternatives.

A total of 11 CSO regulators provide relief of the local combined sewer system and interceptors through the seven CSO outfalls tributary to North Dorchester Bay. On an annual basis, the CSOs discharge about 34,000 m^3 (9 million gallons) of combined sewage. Activation frequencies among the seven outfalls range from a low of four discharges per year to a high of 15 per year.

The interceptor network serving the 11 North Dorchester Bay CSO regulators is presented schematically in Figure 2. All of the interceptors associated with the regulators, the South Boston Interceptor (SBI) South and Main Branches, the Dorchester Interceptor, and the Boston Main Interceptor (BMI), are tributary to the Columbus Park Headworks. This headworks directs flow into a deep rock tunnel for conveyance to the MWRA Deer Island wastewater treatment facility. The headworks capacity is 8.1 m^3/sec (185 mgd), and typical dry weather flows are about 2.2 m^3/sec (50 mgd), indicating that substantial capacity is available for conveyance of wet weather flows to Deer Island. Since the headworks capacity matches available capacity in the deep rock

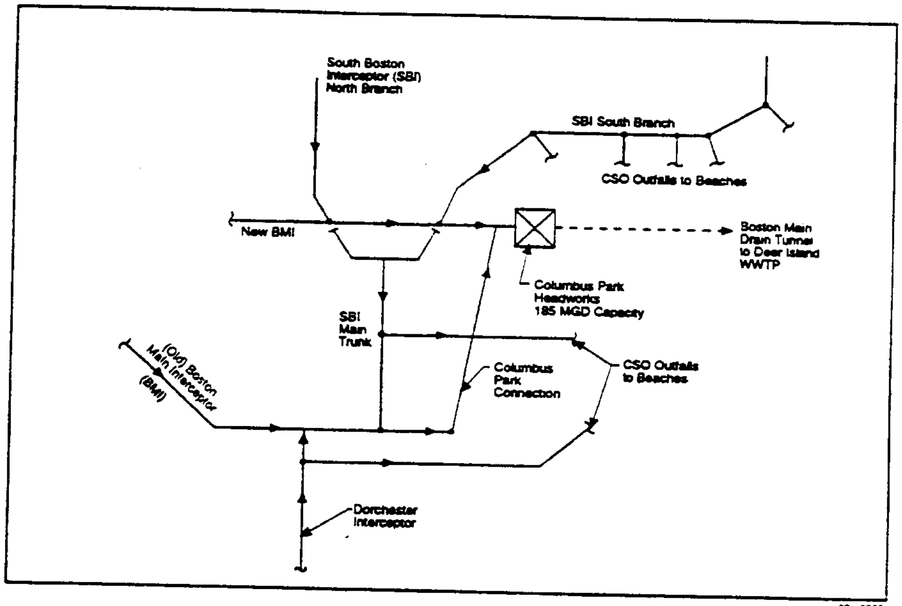

FIGURE 2. SCHEMATIC OF INTERCEPTORS TRIBUTARY TO THE COLUMBUS PARK HEADWORKS

tunnel and at the Deer Island treatment facility, increasing the wet weather capacity of the headworks would not be possible without construction of a new deep rock tunnel and increased treatment capacity at Deer Island.

In smaller storms, much of the combined sewage is captured and conveyed to Deer Island for secondary treatment. During a 3-month, 24-hour storm, the capacity of the Columbus Park Headworks is exceeded, and the headworks must be choked to limit its influent flow to 8.1 m^3/sec (185 mgd). This choking causes surcharging in the South Branch of the SBI, but not in the other interceptors serving the North Dorchester Bay CSOs. In larger storms, such as the 1-year, 24-hour storm, choking at the headworks causes substantial surcharging in all of the interceptors, affecting all of the area CSOs.

This system understanding enabled the following conclusions to be drawn:

- North Dorchester Bay CSOs that activate infrequently (e.g., 4 to 6 times per year) are most likely influenced by interceptor surcharging which results from relatively large storm events.
- North Dorchester Bay CSOs that activate more frequently (e.g, 11 to 15 times per year) are likely affected by local hydraulic restrictions.
- Alternatives based on interceptor relief would not control the North Dorchester Bay CSOs in storm events greater than the 3-month to 1-year, 24-hour storm, due to capacity limitations at the Columbus Park Headworks, the deep rock tunnel to Deer Island, and the Deer Island treatment facility.

This system understanding was necessary to define and evaluate CSO control alternatives for the North Dorchester Bay CSOs, as discussed below.

Regulatory Framework

In addition to understanding the features and uses of the receiving water segment and the wet weather operation of the combined sewer system, an understanding of the regulatory framework established by the

Massachusetts and national CSO control policies was important in developing appropriate control alternatives for the North Dorchester Bay CSOs.

Under the Massachusetts policy, CSO elimination must be considered during the development of CSO control plans for all receiving waters, and CSO elimination is stressed for critical use receiving waters that support swimming and shellfishing, such as North Dorchester Bay. The policy identifies both sewer separation and CSO relocation as technologies for eliminating CSO discharges from critical use areas.

The national CSO control policy also emphasizes CSO elimination in sensitive areas, which include waters that support primary contact recreation. Similar to the Massachusetts policy, the national CSO control policy requires that overflows to sensitive areas be controlled by elimination or relocation wherever physically possible and economically achievable, except where elimination or relocation would provide less environmental protection than additional treatment.

ALTERNATIVES EVALUATION

A broad range of alternatives was considered for the elimination or control of CSO discharges to North Dorchester Bay. The evaluation of CSO control alternatives involved a series of screening steps. Using preliminary hydraulic evaluations, system knowledge, and knowledge of the on-shore and water-based uses of the receiving water segment, certain alternatives were eliminated from further consideration without developing detailed cost and performance data. These included the following:

- Local sewer separation. Sewer separation upstream of only the seven North Dorchester Bay CSO outfalls did not eliminate CSO discharges during the 1-year, 24-hour storm, due to interceptor surcharging and backwater from choking at the Columbus Park Headworks.

- Individual treatment or storage facilities for each outfall. It did not appear to be cost-effective or feasible to site and construct seven separate facilities in a densely populated area featuring heavily used parks and beaches.

- Outfall consolidation to treatment. All of the outfall consolidation alternatives had sufficient storage volume in the conduit to capture the 1-year, 24-hour storm volume, suggesting that treatment processes would operate very infrequently.

For alternatives that passed the initial screening step, information on cost, performance, construction risk, public acceptance, water quality, construction-related impacts, and long-term environmental impacts was developed and assessed. This information was developed for the following alternatives:

- Consolidated near-surface storage conduit. This alternative involved constructing a consolidation conduit, sized for the 1-year or 3-month, 24-hour storms to capture North Dorchester Bay CSOs up to the available conduit storage volume. Captured CSOs would be pumped back to the interceptor system following each storm event. CSOs in excess of the conduit volume would discharge untreated via the seven existing North Dorchester Bay CSOs.

- Interceptor relief with local controls at three CSO outfalls. This alternative involved constructing a new interceptor parallel to the South Branch of the SBI. The relief interceptor was predicted to eliminate CSO discharges at all but three North Dorchester Bay CSO outfalls in the 1-year, 24-hour storm, and local storage and/or system optimization measures would be implemented to control the relatively minor discharges at the three outfalls remaining active. CSOs in larger storm events would continue to be discharged untreated via the seven existing North Dorchester Bay CSOs.

- CSO elimination by system-wide sewer separation. Sewer separation of all combined sewer areas tributary to the Columbus Park Headworks was predicted to eliminate CSO discharges from the seven North Dorchester Bay CSOs.

- CSO relocation to Reserved Channel. This alternative involved a consolidation conduit running along the South Boston beaches to a CSO facility located along the Reserved Channel. The conduit and CSO facility would be sized to convey the maximum peak flow hydraulically capable of reaching the conduit from the CSO regulators tributary to the seven North Dorchester Bay CSOs. The CSO volume stored in the conduit would be returned to the interceptor system by pumping following each storm event.

The alternative to relocate CSOs from North Dorchester Bay to the less-sensitive Reserved Channel was determined to be in compliance with the Massachusetts and national CSO control policies based on the characteristics and land-based uses of the Reserved Channel. The Reserved Channel supports deep water container shipping and cruise ship access into the Port of Boston. In addition, it supports a bulk fuel delivery, storage and distribution operation. These uses preclude the use of the Reserved Channel for primary contact recreation and shellfishing, and limit opportunities for passive recreation. On this basis, the Reserved Channel was considered to be less sensitive than North Dorchester Bay, and CSO relocation was considered to be an appropriate option for eliminating CSO discharges to North Dorchester Bay.

Based on cost-performance evaluations, the initially preferred alternative was interceptor relief with local controls at three CSO outfalls. This alternative would not, however, achieve the goal of CSO elimination in the critical use area of North Dorchester Bay. Of the two alternatives that would eliminate CSO discharges, CSO relocation was determined to be preferable as compared to system-wide sewer separation. Sewer separation would have involved extensive construction impacts in densely populated, residential areas, and the area required to undergo sewer separation would have extended beyond the area tributary to the North Dorchester Bay CSOs. Sewer separation would also have significantly increased the fecal coliform bacteria load to North Dorchester Bay due to the increased stormwater volume. This result would be inconsistent with the national CSO policy, which requires CSO elimination in sensitive areas except where elimination would provide less environmental protection than other alternatives. While the relative impacts and health risks associated with fecal coliform bacteria from stormwater versus CSO origins can be debated, it is clear that as long as fecal coliform bacteria remains the indicator species used to measure compliance with the swimming standard, the standard would continue to be violated if sewer separation were implemented. In contrast, CSO relocation would capture all of the overflow from the 11 North Dorchester Bay CSO regulators and either store it or relocate it to the less sensitive Reserved Channel. For these reasons, CSO relocation was selected as the preferred alternative.

DEVELOPMENT OF PREFERRED ALTERNATIVE

Following selection of the preferred alternative, the CSO relocation concept was further developed. This process involved establishing peak design flows, evaluating conduit construction and lining alternatives, developing technologies for conduit ventilation and odor control, and determining appropriate pumping and treatment technologies for the CSO facility. In addition, a formal process was followed to evaluate and compare alternative routes for the consolidation conduit and alternative sites for the CSO facility.

Design Flows

The peak design flow for the consolidation conduit and CSO facility was assessed by determining the peak flow hydraulically feasible at each of the 11 regulators associated with the seven North Dorchester Bay CSO outfalls. Curves of peak flow versus storm recurrence interval were plotted for each regulator to establish the flow rate at which increasing the storm size did not substantially increase the peak flow. The peak flows, representing the ultimate delivery capacity of the tributary combined sewer system, were generally attained for the 25-year, 24-hour storm, although peak flow was essentially reached at some regulators by the 10-year, 24-hour storm.

To establish the maximum rate of flow in the consolidation conduit, the relationships among timing of peak flows at the individual regulators, travel time in the conduit, and volume of flow in the conduit were evaluated. Since the peak flow into the conduit would occur after the conduit had filled, minimal attenuation of peak flows would occur. The peak flows in the consolidation conduit over a range of storm recurrence intervals are presented in Figure 3. Based on the peak flow of approximately 22.3 m^3/sec (510 mgd) derived from this analysis, an 11-foot diameter conduit at a slope of 0.001 was selected.

R0024770

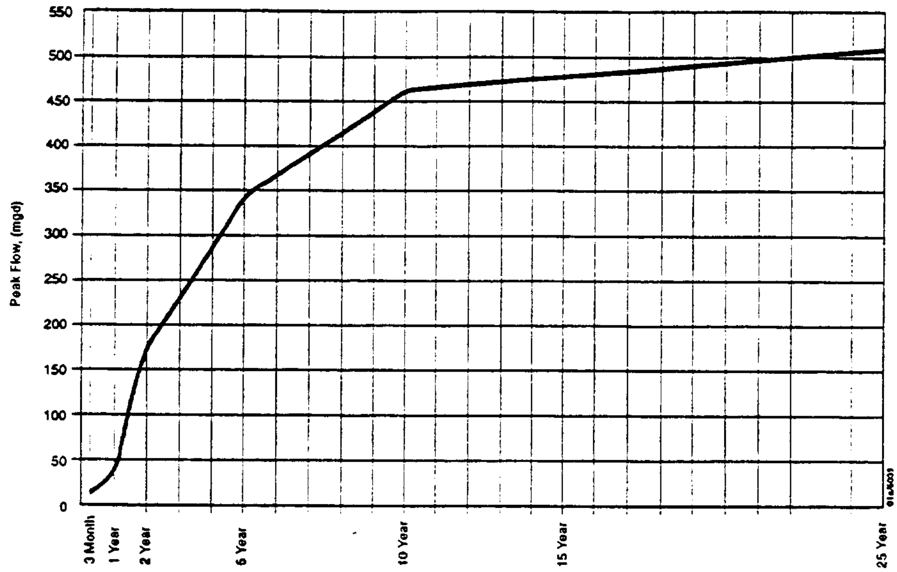

FIGURE 3. PEAK FLOW VS. DESIGN STORM IN THE DOWNSTREAM REACH OF THE NORTH DORCHESTER BAY CONSOLIDATION CONDUIT

With the exception of approximately 24 hectares (60 acres) of separate storm drainage tributary upstream of certain CSO regulators, storm drainage tributary to the seven North Dorchester Bay CSO outfalls enters downstream of the regulators and would continue to be discharged following project completion. Receiving water analyses determined that the continued discharge of separate stormwater would result in violations of the bacteria standard for swimming on a regular basis. Given the critical uses in this receiving water segment, an assessment of the impact of capturing stormwater tributary to the North Dorchester Bay CSO outfalls downstream of the CSO regulators was conducted. Using the same type of analysis described above for assessing peak CSO-only flows, the peak flow of CSO plus separate stormwater tributary to the consolidation conduit was determined to be about 26.3 m^3/sec (600 mgd). This flow rate represented an increase of about 4 m^3/sec (90 mgd) as compared to the CSO-only peak flow, and it was determined that the 11 foot diameter conduit at a slope of 0.001 would be adequate to convey the 26.3 m^3/sec (600 mgd) peak flow. It was also determined that the increase in firm pumping capacity at the CSO facility could be achieved by changing the pump impeller. Based on these assessments, a relatively minor incremental increase in project cost and complexity would be associated with capturing separate storm drainage tributary to the North Dorchester Bay CSO outfalls. Given the critical uses of this receiving water segment, these changes appeared to be justified and the capture of separate stormwater was incorporated into the project.

Conduit Construction Alternatives

Based on hydraulic requirements of the project and available information on local geology, the consolidation conduit was recommended to be constructed in soft ground, as opposed to being constructed in bedrock. The CSO outfalls to be connected to the consolidation conduit are located at relatively shallow depths, and can be readily intercepted by a soft ground tunnel. In the project area, the approximate depth to competent bedrock is greater than 30.5 m (100 ft). A deep rock tunnel would have increased the cost and complexity of appurtenant features such as dropshafts and the pumping components of the CSO facility.

The presence of both soft clays and relatively clean sand and gravel deposits along portions of the conduit alignment, and proximity to North Dorchester Bay dictated that a closed-face tunnel boring machine (TBM) be used to avoid groundwater-related instability. In addition, groundwater contamination involving floating product was encountered along a portion of the alignment. A closed-face TBM represented an effective approach to prevent the drawdown of contaminated groundwater into the tunnel horizon. Open cut construction was not considered to be feasible due to existing development in the project area, as well as construction-related difficulties of maintaining a trench at depths of 7.6 to 18 m (25 to 60 ft) through the soil and groundwater conditions described above. Open face mining techniques were also considered to be infeasible due to the anticipated soil and groundwater conditions.

Conduit Lining Alternatives

A precast concrete bolted and gasketed segmental lining system was recommended for the North Dorchester Bay consolidation conduit over other lining technologies. The anticipated soil and groundwater conditions necessitated the installation of a water-tight liner both for construction and long-term operation. During construction, a water-tight liner was deemed necessary to prevent tunnel instability and groundwater inflow. Since CSO storage in the consolidation conduit is an important project feature, a water-tight liner, which would enable the conduit to remain empty between storm events, was a key project requirement. Other lining technologies considered did not offer the advantages of a precast segmental lining system. A jacked pipe lining was considered, but would have required the installation of shafts at all changes in direction and at distances as required to prevent excessive jacking loads. The precast segmental lining system could be installed along horizontal radii, and would not require intermediate shafts. These features were advantageous given the densely developed character of the project area, where sites for shafts are extremely limited. A cost comparison indicated that the precast segmental liner would be about $10 million less expensive than jacked pipe. This cost comparison also supported selection of the precast segmental liner system.

Conduit Ventilation and Odor Control

An activated carbon odor control system and exhaust fans at the upstream end of the consolidation conduit were recommended to provide conduit ventilation and odor control. The system would consist of two dual-bed

carbon adsorption units, centrifugal fans, ductwork, and isolation dampers. This equipment would be housed within an above ground visual screen. The visual screen would be attached to a small above-ground building housing mechanical and electrical equipment.

Conduit Route Alternatives

The first step in the route selection process was to identify a wide corridor through which the consolidation conduit could pass. Since the purpose of the conduit is to intercept overflows from the seven CSOs tributary to North Dorchester Bay, the corridor was defined by the distance between each CSO regulator and the downstream terminus of each CSO outfall. This corridor was divided into an upstream, middle, and downstream reach, and specific route alternatives were then defined for each reach. Route alternatives were generally confined to public rights-of-way or open areas such as park land and the beach. Routes under buildings or other structures were avoided because of the potential for ground settlement or heave during conduit construction and to reduce the need for taking easements or acquiring properties. Three to five route alternatives were initially identified along each reach of the consolidation conduit. In most cases, any route alternative from an upstream reach could connect to any route alternative in the next downstream reach. Through an evaluation process that compared each route alternative based on engineering, environmental, community, and economic factors, and an extensive public participation program, the number of route alternatives to undergo additional evaluation was reduced. As a result of this evaluation process, three route alternatives were selected for additional evaluation for two of the reaches, and two route alternatives were selected for the third.

A planning-level subsurface exploration program was conducted to obtain necessary information on ground conditions and to define top of rock for the route alternatives undergoing additional evaluation. Soil profiles and rock contours from existing borings and geophysical programs were obtained and reviewed, and additional borings and geophysics were performed. Borings were spaced from 150 to 610 m (500 to 2,000 ft) apart, depending on the availability of existing information. A seismic refraction survey along two of the three reaches of the conduit was performed to determine top of rock in areas where there was concern that rock could rise to the depth of the invert of the soft-ground conduit.

Route alternatives within each conduit reach were compared based on cost and construction risk factors, including soil conditions, groundwater flows, the potential to encounter obstructions, and the potential for soil and groundwater contamination. Environmental impacts were also evaluated and compared. The preferred routes within each reach were combined to create the overall preferred alternative for the North Dorchester Bay consolidation conduit. In general, the selection of preferred routes reflected a balance between cost and construction risk. For the upstream reach of the conduit, the second-lowest-cost route alternative was preferred. The cost for the preferred route alternative was seven percent higher than the low-cost alternative and presented the lowest construction risk of the three alternatives. In the middle reach, cost varied by only five percent among the route alternatives, and the alternative with the lowest construction risk was chosen. For the downstream reach, the higher-cost route alternative was preferred. Even though the preferred alternative had an approximately 15 percent higher cost, the lower-cost route represented an unacceptable construction risk. The lower-cost route would follow a narrow residential street, while the higher-cost, preferred alternative would run through a park. If the TBM were to encounter an obstruction and require recovery by excavation from the surface, the impacts of the excavation on the residential area would be substantially greater than the impacts on the park. Since the potential level of disruption to the residential area was judged to be unacceptable, the higher cost alternative was selected. The overall preferred route for the North Dorchester Bay consolidation conduit was shown in Figure 1.

CSO Facility Treatment and Pumping Technologies

A CSO facility at the downstream end of the North Dorchester Bay consolidation conduit was recommended to provide the necessary treatment, effluent pumping, and dewatering functions for flow conveyed and captured in the consolidation conduit. When the storage capacity of the conduit is exceeded, the facility would provide coarse screening and pump the excess flow to the Reserved Channel. Prior to discharge, flow would be treated by sodium hypochlorite disinfection and sodium bisulfite dechlorination. Flowrates up to the peak which would occur in a typical year would also receive fine screening prior to discharge. At the end of each storm, when interceptor capacity is available, the facility would dewater the consolidation conduit to the local interceptor system.

The CSO facility would consist of an approximately 150-foot diameter circular below-grade structure with five above-grade structures. The following major equipment and features would be included:

- Five 6.6 m^3/sec (150 mgd) wet well / dry well centrifugal effluent pumps installed below grade
- Two 0.44 m^3/sec (10 mgd) wet well / dry well centrifugal dewatering pumps installed below grade
- Two mechanically-cleaned trash racks with 64-mm (2.5-inch) bar spacing installed below grade
- Three mechanically-cleaned fine screens with 6.4-mm (0.25-inch) bar spacing installed in an above-grade building
- Sodium hypochlorite disinfection and sodium bisulfate dechlorination storage and feed equipment housed in an above-grade building
- 22.2 m^3/sec (47,000 cfm) wet scrubber odor control system housed in the same above-grade building as the disinfection and dechlorination equipment
- Above-grade electrical substation
- Personnel spaces, electrical and mechanical equipment, and an area for the removal of coarse screenings housed in an above-grade building

- Above-grade effluent channel around one half of the perimeter of the circular pumping station
- Dual barrel 3,050 mm (10-foot) diameter effluent conduit and subaqueous outfall

Technology evaluations were performed to compare alternative types of effluent pumps, fine screens, and disinfection and dechlorination processes. Alternatives were compared based on capital and O&M costs and non-monetary factors such as effectiveness, operational complexity, and track record for similar prior applications.

In addition to technology evaluations, a total of four alternative CSO facility sites were evaluated and compared. Similar to the process followed to identify alternative routes for the consolidation conduit, the first step in the site selection process was to identify a wide area within which the facility could be located. This area was defined by establishing an optimum location for the facility, based on tunnel route and outfall discharge location, and defining the boundary of the alternative site area based on incremental cost. Moving the facility away from the optimum location would incur additional cost for the consolidation conduit and/or the facility outfall. An increment of 10 percent of the total facility cost was chosen to establish the alternative site area boundary.

A planning-level subsurface exploration program was conducted to obtain necessary information on ground conditions. Site alternatives were compared based on cost, performance, construction risk factors, and environmental impacts. In general, the differences among the sites based on these factors were not pronounced. Cost varied by less than two percent. While the environmental impacts associated with the alternative sites were different, none of the sites was clearly preferred over the others based on environmental impacts. The lowest cost site was determined to offer the greatest performance and the lowest construction risk, and was selected as the preferred CSO facility site.

CONCLUSIONS, RECOMMENDATIONS, AND FUTURE ACTIONS

Based on experience gained on the North Dorchester Bay CSO relocation project, the following conclusions and recommendations are presented:

- CSO relocation should be considered whenever CSO discharges are present in two adjacent or nearby receiving waters, one of which supports critical uses such as swimming or shellfishing while the other does not. The two key factors that made CSO relocation a viable solution for the seven North Dorchester Bay CSOs were proximity of North Dorchester Bay to the Reserved Channel and the bathing and shellfishing uses in North Dorchester Bay as compared to the commercial shipping use of the Reserved Channel.
- In addition to understanding the characteristics and uses of affected receiving waters, it is important to gain an understanding of the configuration and wet weather operating characteristics of the combined sewer system in order to properly size and evaluate CSO control alternatives. A detailed understanding of system hydraulics is necessary to assure that CSOs can be permanently closed by relocating these discharges to another receiving water segment.
- Compared to sewer separation, CSO relocation offers water quality advantages to the receiving water from which CSOs are eliminated. Pollutants in the additional stormwater discharges that result from sewer separation can partially or even completely offset the benefit gained by eliminating CSO. In addition, CSO relocation offers the potential to control existing stormwater discharges in conjunction with relocating the CSOs.

As previously noted, the North Dorchester Bay CSO relocation project is currently under design. Additional subsurface investigations are being performed to develop the consolidation conduit design, and treatment and pumping technologies for the CSO facility are being refined. Additional hydraulic evaluations and modeling are underway to refine the sizing of both the conduit and CSO facility. These steps, along with other aspects of the design process, will lead to the successful implementation of this project to eliminate CSO discharges to North Dorchester Bay.

COST EFFECTIVE CSO REDUCTION: MAXIMIZING WET WEATHER FLOW TO THE POTW

ABSTRACT

The Environmental Protection Agency's (EPA's) combined sewer overflow (CSO) Control Policy encourages municipalities, as part of their long-term CSO control planning, to maximize treatment of wet weather flow at existing POTWs. EPA points out the benefit of this action includes:

- Minimizes wet weather overflows.
- Ensures that wet weather flows receive primary treatment.

This paper illustrates another important benefit of maximizing wet weather flow to the POTW, its cost effectiveness. This is demonstrated using data from New York City's (NYC's) Inner Harbor CSO Facility Planning Project, which has shown that this control strategy can lead to a 74 to 88% capture of CSO.

NYC's Inner Harbor CSO project area is served by three (3) wastewater treatment plants with a total CSO drainage area of 20,000 acres. The Inner Harbor has 165 CSO locations and a residential population of 1.7 million people.

The Inner Harbor treatment plants have the capacity to treat up to twice their design flow during wet weather. Calculations were performed during CSO facilities planning using a rainfall runoff model to simulate the annual average capture of combined sewage at each of the three POTWs. The analysis indicated that a significant portion (74 to 88%) of the potential CSO could be captured and treated to primary treatment levels maximizing wet weather flows to the treatment plant.

This CSO control strategy has been shown to be the most cost-effective method of addressing CSO in NYC's Inner Harbor since it makes use of existing treatment and conveyance capacities.

INTRODUCTION

In April 1994, the EPA finalized and signed its CSO Control Policy in the Federal Register (EPA, 1994). The Policy set a comprehensive national framework for CSO control planning and provided guidance to municipalities and permitting authorities in their CSO planning. With almost 1,000 communities nationally with CSO systems and a projected cost of over $40 billion to control CSO discharges, the Policy has a significant national impact.

This paper addresses one of the required control strategies in EPA's CSO Policy, maximizing wet weather flow to the treatment plant, and demonstrates its cost-effectiveness based on New York City's Department of Environmental Protection's (NYCDEP) implementation of this strategy. Maximizing wet weather flow is beneficial since it: 1) reduces the magnitude, frequency, and duration of CSO events; and 2) provides the required minimum treatment of CSOs, which includes screening, settling and disinfection.

The EPA's CSO Control Policy requires CSO communities, as part of their planning efforts, to maximize treatment of wet weather flow at the treatment plant. Specifically, both the nine minimum controls section and the long-term control plan section of the Policy require that wet weather flows be maximized to the wastewater treatment plant. The "Guidance Document for Nine Minimum Controls" (EPA, 1995) in its description of this control strategy, calls for an analysis of plant flow capacity on evaluation of treatment performance for both dry and wet weather periods, and states that municipalities should further evaluate this control during the development of the long-term control plan.

In addition to the CSO Policy requirements, POTW discharge permits generally require that the existing plant capacity be maximized during wet weather conditions. This is a requirement of NYC's State Pollution Discharge Elimination System (SPDES) permits for its 13 treatment plants that serve combined sewer areas. In NYC, the treatment plants primary facilities (i.e., screens, primary tanks, and chlorine contact tanks) are designed to treat up to twice their design dry weather flow capacity during wet weather. The use of this treatment capacity is required by the EPA CSO Policy and plant discharge permit.

NYC's Program

The NYCDEP is currently developing and implementing its City-Wide CSO Facility Planning Program. This $1.5 billion program is addressing CSO pollution in New York City. With over 4,800 miles of combined sewers and approximately 400 CSO discharge locations, New York City has the largest and most extensive CSO system in the nation.

To make city-wide CSO planning manageable, the City has been broken down into four area-wide planning areas (see Figure 1). One of the four facility planning areas is the Inner Harbor. The Inner Harbor study area contains a population of approximately 1.7 million people, encompasses over 20,000 acres of land, has approximately 160 CSO locations, and includes the drainage area of three major wastewater treatment plants: North River, Newtown Creek and Red Hook as shown in Table 1.

Table 1

Inner Harbor – Existing Conditions

Treatment Plant	Dry Weather Flow Capacity (mgd)	Wet Weather Flow Capacity (mgd)	Combined Sewer Drainage Area (acres)	No. of CSOs	Population (Thousands)
North River	170	340	5,600	61	560
Newtown Creek	310	700(1)	12,000	78	970
Red Hook	60	120	3,400	28	195

(1) Currently be upgraded from 620 to 700 mgd wet weather capacity

METHODOLOGY

To estimate the CSO volume capture of the Inner Harbor treatment plants, a rainfall-runoff computer model was developed. The model was developed to have the ability to quickly run long-term hourly rainfall records which was found to be time consuming and cumbersome with the SWMM EXTRAN models developed for this project. A one-year hourly rainfall record can be analyzed in minutes with the rainfall-runoff models, as compared to SWMM EXTRAN, which requires several days to perform a similar calculation.

The rainfall-runoff model can be used to calculate CSO capture for a given treatment plant drainage area based on the following input parameters:

- Regulator Drainage Area
- Regulator Dry Weather Flow
- Regulator Hydraulic Capacity

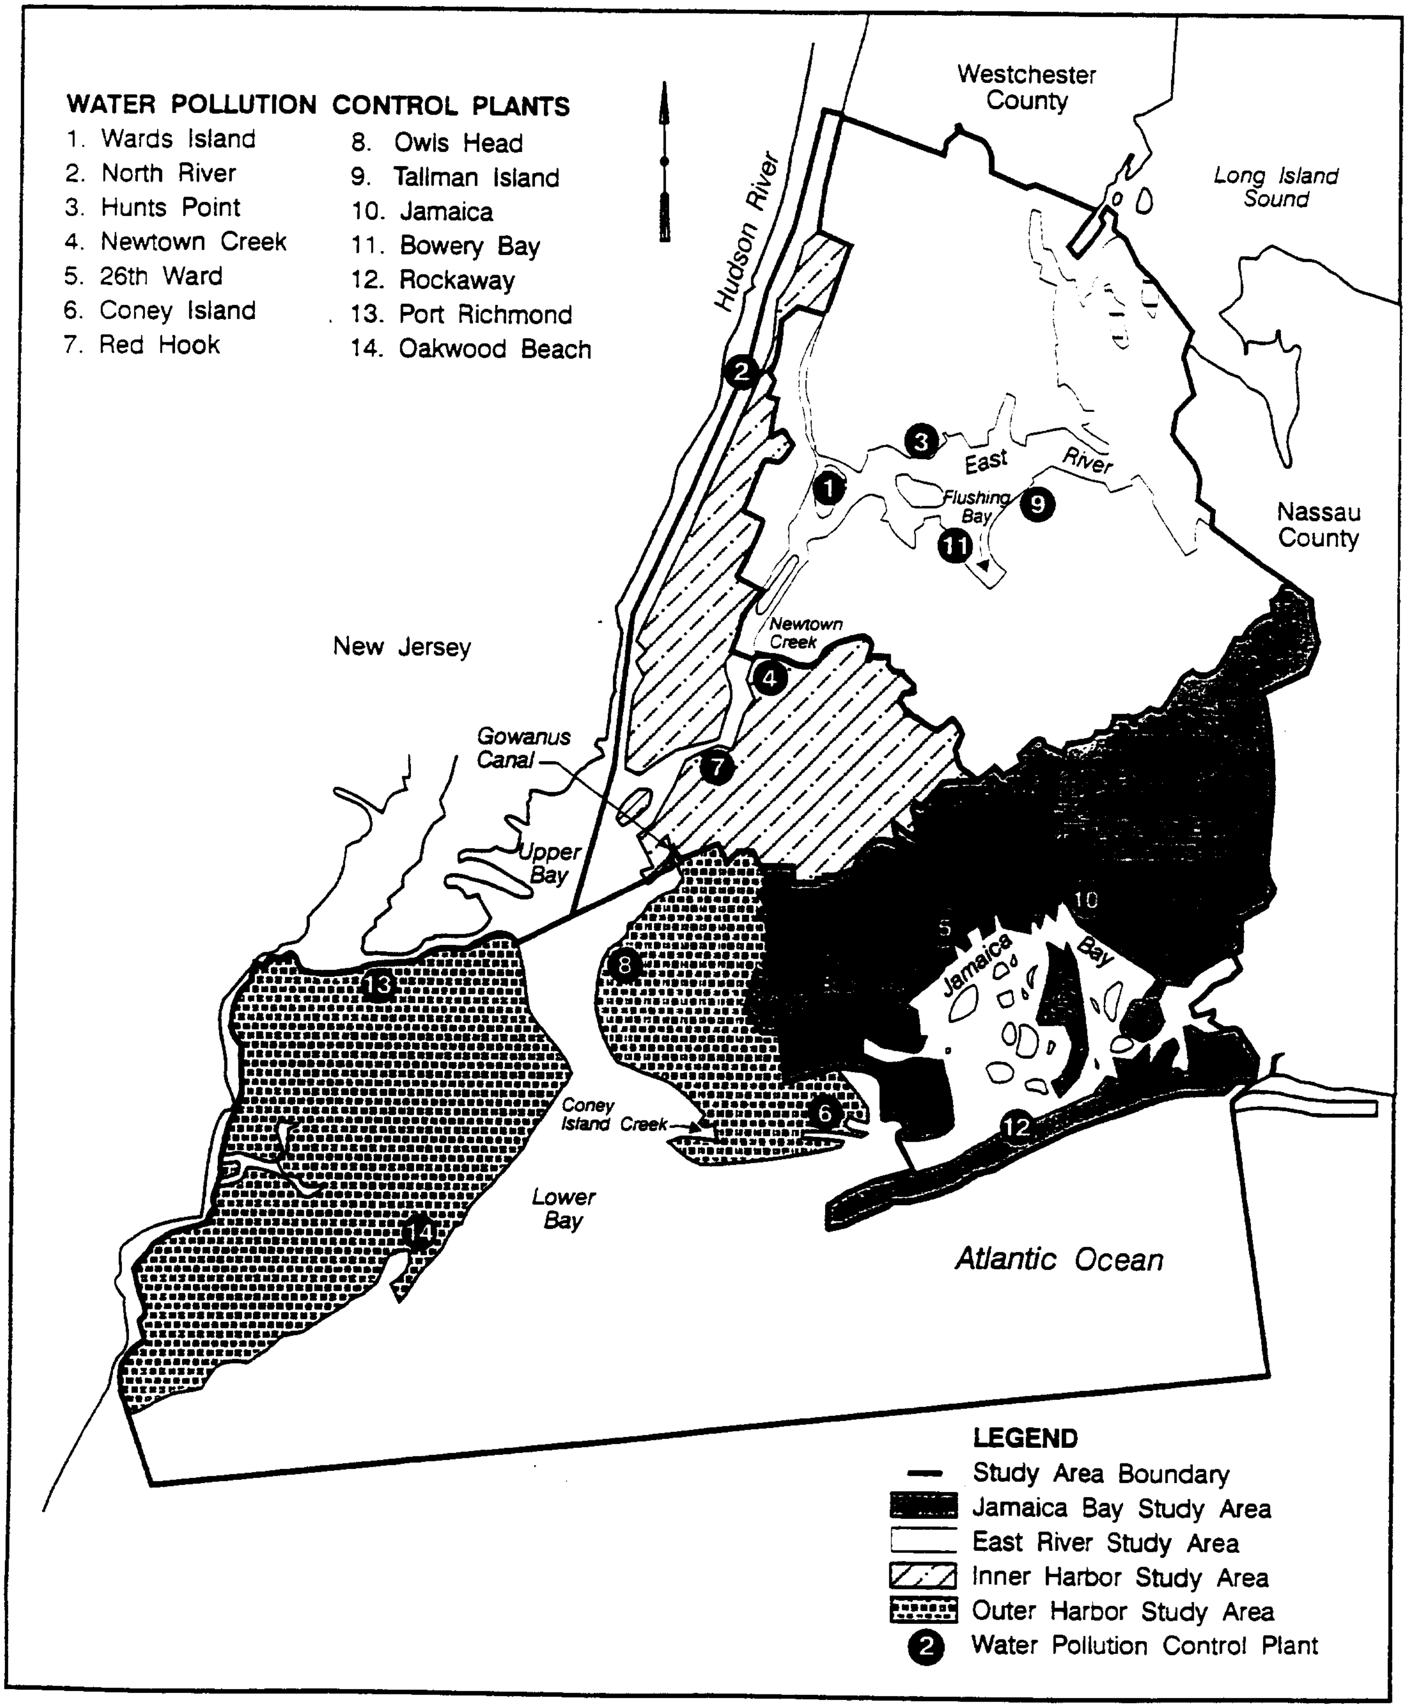

Figure 1 - New York City Areawide CSO Areas

- Regulator Drainage Area Runoff Coefficient
- Treatment Plant Diurnal Flow Pattern
- Treatment Plant Hydraulic Capacity
- Hourly Rainfall

For the three treatment plant drainage areas in the Inner Harbor, the above listed input parameters were collected and developed. The model was executed with over 30 years of historical hourly rainfall from a National Weather Service rain gauge located in Manhattan's Central Park. The results of the model runs are described in the next section.

RESULTS

The results of the rainfall-runoff model runs are presented in Figure 2 and Table 2. Figure 2 graphically presents the resulting total CSO capture from maximizing wet weather flow to the Inner Harbor treatment plants. The hydrographs show that by using the available wet weather treatment capacity (i.e., twice the design dry weather design flow) a significant portion of the potential CSO volume is captured at the plant. CSO capture at the plants ranges between 69 to 83% with an additional 2 to 5% capture due to in-line storage, mainly in the interceptor sewers. The total CSO capture at the plants ranges between 74 to 88% by maximizing the use of existing facilities.

Table 2 summarizes the results of the rainfall-runoff model for the three treatment plant drainage areas. Annual average volumes and percent capture are presented and are based on the 33-year rainfall record.

Table 2

Annual Average CSO Capture

	Annual Average		
Treatment Plant	Wet Weather Captured at Treatment plant (mg)	CSO Volume (mg)	% CSO Capture
North River	8,570	1,220	88
Newtown Creek	15,750	5,430	74
Red Hook	3,220	1,110	74

The volume captures presented have been calculated based on the "Guidance for Long-Term Control Plan" (EPA, 1995) which states that volume capture is based on "the total volume of flow collected in the combined sewer system during precipitation events on a system-wide, annual average basis".

DISCUSSION

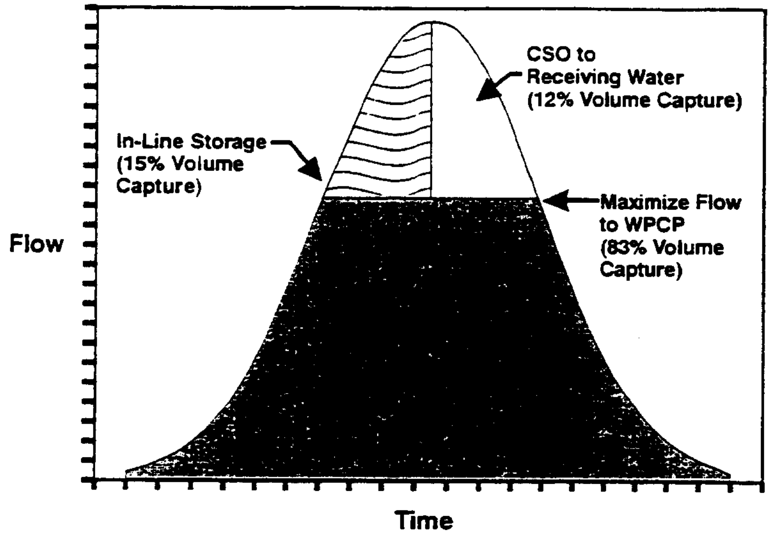
The analysis of wet weather capture at the Inner Harbor plants indicates that a significant portion of the wet weather flow generated can be captured and treated to primary treatment levels. By using the existing regulator, interceptors, and wastewater treatment plant capacities results in a cost-effective method of CSO reduction.

The Inner Harbor long-term CSO facility plan (NYCDEP, 1993) recommended the capture of wet weather flows at the treatment plants to address CSO pollution. It was demonstrated during the facility planning process that Inner Harbor CSOs have a minimal impact on dissolved oxygen and coliform levels in the open waters of the study area. This is due to the fact that the open waters (i.e., Hudson River, East River, and Upper Bay) are large waterbodies with substantially mixing and dilution capabilities. No water quality violations of DO or coliforms in the Inner Harbor are attributable to CSO discharges.

CONCLUSION

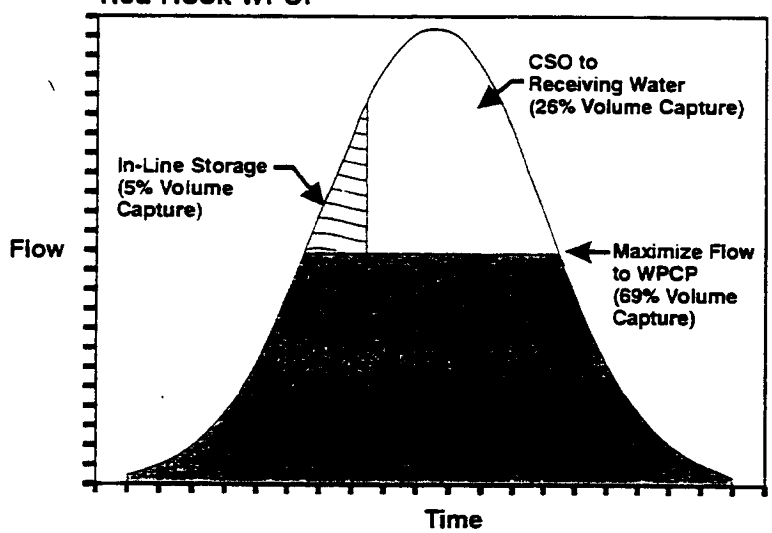
By maximizing wet weather flow and using existing facilities, traditional capital intensive CSO solutions such as off-line storage tanks, tunnels, and swirl concentrators, were avoided resulting in significant cost

North River WPCP



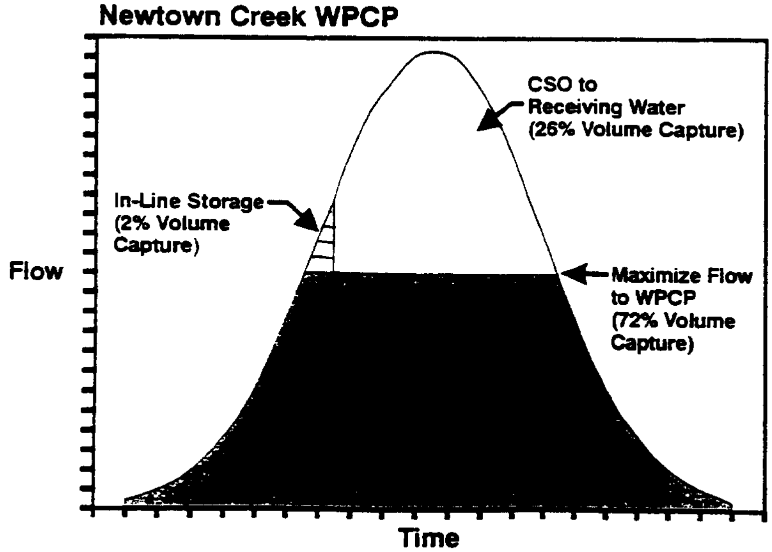
Total CSO
Volume Capture = 88%
(Annual Average)

Red Hook WPCP



Total CSO
Volume Capture = 74%
(Annual Average)

Newtown Creek WPCP



Total CSO
Volume Capture = 74%
(Annual Average)

Figure 2- CSO Volume Capture

savings. EPA's CSO Needs Survey projected a CSO control costs of approximately $630 million for the Inner Harbor area based on area and population. However, the recommended plan, which relies on maximizing wet weather flow to the treatment plant , is estimated to cost $15 million.

Thus, this control strategy is cost-effective and results in a significant reduction in CSO volume.

ABSTRACT

The City of Winnipeg initiated a major Combined Sewer Overflow (CSO) Management study in 1994 to "establish a cost-effective prioritized implementation plan for remedial works based on assessment of costs and benefits of practicable alternatives". Results from phase 3 of the 4-phase study strongly indicate that use of available in-line storage in the 43 individual combined sewer districts (total area about 10,000 ha) is the most effective and logical first step in the emerging wet weather pollution control plan. A "demonstration approach" was used to assess whether or not a proposed control plan could effectively achieve specific water quality objectives. As well, it was deemed important to asses options that were consistent with the EPA "presumptive approach" goals of 4 overflows and 85% capture.

A detailed review of Winnipeg's combined sewer systems confirmed that the volume of available in-line storage was substantial but unevenly distributed. Planning level models were developed to assess the use of existing in-line storage, identify strategic locations for additional storage/district transfers, optimize dewatering and conveyance rates, evaluate wastewater treatment plant limitation/upgrade requirements, and assess receiving stream water quality improvements. Real-time control and non-RTC strategies were evaluated to identify practicable control options which could maximize the use of available in-line storage without increasing the risk of basement flooding. It was found that strategies involving local RTC were less costly and could fully utilize available storage but contained a small element of risk. A non-RTC option involving "finger" weirs was found to be effective, contained no risk, but could not fully utilize storage.

This paper will present the analyses and the description of trade-offs between cost, risk, and performance measures of the range of storage options.

KEYWORDS

combined sewer overflows, in-line storage, real time control

INTRODUCTION

Winnipeg is the capital city of the Province of Manitoba, Canada, and is situated on the confluence of two major rivers, the Red and the Assiniboine rivers. Winnipeg's current population is about 650,000 and comprises a developed area of about 28,000 ha. The older central portion of the City is about 10,000 ha in size, and is serviced by a combined sewer system. The combined sewer serviced area is divided into 43 combined sewer districts, each of which overflow from 7 to 37 times during the recreation season (May to September, inclusive). During dry weather, the flow is diverted into interceptors and brought to three water pollution control centers (WPCCs) for complete secondary treatment. Plans are underway to disinfect the dry weather effluent from one of the treatment plants and the other two plants are under study.

The City is currently working on a combined sewer overflow (CSO) management strategy to develop various plans to control CSOs in the future. The CSO control strategy plan development involved an extensive technology review. This included:

- Best Management Practices (BMP);
- Separation (either full or partial) of the combined system;
- Storage (with and without district transfers)
  - off-line
  - tunnel/transport
  - in-line
- High rate treatment
  - Retention Treatment Basins (RTB)
  - Vortex Solid Separators (VSS)
- Floatables capture.

An integrated modeling approach was used to determine how each of the various candidate options for CSO control would perform. The integrated modeling approach involved three types of models which were sequentially linked:

- an urban hydrology model to estimate the runoff from a wide-variety of rainstorms over the year;

- a sewer system/control alternative model to simulate behaviour of the hydraulic system and thus determine when and where overflows would occur, the volume of interception, the volume of overflow, and the benefits of various control measures; and

- a receiving stream model was used to assess the hydrodynamics and biokinetics of the river water quality, i.e., transport, mixing, fecal coliform die-off, etc., in response to dry and wet weather loadings from the full range of urban discharges.

The various alternatives were assessed in terms of their performance with respect to various performance measures such as number of overflows, volume of overflows and compliance with surface water quality objectives for the receiving streams.

SEWER SYSTEM CHARACTERISTICS

Winnipeg is a very flat prairie city located in the Red River Valley. Generally, the elevation difference throughout the City is about 3 to 4 m (10 to 13 ft.). The Red and Assiniboine rivers water level is only 3 to 4 m below street level along the riverbanks. In addition, the hydrology of the prairie region, which may be relatively dry compared to the East Coast cities, creates large and intensive thunderstorms at least once a year. These geographical factors resulted in the design of existing sewer systems for protection of basement flooding with very flat grades and large diameters.

During dry weather flow, all wastewater is diverted into an interceptor and subsequently conveyed by a gravity to one of three wastewater pollution control centers (WPCC) for full secondary treatment processing before it is discharged to the rivers. However, during wet weather conditions, flow into the system is significantly greater than dry weather flow (DWF) and results in combined sewage overtopping the diversion weir and spilling into the river.

A typical sewer in one of the 43 districts has a 3 m diameter pipe extending 2 to 3 km perpendicular to one of the rivers. During typical operation, the dry weather flow in the combined sewer occupies only a small depth in the bottom of the sewer. A low weir, 0.3 to 0.6 m in height, typically diverts dry weather flow (DWF) either directly into an interceptor or to a pump station where it is delivered to the interceptor. During severe rainstorms, these same sewers are often surcharged, however, significant sewer storage volume is available for more routine rainstorms and could be potentially accessed for use as in-line storage.

The original sewer designs in the city allowed for flood protection of up to a storm of a 1-in-2 year occurrence. Over the past three decades, the City has been upgrading the combined sewer system to allow protection from basement flooding for a storm of up to a 5-year occurrence. These sewer relief programs have often resulted in the addition of a second major sewer pipe in each combined sewer district of comparable size to the main combined sewer trunk (e.g., 3 metres). These relief pipes offers the potential for increasing the volume available for in-line storage in each district.

DEVELOPMENT OF IN-LINE STORAGE ESTIMATES

In-line storage is the latent volume contained within the existing sewer pipe network that can be safely accessed through the use of a control device. Specifically, the control device is intended to cause excessive flows in a the sewer system to be stored in the pipes up to a safe level that does not decrease the existing level of the basement of flood protection. Figure 1 illustrates a typical profile of a combined sewer trunk found in Winnipeg.

Preliminary analysis of Winnipeg's combined sewer system found that large volumes of in-line storage may be available and could significantly reduce the number and volume of CSOs in a cost-effective manner. Accordingly, it was necessary to conduct a detailed review of the combined sewer systems to assemble the data needed on pipe geometry and critical elevations (invert and ground) to improve the accuracy of in-line storage volume calculations for all 43 combined sewer districts in Winnipeg. Once this information was assembled, it was possible to calculate the volume of storage available in each pipe for a specified weir or control elevation.

During the course of the CSO study, the need to investigate the different in-line storage concepts and control technologies evolved. The following three control concepts are the most relevant to the Winnipeg situation.

- Automated gate control
- Fixed finger weirs
- Accessing existing passive / latent storage.

The following discussion elaborates on these three control concepts as they relate to Winnipeg's CSO study and relevant local circumstances.

Real Time Control Gate Option

A review of rainfall history (recent 35 years) was conducted to understand the number and size of rainfall/runoff events that Winnipeg typically experiences during the open water recreation season (May 1 to Sept. 30 inclusive). It was found that most rainfall events are well below the hydraulic capacity of the combined sewer and could be stored within the system. The use of an automated gate system to access available in-line storage by temporarily holding wet weather flows (WWF) within the system during and after small rainfall events is one option under consideration. Runoff from these small rainfall events could be completely stored within the combined sewer system and then dewatered during and after the storm event (see Figure 2b).

The gate control option was assessed to estimate receiving stream impacts. The gate, initially open and in the "home position", would shut during the start of a wet weather event and remain shut until the event was completely over and the sewer was dewatered unless the water level in the sewer rose to a specified critical condition. If the water level or the rate of rise met a predefined trigger condition at selected strategic locations within the sewer system, the gate could be operated in the following two different modes.

- continuous modulation of the automated gate to fully utilized in-system storage while maintaining the existing level of basement flood protection; or
- opening the gate fully and leaving it open to assure that levels in the sewer would not threaten basement flooding.

In the first method, the maintenance of the level in the sewer at an elevation that would not threaten basement flooding would maximize the volume of in-line storage. It requires accurate hydraulic representation of the sewer system under the range of gate operating procedures to achieve this available storage without a threat to basement flooding.

Other operating concerns related to repeated surcharging of the systems presented serious design considerations. There was concern that the modulating method may lead to waterhammer, air surges, weakening of structural integrity, and increased the formation of sinkholes in or along the sewer system due to repeated surcharging.

An alternative gate protocol was developed involving the release of all of the stored combined sewage whenever the water level reached the specified critical elevation. This operation would cause more volume of combined sewage to be released to the river. Since even a small overflow would likely cause a violation of the microbiological water quality objective (i.e., fecal coliforms) designated to protect recreation (either 200 fc/100 mL or 1,000 fc/100 mL), the number of overflow events throughout the recreation season would be the same regardless of the operating protocol used. It should be noted that the automatic gate operation can be accomplished by local, i.e., district-specific RTC, since each district acts as a relatively discrete watershed to the interceptor. The dewatering of the various in-line storage elements in the different districts may require a system-wide or global RTC.

A second consideration used in the development of the gate operation strategy was the selection of the specified target elevation below which the combined sewage could be safely stored without affecting the existing level of basement flood protection. The water level and/or its rate of rise would be closely monitored and used to initiate gate opening to maintain the existing level of service with respect to basement flood protection. A key factor in gate automation is the speed at which it could be opened to permit system hydraulics to react quickly enough to keep pace with changes in a storm intensity and associated runoff and inflows. The gate operation is considered to have a fully automated real-time control system. Selection of these "trigger" conditions would have to be developed using sophisticated computer modeling.

A Workshop involving North American and European experts was held on the operations of in-line storage systems to review and assess its practicability to local conditions. The session identified that, due to the very flat sewer grades found in Winnipeg, there was the potential that air could be trapped in pockets at the top of the sewer and result in a air surges during wet weather operation of the gates. These air pockets could cause air surges to develop in response to the rapid filling of the combined sewer system under close gate conditions and could translate into pressure surges in service connections of homes and businesses at various locations along the sewer system. To prevent this conditioned from forming, it was determined that in-system storage levels should not exceed the obvert elevation of the sewer pipe at the selected location for automated gate control. Due to the relatively flat grades of the sewers, limiting levels to this control elevation would still allow for substantial realization of available in-line storage in each combined sewer district.

A second constraint was placed on the water surface profile to maintaining existing basement flood protection levels. A minimum depth of 3.0 m (approximately 10 ft) below minimum ground level was used as the maximum elevation the water surface profile would be allowed to reach in order to protect against basement flooding under in-line storage conditions, i.e., depths greater than 3.0 m below minimum ground elevation were considered adequate to protect against basement flooding for the current level of service. Accordingly, the minimum elevation of either the obvert or minimum ground elevation less 3.0 m was used as the control elevation to estimate available in-line storage.

One of the primary concerns associated with the use of real-time control for an automated gate to access available in-line storage is the potential increase in basement flood threatening risk . In order to minimize basement-flooding risk associated with gate control to a "virtually fail-safe" condition, additional design factors were considered:

- inlet restriction on catchbasins should be utilized to reduce the rate of inflow into the combined sewer system and result in system flow hydraulics no worse than that generated by a one in five year synthetic design storm;
- the logic of gate control systems (with redundancy) have to be developed to open the gate if there is a malfunction or failure in any of the water level sensing monitors;
- gates would have to be designed to open automatically in case of power failures or interruptions (e.g., an air-accumulator connected to a hydraulic operator or an air-driven motor); and
- utilization of the existing flood pumping stations to initiate emergency dewatering of the combined sewer system if the gate fails to open, (e.g., shaft breakage or mechanical malfunction).

Fixed Weir Option

The control concept described above was considered to be "virtually fail-safe". Given a history of basement flooding, there was still concern about added risk of basement flooding to the citizens of Winnipeg under extreme contingencies. Accordingly, other alternatives, which were inherently fail-safe, were considered. A fixed weir utilizing long weir lengths to minimize flow depth over the weir was considered both fail-safe and practicable (see Figure 2c). This option requires the construction of a large weir chamber utilizing finger weirs in the sewer system to achieve the lengths of weir needed (60 m in some cases) to access available in-line storage. The weir chamber would be 13 metres wide, and fit within the roadway right-of-way. A design condition of 150 mm (6 inches) depth of flow over the weir to safely pass a 1-in-5 year design storm was selected. The existing hydraulic gradeline (HGL) for each sewer system under the design event was reviewed to establish the top elevation of the weir (i.e. each HGL-0.15 m).

To maintaining existing basement flood protection levels under this option, a minimum depth of 3.2 m (approximately 10.5 ft) below minimum ground level was used to protect against basement flooding. Accordingly, the minimum elevation of either (HGL less 0.15 m or minimum ground less 3.2 m) was used as the control elevation to calculate available in-line storage.

A fixed finger-weir system to utilize available in-line storage has the advantage of little need for operational attention relative to an automated gate control system and is inherently more fail-safe. However, it is more costly to construct and will only utilize about 80% of the in-line storage that could be achieved through the use of an automated gate control system.

Passive and Latent Storage

Many of the underground combined sewer districts have relief sewers to reduce basement flooding. The primary purpose of the relief systems in Winnipeg is to improve the hydraulic conveyance of wet weather flows (WWF)so as to protect basements from flooding for a given design level of service (e.g. 1-in-5 year return frequency storm). The relief systems are designed to be active (i.e., overflow to the rivers) only during rainfall conditions. As described earlier, a low-level weir was historically installed in the combined sewer trunk and used to redirect DWF through an off-take system to the interceptor system. The diversion structures were originally designed to divert about 2.75 times DWF. To avoid dry weather overflows from occurring in the relief systems, careful attention was placed on the hydraulic modeling and design of relief overflow activation levels. Specifically, hydraulics in both systems (combined sewers and relief piping) were synchronized such that overflow from the relief system did not occur prior to overflows from the combined sewer system. The storage of combined sewage contained in the combined sewer system up to this activation level represents existing passive in-line storage volume.

Currently, many of the relief sewer pipes that are part of the combined sewer systems are below normal river water level (see Figure 2d). Each relief system outfall has a flap-gate installed to prevent river water from entering the sewer system. The majority of these relief pipes do not have a dewatering system and remain partially full under normal river water level conditions. As such, the combined sewage will remain in the relief pipe between storms until it is displaced by flows resulting from the next rainfall event. If this combined sewage could be dewatered to the interceptor, a significant amount of storage would be available to store small storms, and accordingly is considered latent storage.

COMPARISON OF IN-LINE STORAGE AVAILABLE

In-line storage calculations were performed for each of the 43 combined sewer districts to quantify the potential volume of storage available for each of the 3 control concepts previously discussed (i.e., gate, weir, and latent storage). The results are summarized on Figure 3. The automated gate option allows for the greatest volume of storage to be utilized, about 360,000 m^3. The fixed-weir option achieves about 300,000 m^3 of storage. Accessing existing passive and latent storage would provide in the order of 130,000 m^3 of storage. The cost of the automated-gate option is about $ 50 Million compared to the higher cost for the fixed weir of $ 100 Million. The risk of failure associated with the automated-gate option must be considered and the economic penalty of failure accounted for in the decision-making process. In order to safely access in-line storage, (i.e., reassure the public that there is no increase in the risk to basement flooding), the fixed weir option may be the only option the public will support. Existing latent storage could be accessed now but would require dewatering facilities to be installed and ensuring flap gates are operating correctly. This cost associated with accessing latent storage would be significantly lower than either of the other two options.

INTEGRATION WITH FUTURE BASEMENT RELIEF PROJECTS

The City of Winnipeg has an ongoing program to improve basement flood protection on a prioritized basis. The most flood-prone combined sewer districts are ranked and given highest priority for installation of relief sewers. Figure 4 shows the combined sewer districts that have been relieved and the remaining districts that require some degree of relief to improve basement flood protection. An estimate of potential increase in the in-line storage that could result from new relief pipes, for each of the in-line storage control concepts considered is shown on Figure 3. The analysis indicates that latent storage could be significant if it were possible to install all new relief pipes at a depth that the normal river level would control (i.e., below river level and held back by flap-gates). Specifically, future relief projects could potentially achieve as much in-line storage as the existing system with an automated gate control scheme, although the distribution of the storage in the system may not be optimal. New relief projects represents a very important opportunity with respect to supplemental in-line storage volumes that could significantly reduce the need for more expensive and complicated control technologies. Clearly, the addition of new relief pipes can provide improved basement flood protection while reducing the number and volume of CSO. The need for CSO control provides the opportunity to expand the design criteria of proposed relief projects to include consideration of cost-effectively maximizing in-line storage and minimize wet weather impacts.

CONCLUSION

In-line storage can be a cost-effective method of reducing combined sewer overflows. The use of automated gate controls is one method of maximizing the use of the available in-line storage at a reasonable cost. Concerns from the public that this automated system may increase the risk of basement flooding under worst-case contingency events, even if the risk is very low, may preempt its use. Alternative methods such as use of fixed weirs and using latent storage may access significant in-line storage for CSO control

Designing future basement relief projects with due consideration for increasing latent storage may prove to be a very effective integrated long term CSO control solution.

ABSTRACT

Performance data and treatment effectiveness at a CSO treatment facility are presented and discussed. During the spring and summer of 1997, extensive flow monitoring and sampling of the influent and effluent of the facility was conducted. Six storm events of various rainfall depths and duration were monitored for influent and effluent activity. Data were analyzed to assess pollutant load removal effectiveness for various parameters, including biochemical oxygen demand (BOD), suspended solids, bacteria, ammonia, and seven metals.

KEYWORDS

combined sewer overflow, treatment effectiveness, wet weather flow, combined sewer overflow storage

INTRODUCTION

A study was undertaken as part of the Westerly CSO Phase II Facilities Plan to evaluate the treatment effectiveness of the Northeast Ohio Regional Sewer District's (District) Westerly Combined Sewer Overflow Treatment Facility (CSOTF). Flows and pollutant loads were measured and the level of treatment determined for the varying storm events evaluated.

The District owns and operates three wastewater treatment plants (WWTP) that serve the Greater Cleveland area: Westerly, Easterly and Southerly. The Westerly District consists of approximately 40.47 km^2 (10,000 acres) on the west side of the City of Cleveland, 75 percent of which are served by combined sewers. Four interceptors—Westerly, Walworth Run, Northwest and Low Level—convey flows to the treatment plant. The Westerly WWTP is currently designed for 1.5 m^3/s (35 mgd) of dry weather flow. Wet weather flows up to 3.1 m^3/s (75 mgd) currently receive full treatment. Additional improvements planned at the plant will increase future wet weather capacity to 4.38 m^3/s (100 mgd). Flows above 3.1 m^3/s (75 mgd) are currently directed to the CSOTF.

The CSOTF was constructed for storage and treatment of combined sewer overflows collected from various locations across the service area. The Northwest Interceptor (NWI) functions with CSOTF to collect combined sewer overflows from the Lake Erie beach areas and Rocky River area and convey them to the CSOTF for storage and treatment.

Description of Facility and Operation

The facility is designed to provide storage for up to 47 300 m^3 (12.5 MG), sedimentation for up to 13.1 m^3/s (300 mgd), coarse screening for up to 39.4 m^3/s (720 mgd), and to hydraulically convey a peak flow rate of 78.9 m^3/s (1,800 mgd). Gates at the northerly end of the CSOTF influent channel open when flow rates exceed 13.1 m^3/s (300 mgd) and excess flow is transported to Lake Erie.

Flow to the CSOTF is controlled by a combination of static and automated regulators in the upstream interceptor system. During wet weather, excess flows from combined sewers and the Westerly Interceptor are routed to the NWI. A sluice gate diverts the Westerly Interceptor flow from the treatment plant to the NWI during high water level conditions at the Westerly weir diversion structure. All flow entering the 6.1 m by 2.74 m (20 ft x 9 ft) rectangular NWI is sent directly to CSOTF. The NWI operates only during overflow conditions. The control strategy during overflow conditions preferentially accepts flow from Walworth Run at the WWTP while diverting the Westerly Interceptor flow to the NWI and CSOTF.

Figure 1 is a site layout of CSOTF. Overflow from the Westerly system passes through 50.8-mm (2-inch) openings in two coarse bar screens into a 6.1 m x 6.71 m (20 ft x 22 ft) concrete center channel. The center channel is lined with 16 sluice gates which control the flow into four quadrants (quads). Each 30.78 m (101 ft) wide by 33.53 m (110 ft) long quad is comprised of four bays. At the entrance to each bay is a 1.22 m by 1.22 m (3 ft x 3 ft) sluice gate. Just past the gates is a 1.68 m (5.5 ft) pocket to collect the settled solids. As the water level climbs above 5.73 m (18.8 ft), a settled overflow begins and wastewater discharges over the weir opposite the sluice gate. The settled flow is collected in an open effluent channel and is directed through the outfall conduit to Lake Erie.

Bypassing the CSOTF is accomplished through the center channel using three downward operating sluice gates at the downstream end of the center channel. The 2.13 m x 3.05 m (7 ft x 10 ft) center gate and the two 3.05 m x 3.05 m (10 ft x 10 ft) outer gates are 2.9 m (9.5 ft) above the center channel floor. The gates are operated independently of each other based on water surface levels in the quads and the center channel. Operation of the various bypass gates is controlled by level rise rates in the center channel. When flow to the quads exceeds 13.1 m^3/s (300 mgd), the sluice gates are opened to allow discharge directly to the outfall. If flow entering CSOTF exceeds the bar screens' capacity, the bar screen bypass gates are opened and the sluice gates to the CSOTF quadrants are closed. All flow then bypasses treatment and travels through the center channel.

The storage volume in the CSOTF is about 22 710 m^3 (6 MG). The NWI provides an estimated 22 710 m^3 (6 MG) of additional storage. Storage of 1892 m^3 (0.5 MG) is also estimated to be available in the downstream portions of Walworth Run and Westerly Interceptors. Mass balancing using the flow monitoring data agreed with this estimates. After high flows subside, the stored volume is pumped back to the Westerly WWTP for full treatment.

After an overflow event ends and influent flows to Westerly WWTP decrease, the return flow volume and settled solids are pumped to the headworks for full treatment. High-rate dewatering pumps, capable of flow rates up to 0.11 m^3/s (18,000 gpm), deliver the return flow to the screen building. Sludge pumps remove the solids and discharge them upstream of either the screen building or the aerated grit tanks.

Recent improvements at Westerly WWTP allow Quad B of CSOTF to be used for primary treatment during short-term maintenance at the headworks and primary clarifiers. During these conditions, influent flow is directed to the CSOTF for primary treatment and is returned to the Westerly WWTP for secondary treatment. The return pipe from CSOTF to the plant has a hydraulic capacity of about 1.3 m^3/s (30 mgd).

METHODOLOGY

CSOTF operations were evaluated based on flow monitoring and water quality sampling results from six rainfall events, each of which resulted in overflows at CSOTF. The flow monitoring and sampling effort to collect data for the CSOTF effectiveness evaluation is described in this section. Water quality sampling results and their use in evaluating pollutant removal effectiveness are presented later in this paper.

Flow Monitoring and Water Quality Sampling Program Description

CSOTF effectiveness was assessed based on monitored flows and water quality samples collected at selected locations on both the influent and effluent sides of the facility. These locations are identified on Figure 2. System-wide flow monitoring in the Westerly WWTP district began in mid-March and extended through mid-June, 1997. Eleven flow monitors—three at CSOTF, two at the Westerly WWTP influent and the six most downstream interceptor monitors—remained in service until mid-August.

Influent water quality sampling occurred at a concrete access chamber, located on the line entering CSOTF (Location 1). Each influent sample consisted of three grab samples collected from three different depths within the channel and composited to account for possible vertical variability in influent quality.

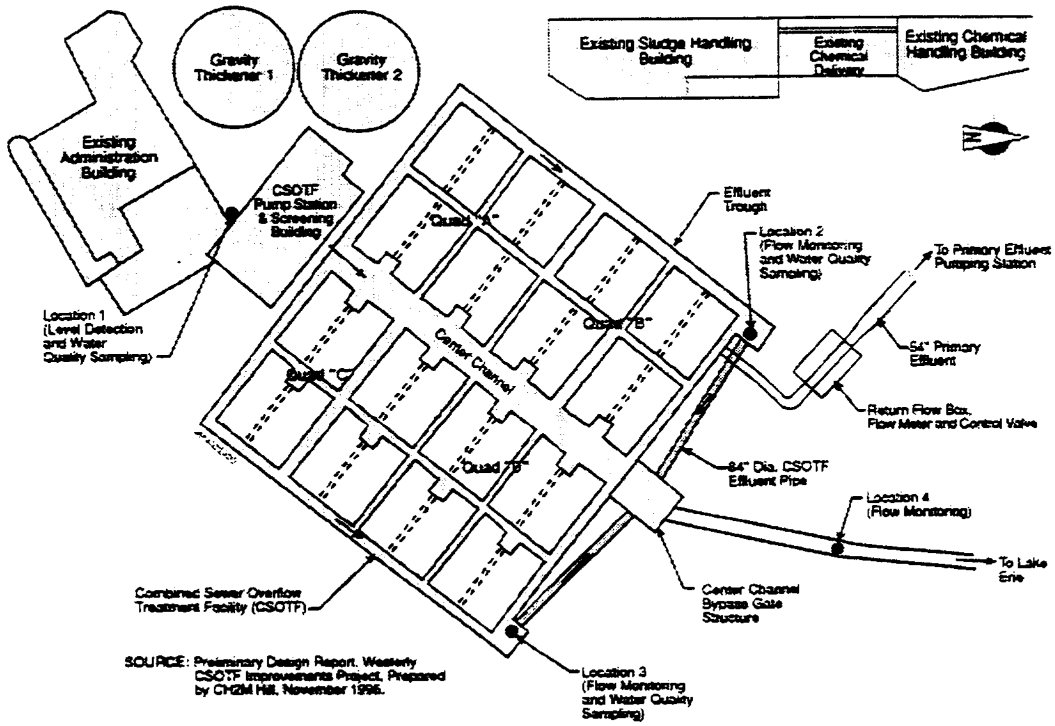

Figure 1. CSOTF Site Plan

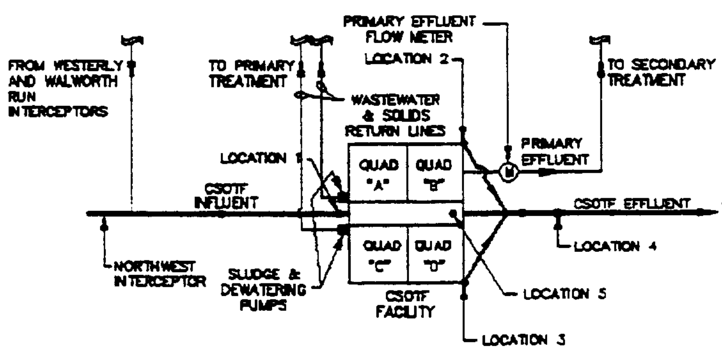

LOCATION	LEVEL DETECTION	FLOW MONITORING	WATER QUALITY SAMPLING
1			X
2		X	X
3		X	X
4		X	
5	X		

Figure 2. CSOTF Operation Schematic

Surcharging of the line, combined with restricted space, prohibited the installation of a flow meter. Therefore, the influent flows into CSOTF are based on the effluent flow meters.

Effluent sampling and flow monitoring occurred in the two settled wastewater discharge channels exiting CSOTF (Locations 2 and 3). Flow meters were installed in each of these two channels. Locations 2 and 3 were also equipped with automatic samplers which were operated manually to retrieve samples at one-hour intervals during overflow events.

Three groups of depth sensor gauges were placed in the center channel near the bypass gates. The depth readings were used to estimate the volume of flow through the center channel bypass gates during a CSOTF overflow. Water quality samples are routinely taken at this location and from the Quadrant B settled overflow by WWTP personnel for compliance reporting. Results from suspended solids and BOD tests of these samples were used in this evaluation.

Water Quality Sampling Parameters

Samples were collected and tested in the laboratory for the following parameters: Total suspended solids (TSS), BOD, COD, ammonia, hardness, oil & grease, *E. coli*, fecal coliform and metals (Cd, Cr, Cu, Pb, Hg, Ni, Zn, Fe). Field analysis of the samples included pH, DO, temperature and conductivity. All parameters were analyzed on the first storm event. Based on the sampling results that tested below detection limits, the decision was made to eliminate cadmium, lead, nickel and oil & grease parameters from analysis for subsequent events.

Overflow Events Monitored

Overall, six events were sampled for the CSOTF evaluation. A summary of these events, based on the rain gauge located at the WWTP, is provided in Table 1.

Table 1. CSOTF Evaluation Events

RESULTS

The results of the monitoring and sampling programs were used in the calculation of removal efficiencies. Tables 2 and 3 present CSOTF removal efficiency for TSS, BOD, chromium, copper, iron and zinc for each of the sampling events. All April 12th field data for the listed parameters and the associated flows is shown in Tables 4 and 5, as an example of the data analysis used to calculate removal efficiencies. Ammonia removals were negligible for all events monitored.

CSOTF Sampling Events

Overflow Event #1 occurred on April 12. The rainfall amounted to 27.94 mm (1.1 in) over a 9-hour-and-20-minute period. CSOTF experienced an 8½-hour settled overflow and about a 1¾-hour CSOTF overflow. Approximately 22.36 tonnes (24.63 tons) of TSS entered CSOTF and 14.20 tonnes (15.64 tons) left it. CSOTF removed an average of 50 percent of the metals that entered the system.

The second overflow event happened on May 19. Rainfall was intense though highly variable and widely scattered. A CSOTF overflow occurred at the beginning of the settled overflow and lasted one-half hour. Over 21.79 tonnes (24 tons) of TSS entered the system during this event and only 4.54 tonnes (5 tons) left it. Removal efficiency was high as the high-intensity storm flushed the sewer system. The short duration of the overflows allowed the majority of the TSS to be captured in CSOTF. This event showed good removal efficiencies for both TSS and BOD. Metals removal efficiency averaged just under 30 percent.

The May 25 rain event produced 21.08 mm of rain (0.83 in) in over 11 hours. CSOTF reacted with a settled overflow lasting 7½ hours. A CSOTF overflow did not occur. The low flows were apparently not high enough to flush out the system, as only 2.04 tonnes (2.5 tons) of TSS entered the system. The CSOTF removal efficiency of TSS for this event was 2 percent. Removal efficiencies were highly variable.

The fourth CSOTF overflow event happened on May 31. 25.4 mm (1.0 in) of rain fell in just over 12 hours. CSOTF experienced a 33½-hour settled overflow and a 1½-hour CSOTF overflow. The influent loadings of all parameters were low compared to Events 1 & 2. The TSS removal efficiency was 7 percent. A pattern similar to May 25 was observed where settled TSS appears to be resuspended and washed out. The removal efficiencies of the metals are negative, indicating the previously settled metals may have been re-suspended and washed out of the system.

The fifth event closely followed the fourth event. About 21.84 mm (0.86 in) of rain fell in 4¾ hours on June 2. CSOTF was already full. The settled overflow which ended at 2:35 a.m. was restarted at 8:45 a.m. A CSOTF overflow occurred from 8:58 a.m. until 11:44 a.m. The settled overflow continued until 12:55 a.m. on June 3. The sampling analysis shows 5-percent TSS removal. The effluent TSS increased during the event while the influent TSS continually decreased.

The sixth and final sampled event occurred on August 13. Roughly 10.16 mm (0.40 in) of rain fell in 4 hours. CSOTF had a settled overflow event that began at 2:40 a.m. and lasted until 4:00 a.m. The sampling analysis showed 10 percent of TSS was removed. The removal efficiencies of BOD and the metals were all negative, possibly reflecting the use of CSOTF earlier on August 12.

The patterns of CSOTF reactions to the various rain events indicate that the facility removed total suspended solids significantly more efficiently when the loading was greater than 20.43 tonnes (45,000 lbs). For the very low TSS loadings, CSOTF was ineffective. A correlation between low removal percentages and timing of quality sampling does not appear to exist. Flows during the initial portion of an event are generally not sufficient to flush the system. CSOTF removal efficiencies for metals generally were 30- to 50-percent.

DISCUSSION

The six studied events had a total rainfall of 117.09 mm (4.61 in) and a total volume of 872 212 m^3 (230.5 MG). Of the total volume, 558 140 m^3 (147.5 MG) was settled flow through CSOTF, 118 060 m^3 (31.2 MG) overflowed CSOTF, and 238 013 m^3 (62.9 MG) was returned flow to the WWTP. Return flow for the May 31 event was recorded as zero since the WWTP flows did not allow return of stored flow from the May 31 to June 2 rainfall events until after June 2.

Overall, CSOTF removed approximately 35.6 percent of both total BOD and suspended solids load (see Tables 6 and 7). As a combined sewer overflow storage facility, approximately 22 percent of the total CSOTF flow and its associated BOD and suspended solids load was stored and returned to the WWTP.

* BOD concentrations for this storm were mostly below detection limit (12 mg/l); thus, calculations could not be performed.

As a primary treatment facility, the CSOTF tanks provided 37.8 percent suspended solids removal and an associated 30.1 percent BOD removal.

Comparing the quantity of solids from the May 19, 1997, storm relative to the other storms is important in evaluating CSOTF performance. The higher peak flows in the May 19, 1997, storm (10.92 mm [0.43 in] of rain) generated more than two times the solids in one quarter the flow compared to the sustained storms of May 31 and June 2 (46.99 mm [1.85 in] of rain). CSOTF solids removal performance at these higher suspended solids loadings was significantly better (78.1 percent) than at the lower suspended solids loadings (4.6 percent). The authors' opinion is that the performance difference relates to a higher concentration of inert materials at the higher loadings but this has not been verified by testing.

CSOTF Loading and Performance Characteristics

A distinct peak loading characteristic was documented for the Westerly District collection system. Peak flows in excess of the CSOTF 13.1 m^3/s (300 mgd) design flow rate appeared to mobilize and convey solids stored in the collection system to the Westerly WWTP. Peak flows of 13.1 m^3/s (300 mgd) and 33.3 m^3/s (760 mgd) for the April 12 and May 19 storms produced peak concentrations of 628 mg/l and 980 mg/l suspended solids and 208 mg/l and 120 mg/l BOD respectively. Over 50 percent of the pollutant loads recorded for these storms were during peak flow conditions.

The May 19 storm was a relatively short duration, widely scattered storm with areas of high rainfall intensity. Rainfall averaged 10.92 mm (0.43 in) with a peak intensity of 70.61 mm (2.78 in) per hour at one rain gauge. The storm produced both the highest peak flow rate through CSOTF of approximately 33.3 m^3/s (760 mgd) and the highest total suspended solids loading of the storms evaluated. This storm generated over 48 percent of the total suspended solids recorded during the evaluation period.

Following peak suspended solids loading conditions, a period of solids carry-out was noted. Effluent concentrations were elevated for 2 to 4 hours following a peak influent loading condition. A shorter period of solids carry-out was also noted when flows increased later in a storm event.

CONCLUSIONS

As a result of the CSOTF performance evaluation, future CSO treatment options should consider improving inlet hydraulic conditions and using lower peak design loading rates. In-system options should be considered to minimize the peak flow/peak loading condition impacts. In-system options should include identification of low-velocity sewers and areas that may accumulate suspended solids during dry weather conditions for replacement or periodic flushing and optimizing treatment plant influent flow control.

ACKNOWLEDGMENTS

The authors would like to thank the operations staff at the District's Westerly WWTP for their work in coordinating with the evaluation sampling personnel, providing plant performance data, and reviewing the CSOTF performance conclusions.

The flow monitoring and quality sampling program involved the District, Metcalf & Eddy (M&E), Dodson-Stilson, Inc. (DSI), ADS Environmental Services, Inc., Enviromatrix Labs and Adams Laboratory. District plant personnel provided daily logs, results from standard water quality sampling and interpretation of operations. DSI provided field services to take the water quality grab samples and collect the automatic samples. Samples were analyzed for bacteria by Adams Laboratory and for all remaining parameters by Enviromatrix Labs. ADS provided, installed and maintained the flow meters throughout the project. M&E coordinated the field and laboratory efforts. Data was submitted to M&E for use in the system analysis.

GLOSSARY

Settled Overflow: A CSOTF event in which settled flow goes over the quadrant weirs to Lake Erie.

CSOTF Overflow: The portion of flow that passes through the center channel bypass gates directly to Lake Erie.

Return Flow: The quantity of combined sewer system overflow retained in the CSOTF and NWI and returned to the Westerly WWTP for full treatment.

STORAGE/SEDIMENTATION FACILITIES FOR CONTROL OF STORM AND COMBINED SEWER OVERFLOWS: DESIGN MANUAL

Joyce M. Perdek, Richard Field, and Mary Stinson, U.S. Environmental Protection Agency*

ABSTRACT

This paper summarizes a report of the same title (Stallard *et al.*, 1998), which describes applications of storage facilities for wet-weather flow (WWF) control and also presents step-by-step procedures for the analysis and design of storage-treatment facilities. In both the report and this paper, retention and detention storage, and sedimentation treatment are classified and described. Retention storage facilities capture and dispose of stormwater runoff through infiltration, percolation, and evaporation. Detention storage is temporary storage for stormwater runoff or combined sewer overflow (CSO). Stored flows are subsequently returned to the sewerage system at a reduced rate of flow when downstream capacity is available, or the flows are discharged to the receiving water with or without further treatment. Sedimentation in storage basins alters the WWF stream by gravity separation. The stormwater runoff and CSO must be characterized to estimate the efficiency of any sedimentation basin. International as well as national state-of-the-art technologies related to storage and sedimentation treatment are discussed.

KEY WORDS

wet weather flow, sedimentation, detention storage, retention storage, combined sewer overflow, stormwater

INTRODUCTION

Among the earliest examples of public works are urban drainage systems designed to convey urban storm flow or WWF away from populated areas to receiving waters. WWF may consist of stormwater alone, or it may consist of both stormwater and sanitary or domestic wastewater in combined sewer systems, which is known as CSO when it overflows. Discharges from WWF conveyance systems have significant impacts on receiving-water quality. Recognition of their significance has increased as the quality of effluents from municipal wastewater treatment plants has improved as a result of the Clean Water Act. National cost estimates for controlling pollution from WWFs are substantial. As reported by the U.S. Environmental Protection Agency (EPA) (Field *et al.*, 1996), the cost of meeting water quality standards for stormwater discharges has been projected to be as high as $400 billion in capital costs and $540 billion/year in operation and maintenance (O&M) costs. Capital costs for CSO abatement are estimated to be more than $50 billion for eleven hundred communities served by combined sewer systems.

The variable nature of WWFs makes controlling them difficult. Transport and treatment facilities for controlling excess WWF, which generally are designed to handle medium-intensity, medium-duration storm-flow volumes, are frequently idle during dry periods and overflow during large storms. Temporary storage of excess WWF can be an effective and economical method of controlling flooding and pollution. Excess WWF stored during large storms or during more intense rainfall periods can be released slowly when capacity in the drainage and treatment system is available. As a result, overflows occur less often than they would without this storage.

PLANNING METHODOLOGY

The solution to WWF problems is most often a combination of various best management practices (*i.e.*, nonstructural and low-structurally-intensive alternatives) and unit process applications (*i.e.*, physical treatment for removal of settleable and suspended solids and floatable material). Storage and/or sedimentation facilities are and should be the backbone of such an integrated WWF management plan. The following are the elements of planning a storage or sedimentation facility:

- general planning conditions,
- establishment of treatment goals,
- planning methodology,
- cost optimization methodologies,
- storage-volume determination methods,
- effect of storage and/or sedimentation, and
- integration with existing system.

General planning conditions include determining whether storage or sedimentation is the best solution for dealing with the problems involved in terms of the type of WWF and the treatment goals. The feasibility of locating such a facility must be examined. **Treatment goals** include, but are not limited to, the maximum number of yearly overflow events, maximum overflow volume, and desired detention time.

Figure 1 illustrates the planning methodology for source control options. The basic **planning methodology** includes the following steps:

- identify functional requirements,
- identify site constraints,
- establish basis of design,
- select storage and/or treatment option,
- estimate costs and cost sensitivities,
- evaluate option for compliance with treatment goals, and
- refine and complete or modify and repeat.

The **cost optimization methodologies** used for storage or sedimentation facilities depends on the purpose of the facility: flow control only, or a combination of flow control and pollutant reduction. The Mass-Diagram Method should be used for flow control facilities, and the Production Theory Method should be used for flow control and pollutant reduction facilities. Both of these methods are described in the report.

Storage-volume determination methods demonstrate the effect of different possible combinations of storage and/or sedimentation design parameters (*e.g.*, settling time and facility size) on flow control. Methodologies for approaching these calculations include the following: desktop hand computations; statistical analysis of rainfall and flow data; simple, continuous simulation of WWF systems; and detailed, continuous or single event simulation of WWF systems. Deciding on the approach to be used depends on the size and complexity of the drainage area and/or sewerage system. For small and simple systems, hand computations can be used. For large and complex systems, computerized continuous simulated models can be used.

To evaluate the **effect of storage/sedimentation** alternatives being considered, the degree to which they achieve the goals developed must be compared. Cost and performance of each should be considered. Thus, the best apparent alternative should be the most cost-effective one meeting the technical goals established.

Integration of a storage or sedimentation facility with an existing sewerage or drainage system involves selecting control methods that are both applicable to and compatible with the existing facilities and goals. The following steps should be taken: identify existing components and function, establish system needs, identify applicable control alternatives, and determine control method compatibility.

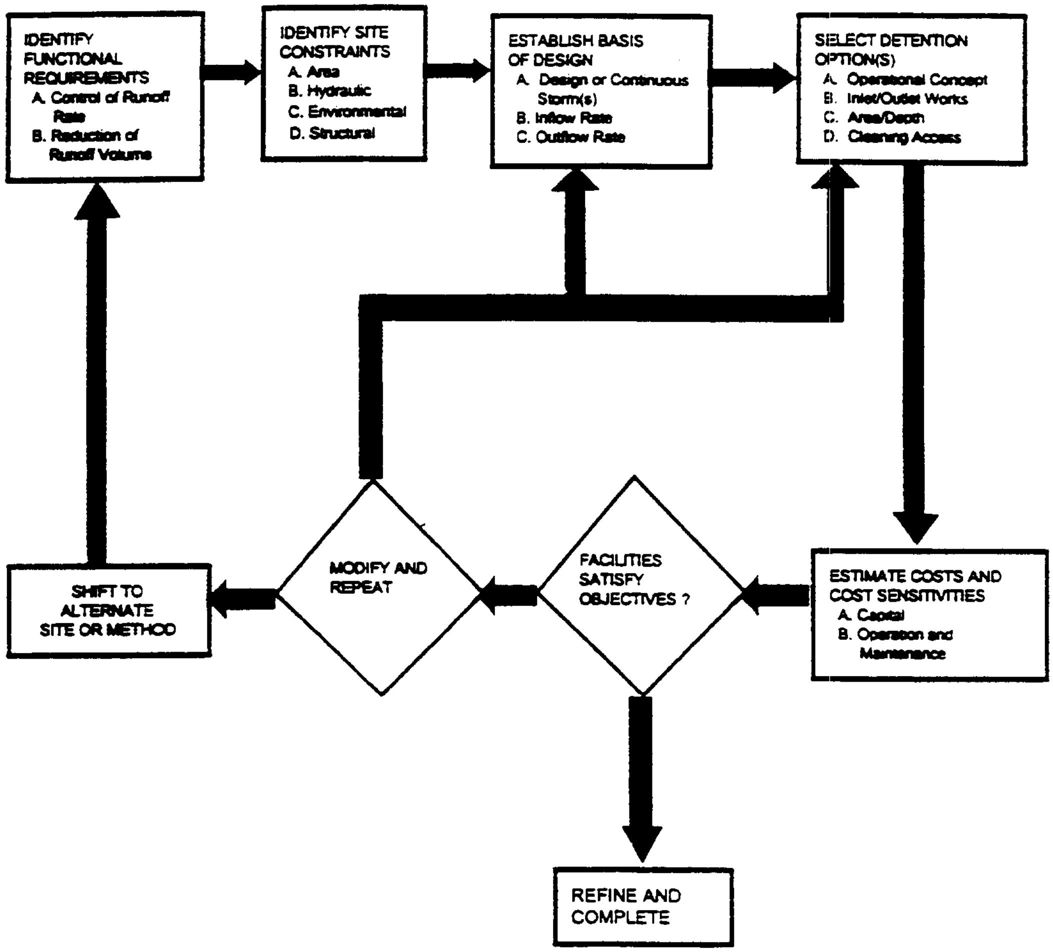

Figure 1. Source Control Planning Methodology

FACILITY DESIGN

The main steps to be followed in designing storage/sedimentation facilities for both combined sewer and separate storm sewer systems are:

- identifying problem,
- identifying data needs,
- determining the pollution load,
- identifying the flood control and pollutant removal objectives,
- optimizing control effectiveness,
- conducting a pollutant budget analysis,
- determining an operating strategy, and
- selecting the instrumentation and control strategy to be used.

Design of Retention Storage Facilities Stormwater retention is the storage of excess runoff for complete removal from the surface drainage and discharge system. The water collected percolates through the bottom of the retention facility and may reach the groundwater. Stormwater retention facilities may take a variety of forms, such as ponds and perforated culverts. This section describes design procedures and operation considerations for the most common retention storage facility types – dry and wet ponds.

Size and location are important design considerations for both types of ponds. Size requirements include not only volumetric capacity but also surface area and soil interface area requirements. The **pond configuration** depends on:

- the runoff storage volume needed,
- the surface area, configuration, and weir length required to assure adequate settling during sedimentation operation,
- the surface area needed for adequate transfer of oxygen into the pond water to allow aerobic decomposition of organic pollutants,
- the soil-water interface area needed for adequate percolation of stored runoff between storm events, and
- the area needed to serve whatever multiple uses the basin may have.

The suitability of a site within a drainage area for **locating a retention pond facility** depends on:

- site availability,
- compatibility of surrounding land uses with a stormwater retention facility and its other functions,
- the area required,
- soil permeability,
- tributary catchment size, and
- the site's relationship to other sewer or drainage facilities.

The procedure presented for **design of retention facilities** consists of the following steps:

- quantify functional requirements,
- identify waste load and flow reduction,
- determine preliminary basin size,
- identify feasible pond sites,
- investigate most promising sites,
- establish basin sizes,
- design solids removal facilities, and
- determine pond configuration.

The approach, which should make use of existing experience, known concepts, or developed theories, must be integrated to insure that the desired functions of the ponds (sediment removal, infiltration and percolation, flood control, or flow reduction) are compatible with the type of flow reaching the pond (stormwater runoff or CSO) and any other multi-use aspects (recreation, irrigation, aesthetics, etc.). In actual practice, retention ponds are very seldom used for CSOs because the organic solids tend to seal the pond bottom and reduce the soil infiltration capacity.

The efficiency of retention ponds in reducing stormwater pollutant loadings depends heavily on the underlying soil as a treatment medium. The mechanisms of removal include settling, filtering, biological activity, coagulation, adsorption, and chemical reaction. The major operational problems with ponds center around handling captured solids. Other operational concerns are the inlet and outlet structures, maintenance of vegetative cover through alternating wetting and drying periods, insect control, odor control, and maximizing availability of the pond for alternative uses. Pond construction costs can be estimated from graphs that show the costs for either area or storage capacity required such as the 1979 and 1980 figures presented in the report. Operational costs must be estimated on a site by site basis.

Design of Detention Storage Facilities Detention storage delays excess runoff and attenuates peak flows in the surface drainage system. During peak flows, detention storage holds excess water until the inflow decreases and releases it during low-flow periods. Because of sedimentation that occurs during detention, detention storage in tanks or basins can also be considered a treatment process for high storm flow volumes that create tank or basin overflow. Site constraints to be considered for detention storage facilities include tributary area, topography, local land use, and area available for the structure or basin.

The types of detention storage include onsite and in-system. Onsite detention is the detention of stormwater or CSO at the source before it reaches a sewer network or receiving water. Onsite detention occurs in natural ditches, open ponds or basins, rooftops, parking lots, or recreational facilities. In-system detention storage holds storm flow either in series or in parallel within the collection system. In-system detention storage includes inline storage and offline storage. Inline storage can be accomplished by using the available volume in trunk sewers, interceptors, wet wells, and tunnels to store excess WWF. Excess flows are stored off line in open or covered basins, caverns, mined labyrinths, and lined or unlined tunnels. Functionally, the application of onsite detention differs little from in-system storage other than the location where the storage occurs. However, while onsite detention is used primarily to minimize the cost of constructing new storm sewers to serve a developing area, in-system storage is generally used to decrease the frequency and volume of overflows from combined sewer systems.

Factors to be considered in the design of **onsite detention storage** facilities are:

- tributary area,
- storage area and volume,
- structural integrity, and
- responsibility of the owner.

Factors to be considered in the design of **in-system detention storage** facilities are:

- size and slope of sewers,
- peak flow rates,
- controls required for system operation, and
- resuspension of sediment.

The **design methodologies for onsite storage and in-system storage** are very similar and consist of the following steps:

- identify functional requirements,
- identify site constraints,
- establish basis of design,
- select storage options and locations,
- estimate costs, and
- complete design.

The construction costs for in-system storage have been reported for selected demonstration sites. Since construction costs are highly site specific, they are not very useful as a basis for estimating costs. These costs also vary considerably depending on the complexity of the flow regulators and control systems. Detailed O&M cost data are limited. O&M costs must be estimated for specific facilities from the operation plan and maintenance schedule.

Design of Sedimentation Facilities Sedimentation in storage basins, commonly referred to as storage/sedimentation, alters the WWF stream by gravity separation. Storage/sedimentation is the most commonly and, perhaps, most effectively practiced method of urban CSO and stormwater runoff control in terms of the number of operating installations and length of service. Conversely, storage/sedimentation is frequently criticized for lack of innovation because of its simplicity and high cost due to size and structural requirements.

Functionally, the applications of downstream storage/sedimentation facilities vary from essentially total containment, experiencing only a few overflows per year, to flow-through treatment systems where total containment is the exception rather than the rule. For total containment, the major concerns are the large storage volume, the provisions of dewatering, and post-storm cleanup. For flow-through treatment systems, performance hinges on treatment effectiveness and design considerations including loading rates, inlet and outlet controls, short circuiting, and sludge and scum removal systems. In the case of offline facilities, the option exists to selectively capture the portion of storm flow with the highest pollutant load, referred to as the first flush, and bypass the balance of the flow to avoid the discharge of much of the pollution.

Factors to be evaluated in the design of storage/sedimentation facilities include the following:

- storage volume,
- treatment efficiency,
- need for disinfection, and
- site constraints.

The following are **storage/sedimentation facility design procedures**:

- identify functional requirements,
- identify site constraints,
- establish basis of design,
- select sedimentation facility configuration,
- identify and select pretreatment,
- determine auxiliary systems needed,
- estimate costs and conduct cost-effectiveness analysis, and
- complete design.

The major O&M goal of downstream storage/sedimentation basins is to provide a facility that is available to its full design capacity as long as needed. Secondary goals include clear, prompt, and complete records of performance, reliability to provide for real location of personnel and facilities in non-storm periods, and dual-use operations, such as, backup treatment and/or flow equalization for dry-weather plants. The O&M requirements and procedures should be developed from the operational plan; there are no industry-wide standards.

The report presents detailed design considerations and procedures for downstream storage/ sedimentation basins, which are illustrated by example and through references of designed and operated facilities. Cost information is also provided. Examples of representative CSO storage/sedimentation basins and auxiliary support facilities are shown in Figure 2.

INTERNATIONAL PERSPECTIVE

The application of storage/sedimentation controls for urban WWF problems is not unique to the United States. In this era of excellent communications and increasing technology-sharing on an international scale, similar approaches are found in many areas of the world. Several technologies developed internationally are introduced including flow-control devices developed in Sweden, Denmark, and Germany; an in-receiving water flow balancing system developed and applied in Sweden; and an innovative self-cleaning storage/sedimentation basin used in Zurich, Switzerland.

For certain cases, the flow from storage/sedimentation facilities can be controlled by means of specially-designed flow-control devices, which provide more effective flow control than can be accomplished with conventional static devices. An advanced static device, the Steinscruv flow regulator, developed in Sweden in the 1970s by Stein Bendixsen, consists of a stationary, anchored, screw-shaped plate that is installed in a pipe. In that part of the plate which fits against the bottom of the pipe, there is a bottom opening to release a specified base dry-weather flow. The Hydrobrake, developed in Denmark in the mid-1960s, is used to control outflows from storage structures. Hydrostatic pressure associated with the water level controls the rate of flow through this device. A device with a similar operating principle, the Wirbeldrossel or turbulent throttle, developed in Germany in the mid-1970s, also regulates flow from a storage facility. Another flow regulator valve, developed in Sweden in the late 1970s, is a central outlet pipe surrounded by a pressure chamber filled with air. Water pressure on the upper portion of the device

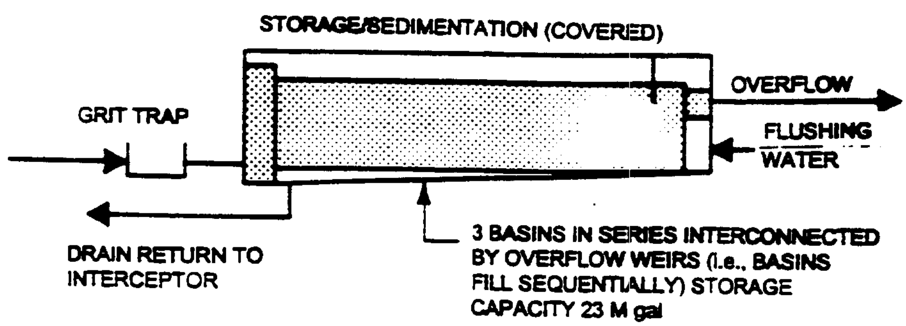
NEW YORK CITY (SPRING CREEK), NEW YORK



SACRAMENTO (PIONEER RESERVOIR), CALIFORNIA

Figure 2
Representative CSO Storage/Sedimentation Basins and Auxiliary Support Facilities

displaces the fabric at the outlet, which controls the discharge volume.

The Flow Balance Method, an innovative approach to urban WWF treatment for the protection of lakes, has been developed and applied at several locations in Sweden by Karl Dunkers. Also being used in other locations, the Flow Balance Method uses a portion of receiving-water volume within a hanging curtain to store runoff, while allowing for suspended solids sedimentation, before discharge.

Typically, removal of settled solids from an inline storage facility has been a problem that requires an auxiliary flushing system of some sort. An innovative approach to eliminating this problem has been implemented in Zurich, Switzerland. A continuous dry-weather channel, which is an extension of the tank's combined sewer inlet, is formed by a number of parallel grooves connected at their end points. Any solids that have settled in the basin during its storage operation are resuspended by the channelized high-velocity flow during the drawdown following a storm event.

ACKNOWLEDGMENT

The authors acknowledge the efforts of the authors of the full report: W. Michael Stallard, William G. Smith, Ronald W. Crites, and John A. Lager. Ramjee Raghavan and Helen Egidio provided support for developing the figures.

DISCLAIMER

The full report (Stallard *et al.*, 1998) was drafted between September 1979 and October 1981 by Metcalf & Eddy, Inc., under the sponsorship of the U.S. Environmental Protection Agency's Office of Research and Development in Cincinnati, Ohio, in partial fulfillment of Contract No. 68-03-2877. Along with this paper, the 1998 revision is being released currently to provide information to communities in support of their stormwater and CSO management efforts. Despite the revision, some of the content may no longer be entirely current.

REPORT AVAILABILITY

Copies of the report are available from the National Technical Information Service (Order No. PB98-132228), which can be contacted via the EPA's National Risk Management Research Laboratory Wet Weather Flow Home Page at "www.epa.gov/ednnrmrl/".

INTRODUCTION

Monroe County has a long standing history of being at the forefront of protecting water quality and enhancing the recreational use of area surface waters. In the early 1970's, Monroe County had begun developing one of the first Combined Sewer Overflow Abatement Programs in the nation. During the planning phases of the program, several abatement technologies were evaluated with a deep-rock tunnel storage and treatment system being selected for construction. Continuing Monroe County's philosophy of improving the protection of water quality, enhanced methods of operation and maintenance of the storage and treatment system are being developed.

Monroe County and its consultants recognized the value of the mathematical models used during the planning and design phases of the program. The huge modeling effort put forth during the early 1970's is being brought forward to the 1990's to assist in the development of an operations model. This work increases the value of the initial modeling efforts by facilitating the development of an operation and maintenance model to enhance the day-to-day operation of the system.

HISTORY OF THE SYSTEM

In December 1976, the Wastewater Facilities Plan for the Rochester Pure Waters District's Combined Sewer Overflow Abatement Program (CSOAP) was completed by a joint venture of Erdman Anthony Associates; Lozier Engineers, Inc.; and Seelye Stevenson Value & Knecht, Inc. This plan contained recommendations for a deep-rock tunnel storage system for storing and conveying combined sewage overflowing from various points in the surface sewer system.

The final plan included the design and construction of a 33 mile network of deep-rock tunnels, 54 drop shafts, five control/relief structures, a bridge, and wastewater treatment facility upgrades. The service area for Monroe County's Rochester Pure Waters District encompassed more than 10,000 urban acres.

The design basis for determining the amount of storage volume and level of pollution abatement for the tunnel system included an analysis of the quantity and quality of overflows from the surface sewer system. This analysis was based on historical rainfall events and their effect on established water quality standards for the local receiving waters. The volumes of overflow from each rainfall event were calculated through the use of the Hydrograph-Volume Method (HVM) Model and the Quantity-Quality Simulation (QQS) Model developed by Dorsch Consult Ltd. of Munich, Germany.

The effective storage volume recommended in the 1976 Facilities Plan was approximately 10 million cubic feet. This related to approximately 2 water quality contraventions per year.

Subsequent to the review of this methodology by the United States Environmental Protection Agency (US EPA) and New York State Department of Environmental Conservation (NYS DEC), the size of the project was reduced by establishing an effective target volume of 6.3 million cubic feet of storage. This volume related to approximately 3.5 water quality contraventions per year. This target volume was contingent upon the results of hydraulic analyses of the tunnel system to determine the sensitivity of the tunnel volume on the dynamic performance of the system and the effect on water quality.

The study report for the 1976 Facilities Plan was published in eight volumes. Each of the volumes presented the data, methodology, results, conclusions, and recommendations of its respective study task.

The subject of each volume were Volume I - Planning Analysis; Volume II - Network Analysis; Volume III - Overflow Quantity-Quality Analysis; Volume IV - Receiving Water Quality Study; Volume V - Geotechnical Report; Volume VI - Infiltration/Inflow Study; Volume VII - Environmental Assessment Statement; and Volume VIII - Network Analysis Data. The study conducted for the 1976 Facilities Plan represented a huge planning effort where extensive hydrogeometric data (land surface characteristics) and hydraulic data (sewer network characteristics) for the vast majority of the Rochester Pure Waters District's surface sewer system were developed.

During the design, technical questions had to be resolved involving the behavior of flows in the proposed tunnel system. The tunnel system would be receiving substantial inflows at various points within the system. Depending on the path of any given storm, these inflows would be proceeding both upstream and downstream within the tunnel system. Also, at any given point in time, some portions of the tunnel system could be partially full while other portions of the system are pressurized. These conditions could induce severe pressures in the system that could cause damage to the tunnel or cause geysering of flows back up the drop shafts.

The St. Anthony Falls Hydraulic Laboratory (SAFHL) of the University of Minnesota and Dr. Charles C. S. Song were retained to develop a mathematical mixed flow hydraulic transient model for the tunnel system. The model could accurately simulate the actual process of pressurization and depressurization during the filling and emptying periods of the tunnels. It traced the pressurization surges and calculated flow and pressure at every node along the system continuously throughout a simulation.

The purpose of Dr. Song's model was to assist in the preliminary geometric design and to analyze hydraulic transient effects on the proposed tunnel system. Larger diameters were recommended in certain tunnel sections to reduce the potential for hydraulic transients such as geysering, column consolidation, water hammer, excessive backflows, and to attenuate peak hydraulic pressures generated in the system. From a hydraulic stability standpoint, the analysis indicated that 11.3 million cubic feet of static storage was required for proper hydraulic performance of the proposed tunnel system and to meet the water quality goals set for the program.

The federal grant programs of the 1980's made the construction of the CSOAP Tunnel System possible. To date, the wastewater treatment facility upgrades and 30 miles of the originally planned 33 miles of the tunnel system with associated dropshafts and control structures have been constructed and are in operation. All combined sewer overflow discharge points to local receiving waters have been redirected to the tunnel system. A schematic plan of the CSOAP Tunnel System is presented in Figure 1.

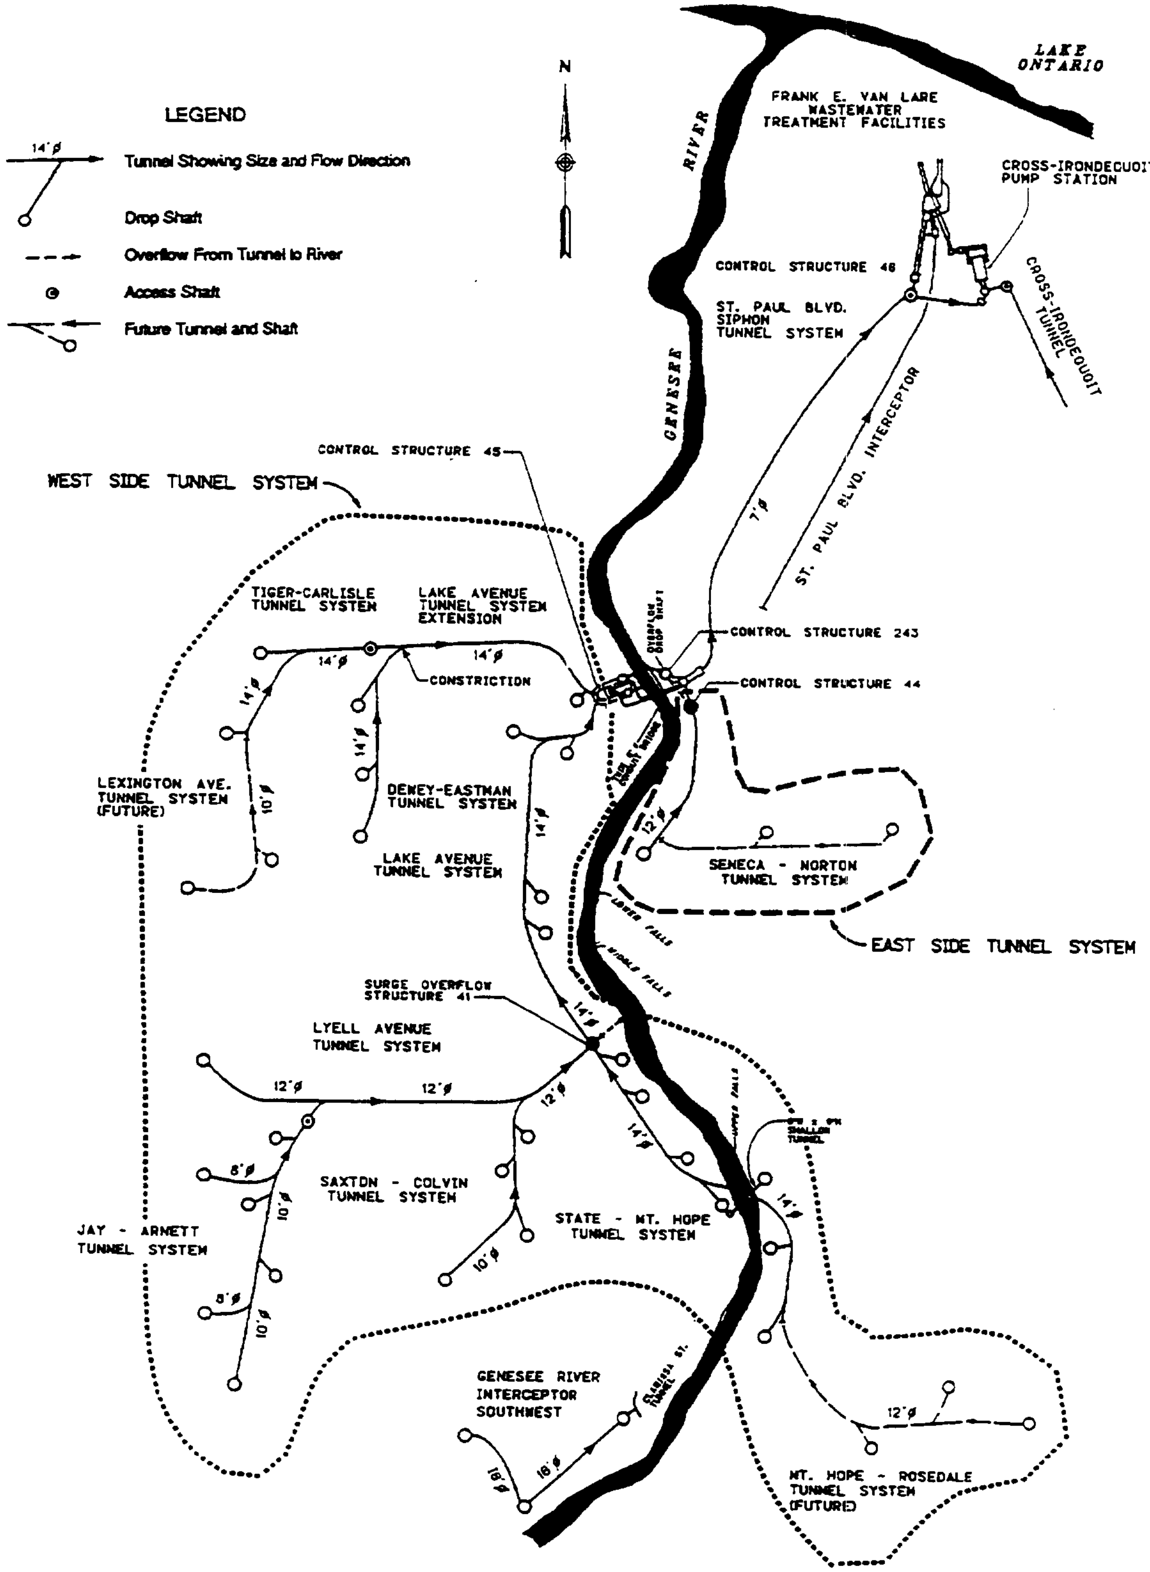
THE DISCOVERY

A condition of the federal grant required Monroe County to complete the estimated $750 million project regardless of the status of the availability of federal funds in future years. By the early 1990's, the federal grant program had essentially ended, leaving three segments of the tunnel system unconstructed. These three segments represented approximately 15 percent of the originally planned volume for the tunnel system. Monroe County was facing the financial issue of locally financing approximately $75 million of additional tunnels.

Monroe County suspected that the portion of the tunnel system which was already constructed, could meet the water quality goals originally set for the program. These suspicions were based on the following: constrictions in the surface collection system were attenuating the design peak inflows to the tunnel system; portions of the tunnel system were constructed to diameters larger than designed due to favorable competitive bidding; and operational strategies were refined as operators gained experience with the system.

The hydraulic stability of the tunnel system is related to the conveyance capacity of the tributary sewer network and the resulting rate of flow entering the tunnel system. Dr. Song's original modeling work was based on flow rates for a long-range future condition where the entire tributary system would be upgraded to eliminate in-system flow restrictions. The implementation of these surface improvements was not part

Figure 1. **Schematic Plan of CSOAP Tunnel System**



R0024815

of the program and was to be accomplished over an extended period of time. Some improvements have been made, but most have not. Therefore, the rates of inflow to the tunnel system for which the effective storage was designed have not yet been achieved, and all the effective volume may not be required until those improvements are made.

Proving Monroe County's theory required development of revised inflow hydrographs, representing the existing tributary sewer network, for selected drop shafts. It also required the development of a model to simulate the hydraulic performance of the existing tunnel system.

The original model of the tributary sewer network was completed using the HVM and QQS models on a mainframe computer. This work was well documented in hard copy format, with the majority of the design variables and calculations detailed in the study report. Almost twenty years later, the original HVM and QQS models used in the 1976 Facilities Plan were unavailable. The original model was recreated on a PC platform using the US EPA's Storm Water Management Model (SWMM) to develop the revised inflow hydrographs. The superior documentation and verification of the original modeling work greatly facilitated the recreation in a fraction of the time. The subsequent modeling work using SWMM was again well documented, this time in electronic format.

The effective storage volume and hydraulic performance of the constructed portions of the tunnel system were analyzed using an improved version of Dr. Song's mixed flow hydraulic transient model based on the revised inflow hydrographs.

A revised water quality contravention analysis, similar to that presented in the 1976 Facilities Plan, was conducted to assess the performance of the existing tunnel system in abating combined sewage overflows. The analysis indicated that the constructed tunnel system volume and configuration meets the water quality goals (3.5 contraventions per year) associated with the target volume set by the US EPA and NYS DEC for the program. The unconstructed portions of the tunnel system are not presently needed provided the water quality classification of the receiving waters remains unchanged and until extensive improvements are made to the tributary sewer network.

A secondary goal of the program was to minimize surface flooding and reduce the frequency of basement backups. The performance of the tunnel system, as constructed, has reduced the occurrence of flooding and backups. Currently, there are no plans to make additional major improvements to the tributary sewer network. However, over an extended period of time, the tributary sewer network will undoubtedly be upgraded and inflows to the tunnel system will increase. Larger inflows will eventually result in increased hydraulic pressures generated in the tunnel system and increase the potential for adverse hydraulic transients. The need for additional facilities will be evaluated when significant changes to the tributary sewer network are proposed, when additional inflows are directed to the tunnel system, or when changes are made to the water quality classification of the local receiving waters. Hence, the analysis models originally developed in the 1970's and recreated in the early 1990's, will be used again at some point in the future.

WHAT WAS LEARNED

Monroe County's Combined Sewer Overflow Abatement System consists of a network of deep-rock tunnels. These storage-conveyance tunnels are an extension of the wastewater treatment system. The operational objectives of the total system can be expressed as follows:

- Provide the maximum level of treatment for all flows through the treatment system prior to discharge to the local receiving waters.
- Minimize both the number of combined sewage overflow events and the volume of combined sewage discharged into the more sensitive local receiving waters.
- Minimize the cost of operating and upgrading the system to meet future needs.

The studies of the early 1990's highlighted the interdependence between the surface sewer system, storage tunnels, and treatment system. A more in-depth understanding of the relationship between the surface sewer system efficiency, storage volume, treatment rate, and impact on water quality will improve Monroe County's ability to maintain the objectives of the combined sewer overflow abatement system.

These studies have also brought to light the importance of the real-time operation and control strategies which are currently being employed, and their potential effect on water quality. There are two systems which aid in the operation of the tunnel and treatment systems, the Supervisory Control System (SCS), and the Data Acquisition System (DAS). These systems combine to form a supervisory control and data acquisition (SCADA) system and provide operational recommendations as flow rates and levels are detected. The various set points defined in the SCS can then be modified, but this modification is made after the flow rates or levels have already been observed. These systems do not provide forecasting of anticipated storm flows for the specific event to allow operators to make modifications which would enable them to better utilize the treatment plant and tunnel system, maximize the level of treatment, and minimize overflows.

The flow regime in the tunnel system can be very dynamic. Pressurization surges can move both upstream and downstream within the system. Some portions of the tunnel system can be partially full while other portions of the system are pressurized. During the course of the studies of the early 1990's, it was revealed that only five sensors measuring water depth, in a 30 mile tunnel system, were used by the operators to indicate the tunnel system's storage status. Four of the sensors were located at the downstream end of tunnel subsystems.

A real-time model which integrates the tunnel system operations with the treatment plant's ability to accept flows would help in the evaluation of a multitude of storm flow conditions.

REAL-TIME APPROACH

Monroe County is currently in the process of the phased development of a real-time Operations/System Management Model. This operations tool will: show the current status of the system based on real-time data measured within the system; forecast the status of various portions of the system into the near future during a rain event, based on current status and current rainfall; and suggest operational strategies to reduce the frequency and magnitude of overflows and maximize the degree of treatment for all wastewater discharged to the local receiving waters.

The first phase of the Operations/System Management Model development consisted of the refinement of a storage volume model for the tunnel system, giving real-time tunnel storage status and the instantaneous rate of filling or emptying. The storage and rate of increase or decrease of storage data for each tunnel subsystem is provided by sensors measuring water depth at various locations. Because the filling process is very dynamic, characterized by the existence of surges, a single depth measuring device is not sufficient to provide the knowledge of storage in a tunnel subsystem. Depth information at two or three locations in a tunnel subsystem with an associated empirical equation, relating the multiple depth data with storage volume, was necessary. These empirical equations were derived from the output of Dr. Song's mixed flow hydraulic transient model operating under a range of storm inflow conditions.

The real-time data obtained from the depth sensing devices will be conveyed to a central control room via a combination of telephone lease-lines, radio, and a fiber network. The empirical equations will be incorporated into a graphical user interface where the operators will be able to monitor the status of the tunnel system throughout the course of a rain event. The first phase of development is nearly complete and is scheduled to be operational in 1998.

WHAT'S NEXT

The second phase of the Operations/System Management Model development will incorporate a network of rain gauges into the model. This will give the model the capability to predict what the tunnel storage status will be in the near future during a rain event, thus giving operators additional response time to make adjustments to the system. The relationship between rainfall intensity versus measured tunnel inflow at key locations, and tunnel inflow versus near future tunnel storage status will be developed. This will improve the model's accuracy in predicting storage status and an estimated time to overflow/empty, based on rainfall.

This phase will also include the development of objective functions specific to the tunnel system. The goal of the objective functions will be to optimize the storage capabilities of the existing system. Key control issues that the objective functions will address include simultaneous operation of control structures, diversion of flows within the tunnel system, and diversion of flows within the surface system.

The third phase will involve the development of the treatment portion of the Operations/System Management Model and incorporating the model developed in phase two, into the framework of the overall model. This framework will consist of a model composed of several algorithms and subroutines representing the treatment plant, the tunnel system, major pump stations, and interceptors. It is envisioned that the treatment portion of the model will include each liquid treatment unit process within the plant and their associated treatment efficiencies versus hydraulic capacities. An objective function will be developed for the storage/treatment/overflow decisions to minimize the impact of overflows on the most sensitive receiving waters.

CONCLUSIONS

Modeling of wastewater collection systems began as a way to analyze and design the hydraulic performance of systems. When these models are correlated with actual flow data and modified to compute in real-time, they are very useful operational and maintenance tools. Modeling to improve operation and maintenance is seen as a growth area.

Monroe County has demonstrated that design models can be modified to compute in real-time to be effective operational and maintenance tools. This effort was greatly facilitated through the use of well documented planning studies and record drawings.

Modeling completed for the Monroe County system is growing from predicting what has happened to being able to predict what will happen. This will improve the operational and maintenance function, and the quality of the receiving waters. It is the way of the future.

ABSTRACT
The most recent release of the City of Detroit's regional sewerage collection system model includes refinements and improved characterizations of various model parameters such as rainfall dependent inflow and infiltration (RDI/I) and dry weather flow (DWF). After these improvements to the model were implemented, the Michigan Department of Environmental Quality (MDEQ) requested that the parameter uncertainty impacts on model results be evaluated. As part of this evaluation, the seasonally varying parameters were evaluated to assess the impacts of temporal distribution. A simplified approach for evaluating the temporal distribution in seasonally varying parameters was used by comparing model results of annually averaged value conditions and seasonally varying value conditions. The characterization of RDI/I, DWF, and evaporation are discussed followed by an evaluation of the impacts of these seasonally varying parameters on model results with respect to the annual averaged values.

KEYWORDS
dry weather flow, rainfall dependent inflow and infiltration, evaporation, seasonal variation, modeling, combined sewer overflow

INTRODUCTION
The Detroit Water and Sewerage Department (DWSD) developed a Greater Detroit Regional Sewer System (GDRSS) model using a modified United States Environmental Protection Agency (EPA) Stormwater Management Model (SWMM) to assist in developing the best approach to reduce combined sewer overflow discharges. The GDRSS collects flows from the City of Detroit and all or part of 76 surrounding communities covering nearly 2,300 square kilometers and serving approximately three million people. The hydrologic model consists of 337 distinct subbasin drainage areas, and the hydraulic model consists of more than 1,400 explicitly modeled conduits with over 140 combined sewer overflow (CSO) locations. The model has been used to predict system response to various storm events under various CSO control alternatives. At the request of the MDEQ, the variability in model results due to uncertainty in parameters' values was evaluated. As part of this evaluation, the impacts of seasonal variation in certain parameters were investigated.

To address this issue, an approach was developed to investigate seasonal varying parameter impacts on continuous model results. The parameters that were investigated included: DWF, evaporation, and RDI/I volume. The seasonal variation was evaluated to determine the impacts on model results relative to annually averaged values of dry weather flow, evaporation and RDI/I volume parameters. Seasonal variation impacts were evaluated for the continuous model using both an annual and a seasonal extreme period (representing a *wetter* period of the year in Detroit, March through May).

Model simulations were performed and the results compared to that of the baseline model. The parameter values were input as either seasonally varying or annually averaged. The extent of the model parameter impacts depends on the model's sensitivity to the given parameter, the degree of difference between annual average values and the seasonally varying values, and the period of the year evaluated.

The results of six model simulations (five continuous and one baseline simulation) were evaluated to quantify discharge to the Detroit collection system from suburban districts as well as overflow occurring before entry into the Detroit system. Within Detroit, the flow to the wastewater treatment plant (WWTP) and upstream overflows were evaluated. All results were compared to the baseline model conditions with a detailed accounting of continuity error impacts. Conclusions are presented in terms of the relative impacts of these parameters relative to the baseline model.

METHODOLOGY

Parameter Selection

The parameters selected for these analyses were based on the experience of GDRSS model users. This experience includes model development, sensitivity analyses, calibration and validation of the continuous and event models. Furthermore, parameters were chosen for which new methodology was developed or for which substantially increased detail was added throughout the project. During the GDRSS project, new methodology was developed for parameter spatial distribution such as RDI/I C factors that vary as a function of sewer construction age. Furthermore, more detail was added to model seasonal variation in DWF. Seasonal variation in evaporation is not a new methodology; however, it was considered to provide a reference to which the other results could be compared.

Dry Weather Flow

DWF was varied using monthly multiplication factors of the base DWF value. The TRANSPORT monthly flow factor parameters were added to the SWMM model by Camp Dresser and McKee (CDM) to facilitate Phase III GDRSS project needs. The DWF factors were developed using a correlation of district (billing regions) flows to WWTP flows for each district. An example of this is shown in Figure 1 for Western Wayne County. Seasonal DWF factors for each region could then be determined for any year, within reason, based on observed flows at the WWTP. For the GDRSS model, these factors are input as monthly values to account for seasonal variation in these flows. Figure 2 shows the flow factors for Western Wayne County. All district factors are listed in Table 1. Different sets of values are used depending on the location within the system as determined from the source data. Areas of the system with large DWF factor variation throughout the year are typical of older, leakier systems. Whereas, regions of the system with minor variation in DWF factors throughout the year are typical of newer systems. To evaluate the impacts of seasonal variability in DWF, the monthly factors were averaged to obtain an annual value for each region.

Evaporation

The SWMM RUNOFF block allows monthly evaporation values for input. The evaporation parameter ranges were determined from the relative difference of the local variation obtained from a hydrology textbook (Viessman et al.). The relative difference was applied by month to the model's baseline annual distribution. This yielded the ranges shown in Figure 3. The monthly values were averaged to obtain an annual value. The average value is also shown in Figure 3 as a horizontal line. All values for evaporation were applied globally to the model.

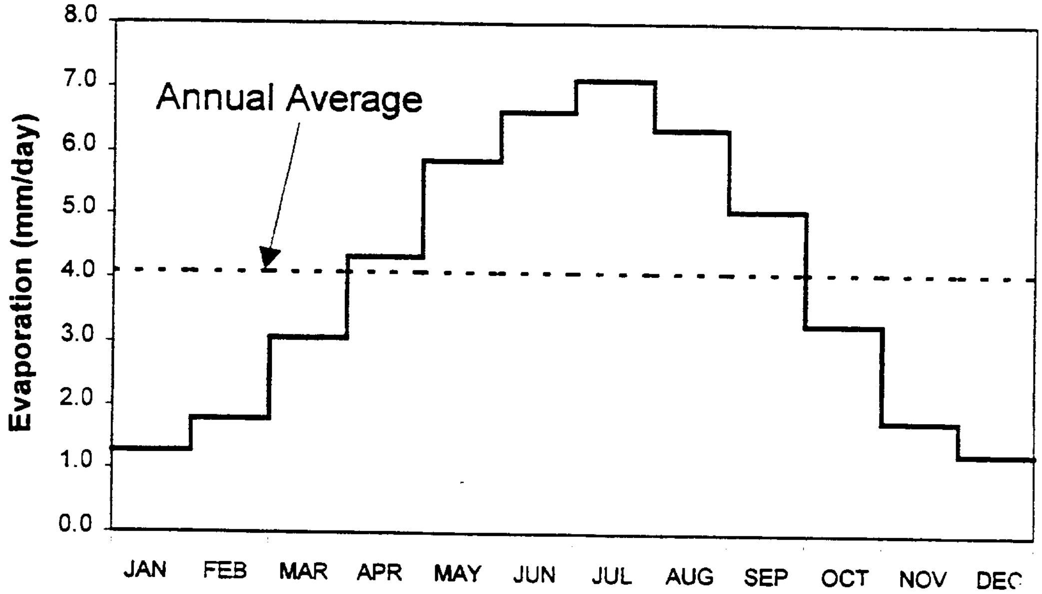

Figure 3 Global Evaporation Parameter

Rainfall Dependent Inflow and Infiltration Volume
RDI/I response volume consists of four parameters. The initial abstraction, V_o, represents the available storage at the beginning of a rainfall event. If the rainfall is below V_o, then no response will occur. However, V_o depends on antecedant moisture and ranges anywhere between zero and the second parameter, maximum V_o. Rainfall causes V_o to reduce and the third RDI/I volume parameter, V_o recovery rate, allows increases in V_o up to the maximum during interevent time periods. When rainfall exceeds V_o, the response volume depends on the fourth parameter, the RDI/I C factor. Each of these parameters is varied seasonally. The V_o parameter is dependent on the maximum V_o and the recovery rate, and is used as model input only in the form of an initial condition.

The model characterization of RDI/I volume is shown in Figure 4. Further information regarding the characterization of RDI/I can be found in the papers by Sherman et al. The four parameters used to characterize RDI/I are varied by season as shown in Figure 5. The bottom chart shown in Figure 5 depicts V_o and maximum V_o as being equal. For initial condition input to the model, V_o was assigned the same value as the maximum V_o. Once the simulation begins, V_o is varied throughout the simulation based on rainfall and interevent recovery. The seasons are defined as *dormant* (December through April), *growth* (June through September) or *transition* (May and November). To address seasonal variability in RDI/I volume, the monthly parameters for maximum initial abstraction, initial storage, recovery rate for storage, and the total response volume originally defined for the dormant, growth, and transition seasons were time weighted averaged to obtain an annual value. The individual parameters were not evaluated independently. That is the four RDI/I volume parameters were aggregated for simulation, either all four parameters treated as seasonally varying or all four parameters treated as annual averages. The seasonal variation in the RDI/I C factors was correlated to housing unit age as a surrogate for sewer construction age and is shown in Figure 6.

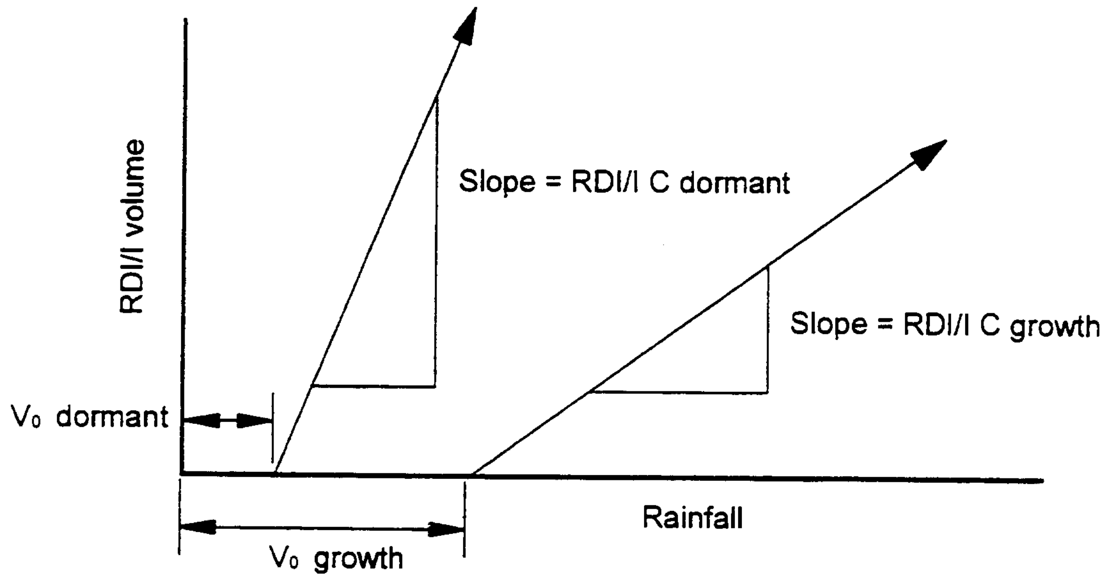

Figure 4 RDI/I Characterization

Accounting of Continuity Error on Results

The EPA SWMM model calculations produce a certain level of continuity error when balancing flows into, out of, and stored in the system. This error is relatively small. However, for simulations in which the seasonal variation impacts are small relative to the baseline simulation, continuity error may be significant. This is because the simulation results may represent either the parameter variation or the differences in the continuity error. This problem is further exacerbated because multiple submodels are used and hydrologic and hydraulic models are coupled i.e., each submodel and each model type had continuity error during the simulations. The use of submodels simplifies debugging and simulation.

An approach was developed to account for the impact of the continuity error on the results. For each RUNOFF submodel, it is assumed that all the continuity error is due to the calculation of RUNOFF outflow volume i.e., assumes all modeled volumes are calculated without error except the RUNOFF outflow. This gives a worst case evaluation of continuity error impact on the resulting objective statistics, *toward treatment* and *to overflow* volumes. This RUNOFF outflow volume is that which is used as input to the TRANSPORT model.

By assuming all continuity error is due to the calculation of RUNOFF outflow, a worst case outflow volume is calculated by setting the continuity equation equal to zero. The worst case classification applies, provided the assumption that the other flow components of the mass balance are calculated without error. This new RUNOFF outflow volume is then substituted into the TRANSPORT continuity equation and a composite continuity error is calculated. A similar approach is used for the continuity error in TRANSPORT outflow points from submodels to the central, downstream-most, submodel. The various submodels' output are combined using the SWMM COMBINE block. It was not necessary to consider the effects of combined submodels on continuity error for districts within a given submodel, except that due to the coupling of RUNOFF with TRANSPORT. In either case, a composite continuity error value was obtained for each district. This composite continuity error was compared to the TRANSPORT continuity errors for each district. From this comparison, the largest magnitude continuity error was used to calculate a modified relative difference as follows in Equation 1:

$$Difference = \frac{V_{sim} \cdot (1 + \varepsilon_{sim}) - V_{base} \cdot (1 + \varepsilon_{base})}{V_{base} \cdot (1 + \varepsilon_{base})} \cdot 100 \qquad (1)$$

Where, V is the output volume and ε is the composite continuity error for the simulation in question and the baseline. The results of Equation 1 and 2 are compared to ascertain the impacts of continuity error on the results. The continuity error has a significant contribution to the change observed in the model response to the perturbation of a parameter if the relative differences calculated using Equations 1 and 2 are markedly different.

$$Difference = \frac{V_{sim} - V_{base}}{V_{base}} \cdot 100 \qquad (2)$$

For every simulation these two equations are evaluated and compared. Results are discussed in a qualitative context and have not been used to *correct* model output for continuity error. The continuity error evaluation results are indicators of potential impacts due to numerical error.

Each submodel simulation had continuity error and it was assumed that the error could be uniformly distributed throughout the submodel. This assumption was used to apply the continuity error to the district level. Furthermore, the City of Detroit district is unique because it spans two submodels of the TRANSPORT simulations. Consequently, the continuity error was weighted by total outflow from each of the submodels before applying to the relative difference calculation. Likewise, for the result totals, the continuity error was weighted for each submodel and applied per Equation 1.

Model Configuration of Precipitation

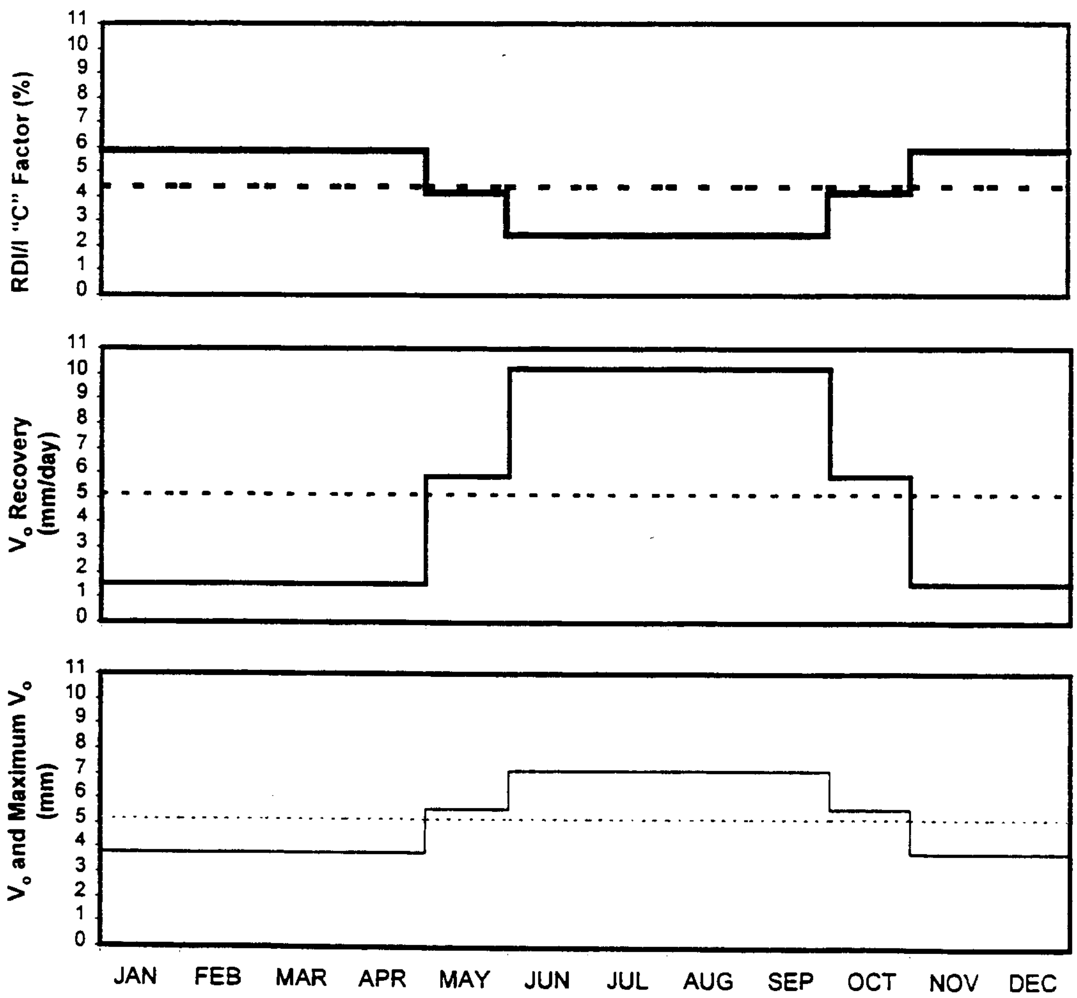
The continuous model (RUNOFF/TRANSPORT) simulations were each evaluated as coupled hydrologic and hydraulic models. A three-year (1984 through 1986) precipitation record was used for all RUNOFF/TRANSPORT simulations. The three-year period was chosen because its data has similar statistics to long-term rainfall averages. The spatial and temporal variation in the rainfall record is assumed uniform throughout the system i.e., no moving front and the same rainfall distribution over all modeled areas. It should be noted that precipitation is a model input that may have significant seasonal impacts on model results, particularly in regions of the country with pronounced rainy seasons, snow accumulation/melt, and year to year changes. The results discussed below could be significantly different if another precipitation record were chosen.

RESULTS

The seasonal variation impacts are discussed in terms of overall model totals and for one of the predominately separate sewered districts, Western Wayne County. It should be noted that the results for other districts that are not discussed and that are either predominately separate or combined sewers will differ significantly from these system-wide results. The system is comprised of approximately 75 percent separate and 25 percent combined sewers. Slightly more than half of the dry weather flow originates from the combined sewer areas. RDI/I is not modeled in the combined sewer areas of the system since the directly connected impervious area runoff dominates any RDI/I components observed for these regions. Therefore, when reviewing the results for the entire system, it is clear that RDI/I yields relatively small impacts. And, when reviewing the results for the separate sewer regions of the system, RDI/I yields significant impacts.

The seasonal variation impacts primarily yield insight to the significance of modeling these parameters seasonally versus modeling these parameters as average annual values. Seasonal variation results for the continuous simulations were expected to have little difference on an annual basis. Consequently, the continuous model was also evaluated for a three-month period (March - May, 1984). This period was considered a seasonal extreme for two of the three parameters. Evaporation was not at the extreme during this period, but was slightly above its annual average as shown in Figure 3. Therefore, a second seasonal extreme period was selected (November 1984 through January 1985) that corresponded to the seasonal extreme for evaporation. The seasonal extreme for each parameter is considered as the period with the *wettest* response. This is because the overall modeling project is focused on overflows, with peak flows being the most important. One could, however, also evaluate the opposite or *driest* response extreme.

Table 2 summarizes all RUNOFF/TRANSPORT seasonal variation impacts for the three-year continuous simulation and a three-month subset. The three-year simulations yielded similar results regardless of whether seasonal variation or average annual values are used. Since there tends to be a predominance of larger or higher intensity storms during the three-month seasonal extreme period the annual results do exhibit a slight reduction in flows *toward treatment* and *to overflow* when annual averages are in place, with the exception of evaporation discussed below. This observation was expected for annual distribution of rainfall for this three-year period.



Solid lines are seasonal
Dashed lines are annual averages

Figure 5 RDI/I Volume Parameters – Seasonal Variation

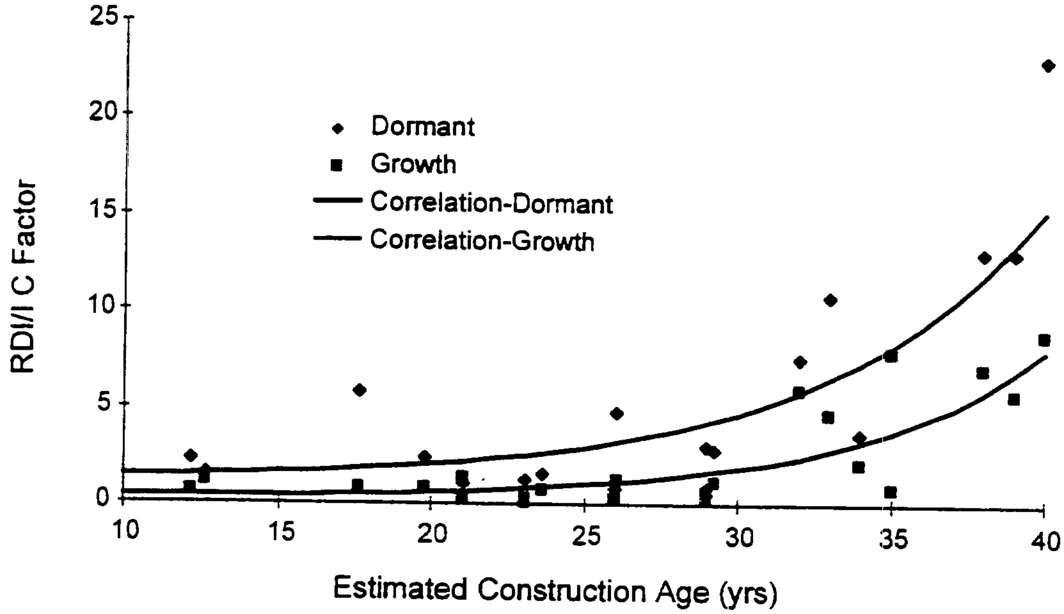


Figure 6 RDI/I C Factor Correlation Surrogate for Construction Age

Table 2 Seasonal Variation Impacts Continuous Simulation Results - Entire System

Simulation ID	Result Type	Baseline 1,000x(m^3/yr)	Annual Avg. 1,000x(m^3/yr)	Relative Difference (%)	Baseline 1,000x(m^3/yr)	Extreme 1,000x(m^3/yr)	Relative Difference (%)
Non Seasonal all as Avg. Annual	Toward Treatment	996,019	990,213	-0.6	90,773	83,273	-8.3
	To Overflow	72,890	72,508	-0.5	4,895	4,619	-5.6
Dry Weather Flow as Avg. Annual	Toward Treatment	996,019	995,501	-0.1	90,773	83,787	-7.7
	To Overflow	72,890	72,825	-0.1	4,895	4,714	-3.7
RDI/I Volume as Avg. Annual	Toward Treatment	996,019	994,480	-0.2	90,773	90,202	-0.6
	To Overflow	72,890	72,965	0.1	4,895	4,835	-1.2
Evaporation as Avg. Annual	Toward Treatment	996,019	992,375	-0.4	90,773	90,833	0.1
	To Overflow	72.890	72,436	-0.6	4,895	4,854	-0.8

The results in Table 2 indicate that the DWF seasonal representation is quite significant during the seasonal extreme period. The seasonal variation in the RDI/I representation yields significantly less impact. Although still dominated by DWF, the districts with primarily separate sewers yielded a significantly greater impact from RDI/I. See Table 3 for results for Western Wayne County, a predominately separately sewered district.

The RDI/I results are important. Without having performed the parameter analyses regarding the seasonal variation of RDI/I, incorrect annual average values would have been obtained in most cases for these parameters. For example, if one assumed that RDI/I parameters could be obtained from data collected during the summer months and used as a single annual average value in the model, the model would grossly underpredict the dormant season flows. The importance of correctly defining annual average RDI/I parameters cannot be overemphasized. Since many modelers will not go through the detailed model characterization as done herein for the seasonal variation in RDI/I, an appropriate annual average must be used to account for the seasonal variation on the annual basis. Regardless of whether or not a reasonable annual average is chosen, one who uses the annual averaged values will still run the risk of inaccurately predicting flows for seasonal extreme periods relative to the average.

Table 3 Seasonal Variation Impacts Results for Western Wayne County (Predominately Separate)

Simulation ID	Result Type	Baseline 1,000x(m^3/yr)	Annual Avg. 1,000x(m^3/yr)	Relative Difference (%)	Baseline 1,000x(m^3/yr)	Extreme 1,000x(m^3/yr)	Relative Difference (%)
Non Seasonal	Toward Treatment	29,140	29,060	-0.3	2,706	2,430	-10.2
all as Avg. Annual	To Overflow	892	885	-0.8	62	59	-4.8
Dry Weather Flow	Toward Treatment	29,140	29,239	0.3	2,706	2,492	-7.9
as Avg. Annual	To Overflow	892	892	0.0	62	61	-1.6
RDI/I Volume	Toward Treatment	29,140	28,987	-0.5	2,706	2,645	-2.3
as Avg. Annual	To Overflow	892	892	0.0	62	60	-3.2
Evaporation	Toward Treatment	29,140	29,117	-0.1	2,706	2,706	0.0
as Avg. Annual	To Overflow	892	884	-0.9	62	62	0.0

The seasonal extreme period evaporation values were slightly above the annual average; consequently, the evaporation only simulation yields even greater difference than when all seasonal variation is converted to annual averages. Evaporation was evaluated at the seasonal extreme for DWF and RDI/I as shown in Tables 2 and 3. However, this period is not the seasonal extreme for evaporation. The seasonal extreme for evaporation is the November to February period, as shown in Figure 3. This time period is a seasonal extreme because lower evaporation can contribute to greater system responses. The evaporation only simulation and the baseline were reanalyzed for a seasonal extreme more relevant to evaporation impacts, November 1984 through January 1985. Table 4 shows the results of this additional analysis, and indicates significant impacts for evaporation during this seasonal extreme.

Table 4 Evaporation Re-evaluated (Nov. – Jan. Extreme)

Simulation ID	Result Type	Baseline 1,000x(m^3/yr)	Annual Avg. 1,000x(m^3/yr)	Relative Difference (%)	Baseline 1,000x(m^3/yr)	Extreme 1,000x(m^3/yr)	Relative Difference (%)
Evaporation	Toward Treatment	996,019	992,375	-0.4	82,506	81,372	-1.4
as Avg. Annual	To Overflow	72,890	72,436	-0.6	2,650	2,563	-3.3

The continuity error influence was negligible for all the RUNOFF/TRANSPORT seasonal variation impacts simulation results. That is Equations 1 and 2 produced the same value. This is not always the case in modeling; therefore, it is important to mention only to show that there are no expected impacts due to continuity error. The three-month seasonal extreme period results were extracted from the three-year continuous simulation results; therefore, continuity error checks during that period may not be representative although assumed accurate. Even though the observed change is minimal between the relative difference calculations, the period considered for the continuity error may be important. Improved confidence in the continuity error impact estimates would be possible if additional simulations for the three-month period were performed; however, additional simulations were not warranted.

DISCUSSION

The results give some insight into model sensitivity to seasonal variation in parameter values. However, some other EPA SWMM seasonally varying parameters were not included in the analysis. For example, these analyses did not include parameters such as precipitation, temperature, snow melt, or RDI/I shape. RDI/I shape parameters define the response hydrograph shape by three component hydrographs, an early direct response (inflow), an intermediate response, and a delayed response (infiltration). For Southeastern Michigan, the seasonal variation in precipitation was not expected to be significant; however, for other systems for which a *rainy* season is more pronounced, seasonal variation in precipitation is likely to yield significant impacts since precipitation is the parameter for which RUNOFF is most sensitive.

Furthermore, a simplification was made when aggregating the parameters included in the characterization of RDI/I volume. These four RDI/I volume parameters were aggregated and not evaluated individually. If each aggregated parameter was evaluated individually, more insight would be gained as to which of the four parameters were of the greatest importance to accurately quantify if the modeler chooses to use annual average values instead. Of the RDI/I volume parameters, the most important parameter to quantify for the GDRSS was the RDI/I C factor. RDI/I volume parameter importance was evaluated through continuous simulation sensitivity analysis by Sherman et al. (1998).

CONCLUSIONS

This work represents an effort to provide a basis for the users of the model to understand how seasonal variation impacts model results. The seasonal variation versus annual average values for DWF, RDI/I volume, and evaporation were considered. From these results, DWF produces the greatest impacts due to seasonal variation throughout the system. RDI/I produced small impacts to the entire system; however, for predominately separate sewer districts the RDI/I yielded significant impacts. The seasonal extreme for evaporation did not occur during the same period as for DWF and RDI/I. Therefore, another period was considered between the months of November and January to better understand the seasonal variation impacts due to the evaporation parameter. Evaporation did exhibit a significant impact during the second seasonal extreme period chosen when compared to the annual average.

The most important conclusion is that when any seasonally varying parameter is modeled as annually averaged values, the data used to generate the average value must account for seasonal variation. Figures 2, 3, and 5 can be used in conjunction with the results to support this claim. For example, if July through December data were used to estimate DWF as shown in Figure 2, the value used as an annual average would be significantly lower than that determined using a full 12 months of data. The seasonal extreme impact during March through May would then be far more significant than that elucidated by the simulations herein. As a result, it is important to base annual averages on an appropriate weighting of data spanning the entire year. If limited data is available for single periods, such as growth or dormant periods, an attempt should be made to make estimates of annual performance values and apply these for long-term simulations. For simulations less than one year, the parameter values chosen should represent the seasons evaluated using either seasonally varying values or an appropriately derived average for the period in question.

DEVELOPMENT OF A COMPLEX INTEGRATED MODEL OF THE BATON ROUGE CITY/PARISH PRESSURIZED AND GRAVITY WASTEWATER COLLECTION SYSTEM

Neil R. Moody, Supervising Professional, Montgomery Watson
Clinton J. Cantrell, P.E., Supervising Professional, Montgomery Watson

ABSTRACT

The City/Parish of Baton Rouge operates a highly complex wastewater collection system that includes a combination of gravity sewers, lift stations, and a very large manifold force main system with in-line booster pumps. In September of 1995, the City/Parish embarked on a comprehensive SSO Corrective Action Plan (SSO CAP) that required an analysis of the wastewater collection system, including the assessment of I/I impacts and the requirements to accommodate future growth. In order to achieve the objectives outlined in the SSO CAP, it was necessary to construct detailed hydraulic models of the collection system that could accurately simulate the dynamics of wet weather impacts and could be used to assess and design cost effective overflow control measures.

Due to the nature and complexity of the collection system, it was necessary to develop a model that is highly robust and can handle both long pressure force main and gravity sewer hydraulics simultaneously, as well as incorporate the real time control mechanisms currently used to operate the in-line booster stations on the pressurized system.

This paper details the steps taken to construct the calibrated model of the South Suburban Transport Network (STN) sewerage system which integrates the large manifolded pressurized trunk system with the gravity collector pipe network. This paper discusses the development of this model, including the data management and GIS system, model calibration, observations and discoveries made during the modeling process and finally application for the model to develop cost-effective improvement schemes for the Baton Rouge City/Parish.

hydraulic modeling, real time control (RTC), pressurized sewer modeling, sewer, hydraulic, hydrologic, model calibration, booster stations

INTRODUCTION

Baton Rouge is the capital of Louisiana with a population nearing 400,000 people and is situated along the east bank of the Mississippi River in southern Louisiana. The land generally falls gently away from the river with a difference in elevation of less than 16m (50ft) between the 5 and 95 percentile manhole. The Baton Rouge sewerage collection system consists of over 36,000 manholes, approximately 2516 km (1564 miles) of gravity sewer, over 400 pumping stations, two major pressurized collection systems containing approximately 307 km (191 miles) of forced mains and three major waste water treatment facilities which discharge to the

Mississippi. Due to rapid growth in development and excessive levels of inflow and infiltration, parts of the system have reached full design capacity 10 years ahead of expectation.

In September of 1995, Phase 1 of the Baton Rouge City/Parish (C/P) SSO Corrective Action Plan was initiated. The objective of this effort was to develop a detailed strategy and scope for a system-wide sewerage master plan that addresses both future growth and the reduction of SSO's. The result of this effort was a strategy for a Phase 2 effort that focused on the detailed analysis of the complex wastewater collection system using sophisticated hydrologic/hydraulic models.

For the Phase 2 effort the collection system has been divided into five discrete catchment models. Three of these catchments consist primarily of older gravity sewers and common lift stations. The other two catchments are comprised of multiple discrete gravity systems that pump into two complex manifolded force main systems, referred to herein as the Suburban Transportation Networks (STN), North and South.

Many other municipalities that operate similar pressurized trunk sewer systems, particularly in the South East United States, have grappled with how to best analyze these complex type of system. This paper will focus on the analysis of the South STN system, discuss in detail how this system has been modeled and analyzed using a state of the art computer model and describe the benefits that this type of tool can provide to a collection system manager. It is intended that this paper will serve as a guideline for wastewater collection managers as to the steps required to develop such a tool and provide an insight into the technology currently available in this field.

BACKGROUND TO SOUTH STN SYSTEM

The South STN sewer system serves the rapidly developing south-east of Baton Rouge and consists of relatively small catchments of 20 to 200 hectares (50 to 500 acres) which drain by gravity pipes and 20 gravity lift stations into 90 pumping stations which inject directly into a manifolded pressurized trunk system. Figure 1 illustrates the extent of the modeled pipe network for the South STN model. Flows within the pressurized trunk system are conveyed to the treatment works via 7 major in-line booster pumping stations and 2 mini-booster stations. Average daily dry weather flows at the South treatment works from the STN are in the order of 0.43 m^3/s (10 MGD) with recorded peak wet weather flows in excess of 2.63 m^3/s (60 MGD).

The in-line booster stations are designed to activate when flows exceed 30% of peak capacity and the pressure in the force main at the booster exceeds a predetermined set point. The objective of each booster station when operating is to maintain a steady pressure on the suction side of the pumping station. During periods of high flow the booster pumps are controlled with variable speed drives to fix the pressure on the suction side which enables the injection pumping stations upstream of the booster to discharge into the system.

Static KY-Pipe models of the trunk system have been historically used to analyze the effect of additional peak flows from proposed developments connecting into the STN system. These models are however unable to simulate the complex dynamic interaction between the gravity sewers, injection pumping stations and booster pumping stations. Furthermore, these static models do not allow analysis of potential optimization schemes that could significantly improve system performance and reduce operation costs.

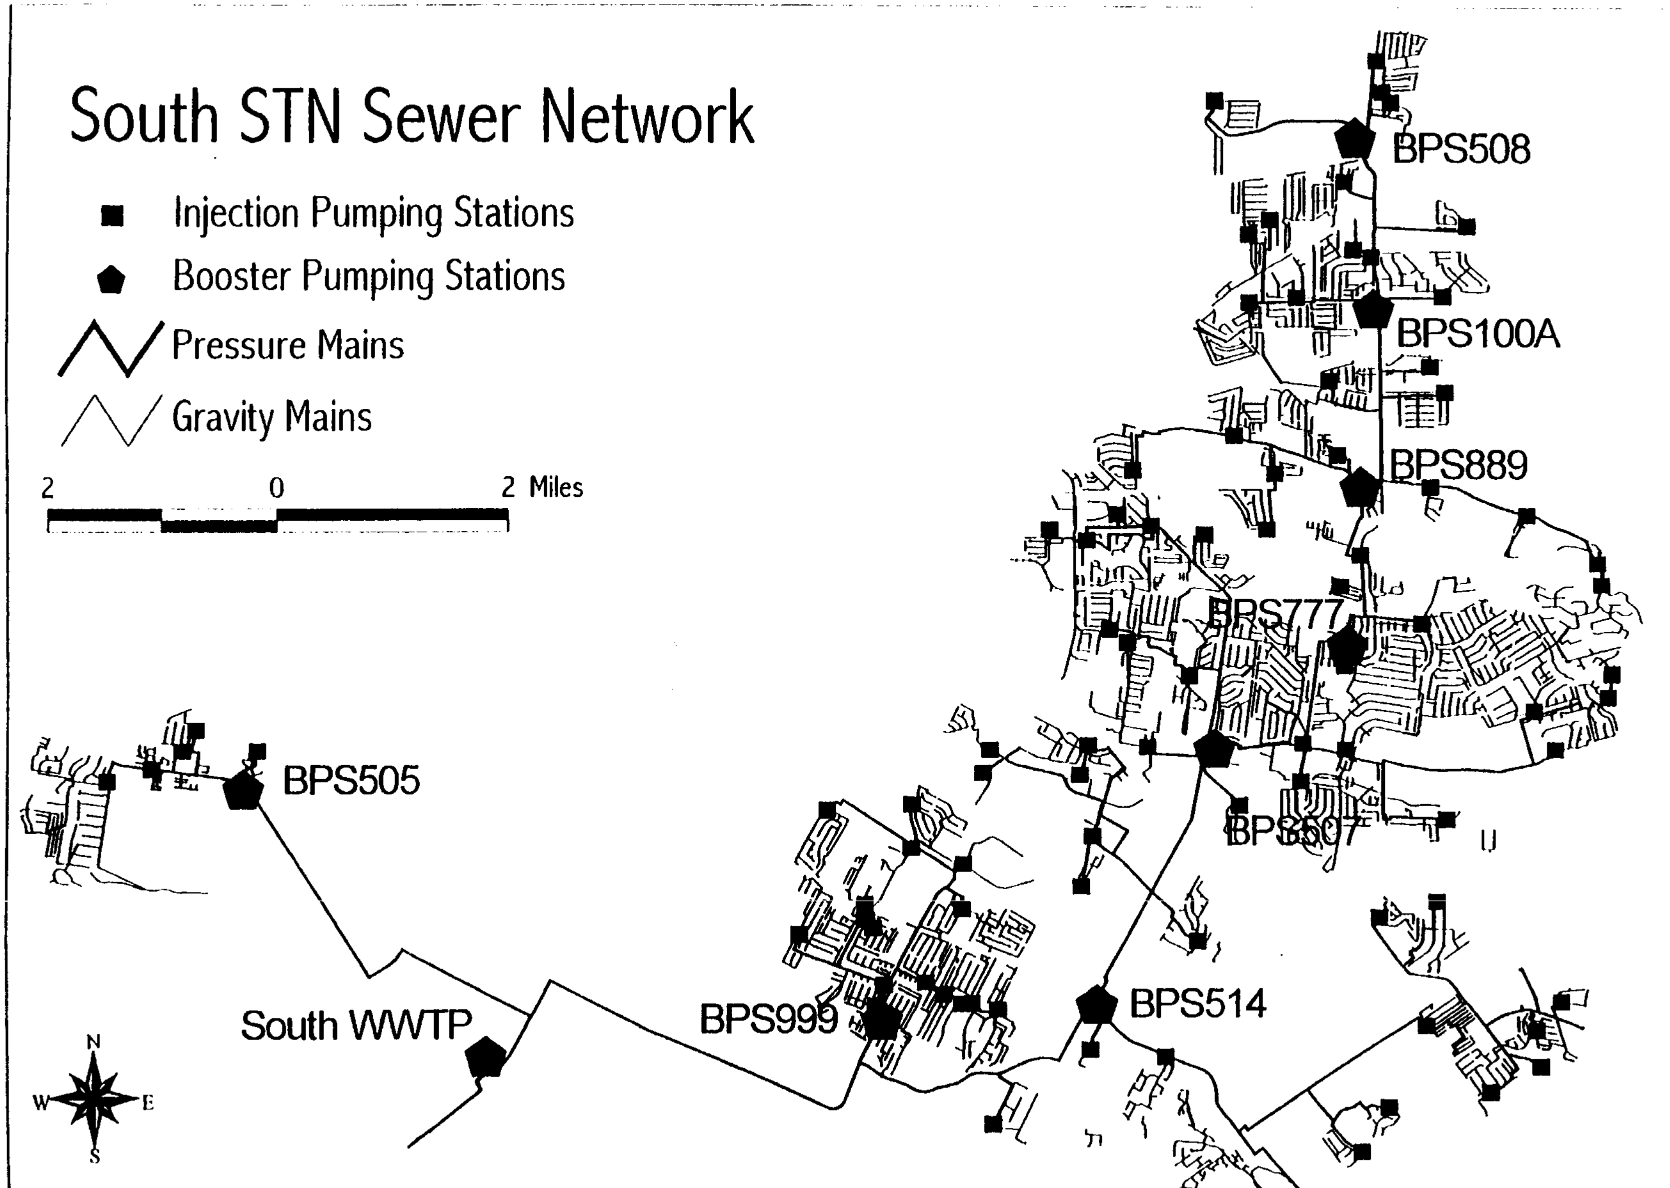

Fig. 1

R0024831

MODEL DEVELOPMENT

The following provides a summary of the key tasks undertaken during the development of the South STN model:

- A physical inspection and survey program of approximately 700 manholes (out of 5,000 manholes system wide) which included all pipes 250mm (10 in.) in diameter and larger as well as selected 200mm (8 in.) pipes in critical locations such as known SSO's or where there is a potential hydraulic throttle.
- Development of a state of the art GIS / data management system capable of storing all sewer and catchment attribute information, producing model input files and processing and displaying results.
- Sub-basin delineation and geoprocessing within the GIS to distribute Census data, water usage data and land use information to the modeled sub-basins.
- Physical inspection and pump testing of major gravity lift stations to construct "actual" pump curves for use in the model.
- Collation of physical attribute data for the pumping stations, booster pumping stations and force mains in the STN systems from "as built" records and input into the GIS.
- Collation of pump curves for each STN pumping station and determination of booster station operation rationale from O&M manuals, discussions with operators and system designers, observations during wet weather, development of real time control (RTC) logic to mimic booster pumping station operation and input of data into the GIS.
- Simplification of the model within the GIS by aggregating pipes of the same size and hydraulic characteristics.

The final model contains;

- 7 in-line booster stations,
- 7 RTC actuated sluice gates,
- 20 lift stations,
- 90 pumping stations injecting into the manifolded force main network,
- a manifolded pressurized network containing 243 pipes, and
- 522 gravity pipes ranging from 200mm (8 inches) to 450mm (18 inches)

The modeling software selected for this project was HydroWorks™ V2.2 as it was the only commercially available dynamic modeling software capable of dealing with pressurized pipes and the real time control (RTC) functionality necessary to model the booster pumping stations.

MODEL CALIBRATION

The models were calibrated with data from the following sources:

- Flow monitoring and rainfall data from a comprehensive 60 day temporary flow monitoring survey of the gravity sewers conducted from August to October 1996.
- Flow records from the influent meter at the treatment works.
- Weekly chart records of flow rates and pressures from the 7 booster pumping stations.

A challenging aspect of the model calibration effort was the development of RTC logic to mimic the complex operation rationale of the booster pumping stations in the STN system. Each station has either 2 or 3 variable speed pumps whose operation and speed is governed by a series of algorithms with inputs from the pressure sensors located upstream and downstream of the booster stations as well as the flow rate recorded by in-line flow meters downstream of each booster.

The models were first calibrated to accurately simulate the weekday and weekend diurnal dry weather flow patterns using an integrated facility within the HydroWorks™ modeling software called the "Waste Water Generator" (WWG). Model files produced from the GIS included residential and equivalent commercial populations, diurnal profile indices and ground water infiltration. When conducting simulations the WWG used this information to develop dry weather inflows "on the fly". Key advantages of developing dry weather flows using this tool include:

- Differentiation between sanitary flows and ground water infiltration.
- An internal clock which references the actual dates and times of the simulation event. By this means the appropriate weekday or weekend diurnal dry weather profile is automatically applied to a simulation trial.
- The model is constructed such that it can be readily migrated for use in Water Quality simulations in the future.
- Using the GIS to store attribute and catchment information facilitates an effective audit trail and efficient model updating for assessing the effects of future development.

Following dry weather calibration the model was calibrated against a range of recorded wet weather events. Wet weather calibration was achieved using a run-off and routing algorithm within the model well suited for the simulation of I/I response characteristics. Interesting aspects of the wet weather calibration process undertaken include:

- The model calculated pump rate for each injection pump station was constantly updated depending upon the level in the wet well and the HGL in the pressurized system.
- The process for producing wet weather response hydrographs is internal to the model as opposed to the traditional method applied in the U.S. where the wet weather hydrographs are generated external to the model.
- The sewerage system and topography of Baton Rouge is particularly flat and susceptible to high levels of surcharge during wet weather. Routines were developed to calculate and apply the additional surcharge storage volume available from the unmodeled pipes and manholes and applied to the modeled manholes.
- During calibration the model results were compared to both the recorded flow and depth to enable differentiation between hydrologic processes and the hydraulic attenuation of flows.
- During the flow monitoring survey a selection of storms were recorded ranging from short intense bursts of just over an hour duration to soaking rains of over 2 days duration and 2 year return period. With the model's integrated hydrologic and hydraulic routines it was possible to calibrate the model to adequately simulate both flow and surcharge depth for both extreme events involving extensive surcharge as well for lesser storm events.
- The model was able to simulate the complex interdependency between the booster pumping station operation in the STN trunk system, the pumping rate delivered by the smaller injection pumping stations and the surcharge levels in the gravity components of the STN.

APPLICATION OF THE CALIBRATED MODEL

The calibrated model can now be readily used to simulate individual storms, a batch of historical storms or conduct long term rainfall simulations. Providing the rainfall file has a start date and time, the model will automatically synchronize and apply the appropriate diurnal dry weather flows for the duration of the simulation as well as the calculated wet weather flows to the model. With this high level of functionality the model can be readily used for the following:

- Optimization of system operation by batch simulating a storm series, analyzing the results to identify any non-optimal practices, developing and simulating revised operational sequences.
- Identifying and simulating the application of proposed SCADA control systems to maximize the utilization of existing in-system surcharge storage.
- Analyzing the effect of future development on the whole of the inter-dependent system to assess optimal augmentation strategies.
- Identifying the cause of flooding from historical rainfall events.
- Analyzing the long term cost benefit of I/I mitigation works versus transfer system augmentation, installation of storage facilities and or treatment plant upgrade.

DISCUSSION

The Baton Rouge south STN model is possibly the largest hybrid pressure / gravity sewer model constructed to date. As the pressurized pipe solution is a relatively new feature in HydroWorks™ a number of "traps for young players" were encountered along the way before coming up with the final model solution. Prior to embarking on a similar modeling effort it is advisable that modelers first become familiar with the nuances of such systems, both in the field and from a modeling viewpoint.

Due to the complexity of the system, calculations required to come up with a stable solution during a simulation tend to require a fairly short time step. A 48 hour dry weather simulation on a Pentium 266–64Mb RAM computer took approximately 6.5 hours. The positive aspect is that major wet weather simulations run for 32 hours on the same computer take approximately 4.5 hours. Thus there is no noticeable time penalty due to heavy surcharge in the gravity pipe system during wet weather events.

As a by-product of the investigative process undertaken from data collection through to model calibration and storm analysis, a number of system characteristics have become evident which were not readily identified from the traditional static analysis. The following examples illustrate some of the observations made to date:

- *Inefficient Dry Weather Pump Operation* - during dry weather operation, which accounts for 90-95% of the run time for each pump, many of the injection pumps, sized primarily for peak wet weather, operate a long way out on their curves. This results in inefficient operation for most of their run hours and in some cases indicates the onset of cavitation and high impeller wear due to low net positive suction head (NPSH).

- *Erratic Booster Station Operation* - during the early stages of modeling a great deal of difficulty was encountered when trying to mimic the speed control algorithm for the booster pumps using RTC logic. With flows near maximum capacity the modeled booster pumps performed in a reasonable manner, however when flows were lower the modeled pumps would behave in a manner which appeared to indicate instability. Subsequent site investigations revealed that the booster pumps did in fact continually speed up and slow down following milder storms in accord with the logic programmed into the PLC controllers. A revised logic was tested on the model to stabilize booster operation and has successfully been installed at 4 of the booster stations and is soon to be installed in the remaining sites.

- *Identification of Cavitation Conditions* - since its commissioning in the early 1990's, booster station 514 had suffered from problematic operation in near all conditions other than dry weather or extreme wet weather. Due to excessive vibration, the impellers from two out of the three pumps at the station had worn loose and were out of action for some months while repairs took place. As this booster station pumps directly to the treatment works the discharge pressure or back pressure on the pumps is directly related to the amount of flow through the station. Through the review of model simulations it became apparent that the differential pressure across the pump station was insufficient for the pumps to remain on their curves at medium to low flows and hence cavitation through insufficient NPSH was the likely source of the vibration. A reasonably successful temporary solution has been to partially close the gate valves downstream of each pump to increase the backpressure.

- *Pumps Exceeding Design Flows* – the static model used to design the injection pumping stations assumed that the water level in the wet well remained at the pump switch on level and conservative friction factors to make allowance for future pipe deterioration. In many of the pumping station basins the peak wet weather flows exceed the pump capacity. As a result the water level in the wet well can rise up to 12 ft above the pump switch on level thus reducing the static head to pump against. Combined with the less than estimated pipe friction loss (from relatively new pipe) this has resulted in some pumps operating further out on their curves than designed and in some cases pumping up to 50% above their design capacity. The down side is that within each "cell" of the system, as defined by an upstream and downstream booster station, there is a finite rate of flow which can be injected into the system. For each pump exceeding its design capacity there is another pump which is restricted from injecting into the trunk system.

CONCLUSIONS

The development of an integrated gravity and pressurized pipe model provides waste water system managers and engineers with a powerful tool to analyze and manage these complex sewer systems. Key features of the Baton Rouge South STN model are:

- A powerful GIS-data management system, which can readily produce model, input files.
- The model is capable of simulating the hydraulics in both gravity sewers and long pressurized force mains.
- The model includes all pipes 10 inches and larger (with some 8 inch sewer included in chronic flooding areas), and includes an allowance for the unmodeled storage to enable differentiation between hydrologic and hydraulic effects in the calibrated model. The inclusion of the unmodeled system storage has been found to be critical in terms of successful calibration efforts.
- By calibrating the model with both surcharge and non-surcharge storm events a greater level of confidence can be attributed to simulation results.
- The ability to simulate the wet weather I/I response to rainfall internal to the model lends to the efficient simulation of multiple storm events with different scenarios.

A robust integrated hydraulic model combining both the gravity and pressurized components of a manifolded sewerage system is a powerful tool to achieve the holistic level of understanding necessary for the operation and optimization of such interdependent systems.

COMBINED SEWER SYSTEM: TO SEPARATE...OR...NOT TO SEPARATE

ABSTRACT

The City of Columbus, OH has implemented the minimum control of maximizing collection system storage as part of the Combined Sewer System Operational Plan. Due to the successful implementation of the storage procedure as designed and the current water quality of the receiving streams, no Long Term Control Plan programs or facilities are required. However, the City is planning to implement previously recommended separation projects to increase collection system capacity. The Chestnut Street Regulator Relief Project was one recommendation which urged separation of a large storm sewer from the combined system.

Concurrently, the City developed a program (Columbus Sewer Capacity Study) to study the hydraulic performance of its sanitary and combined sewerage systems in a comprehensive approach. One purpose of the study is to increase the City's knowledge of real time system hydraulics using modeling techniques and to provide tools to assess system capacity alternatives. Preliminary investigations of the Chestnut Street Regulator project indicate implementing system separation may not reduce the number and duration of overflows from the combined system. This separation project may have a negative impact on the receiving stream and the main intercepting sewer due to the time of concentration change effect on peak flows, and the potential increase in the hydraulic grade line of the combined interceptor.

This paper describes the analysis of a combined sewer system separation project in a global and local approach. It provides insight to the feasibility of utilizing current modeling techniques to offset the expense of a rigorous water quality sampling effort. Results may significantly reduce capital expenditures.

INTRODUCTION

The City of Columbus, Ohio has implemented the minimum control of maximizing collection system storage as part of the Combined Sewer System Operational Plan. Due to the successful implementation of the storage procedure as designed and the current water quality of the receiving streams, no Long Term Control Plan programs or facilities are required. However, the City is planning to implement previously recommended separation projects to increase collection system capacity. The Chestnut Street Regulator Relief Project is one recommendation which urged separation of a large storm sewer from the combined system.

Concurrently, the City developed a program (Columbus Sewer Capacity Study) to study the hydraulic performance of its sanitary and combined sewerage systems in a comprehensive approach. One purpose of the study is to increase the City's knowledge of real time system hydraulics using modeling techniques and to provide tools to assess system capacity alternatives. Preliminary investigations of the Chestnut Street Regulator project indicate implementing system separation may not reduce the number and duration of overflows from the combined system. This separation project may have a negative impact on the receiving stream and the main intercepting sewer due to the time of concentration change effect on peak flows, and the potential increase in the hydraulic grade line of the combined interceptor after bulkheading the storm sewer.

R0024837

BACKGROUND

The city of Columbus, Division of Sewerage and Drainage services a total area of approximately 100,000 acres (40,470 hectare) and designs its facilities for ultimate service area of 564 square miles (1,460 square kilometer). The current (1996) service area includes 5,286 acres (2,139 hectare) of combined sewerage drainage, which represents 5.2% of the current service area. There are approximately 2,016 miles (1,957 km) of sanitary sewers, 1,216 miles (1,957 km) of storm sewer, and 202 miles (325 km) of combined sewers within the service area. Of these sewers, approximately 550 miles (885 km) are major interceptors. There are two wastewater treatment plants (WWTP) with total capacity of 150 million gallons a day (mgd) (6.57 m^3/sec) during dry weather flow (DWF) and 252 mgd (11.03 m^3/sec) during wet weather. In addition, the city operates two primary treatment facilities for wet weather flow. The Whittier Street Storm Tanks (WSST), which were built in Columbus in 1932, are the first combined sewage holding facility built in the United States.

During the mid-1980s, the Division of Sewerage and Drainage (DOSD) determined that knowledge of the operations and flow patterns within the main interceptor system was lacking. The Division raised concerns regarding the physical condition of the system and the adequacy of the hydraulic capacity of the interceptors and trunk sewer segments. A program was developed to increase the city's knowledge of the characteristics of the interceptor system and to provide the tools with which to study possible changes to the system.

The program included the development of a collection system hydraulic model based upon an accurately developed sewer system physical description and calibrated against observed field flow data at key locations. The DOSD uses the model to accurately establish pertinent variables and to conduct statistical analysis for assistance in the decision making process.

Objectives of the program, now known as the "Columbus Sewer Capacity Study", include the following: understanding the sanitary and combined sewer system performance under various flow conditions; identifying the need for additional interceptor sewers; investigating the impact of, and possible solutions for identified problems, zoning variations, and/or development; and to establish the best method to control and manage the combined sewer system (CSS).

In 1989, the city of Columbus undertook a Combined Sewer Overflow (CSO) Study to determine the extent of the pollutant load in the receiving stream caused by combined sewer overflows. One finding of the study was suppressed aquatic life in the Scioto River between the WSST discharge point and the Jackson Pike WWTP (JPWWTP) outfall. The suppressed aquatic life in the Scioto River is attributed largely to the frequent activation of the WSST discharge.

Recommendations of the CSO Study included elimination of the storm discharge from a 108-inch (2700 mm) diameter sewer to the Olentangy Scioto Interceptor Sewer (OSIS), which is the primary interceptor to the JPWWTP. This connection is just upstream of the Chestnut Street Regulator. As shown in Figure 1, the existing system also has a 72-inch (1800 mm) diameter pipe from the 108-inch (2700 mm) diameter into the regulator. The tributary area to this 108-inch (2700 mm) diameter pipe includes highway drainage from Interstate 71 (I-71), Interstate 670 and from their interchange area. The Chestnut Street Regulator also has a 117-inch (2925 mm) diameter combined sewer discharging to it which also carries storm runoff from I-71. The CSO Study recommended that this separate storm sewer from I-71 be diverted to the 108-inch (2700 mm) pipe and then separated from the remaining flow to the regulator.

The CSO Study also recommended that the effluent from JPWWTP be diverted to the vicinity of the WSST outfall during low flow periods to provide dilution (with high quality effluent) for CSO discharges and storm water discharges in this stream section. These recommendations were made as a means of reducing CSOs from the WSST and to reduce the impacts to aquatic life in this river segment.

The DOSD did not immediately proceed with the Chestnut Street Regulator separation work due to other higher priority projects. In addition, the Division put all separation projects on hold due to uncertainties associated with the City's Stormwater NPDES permit.

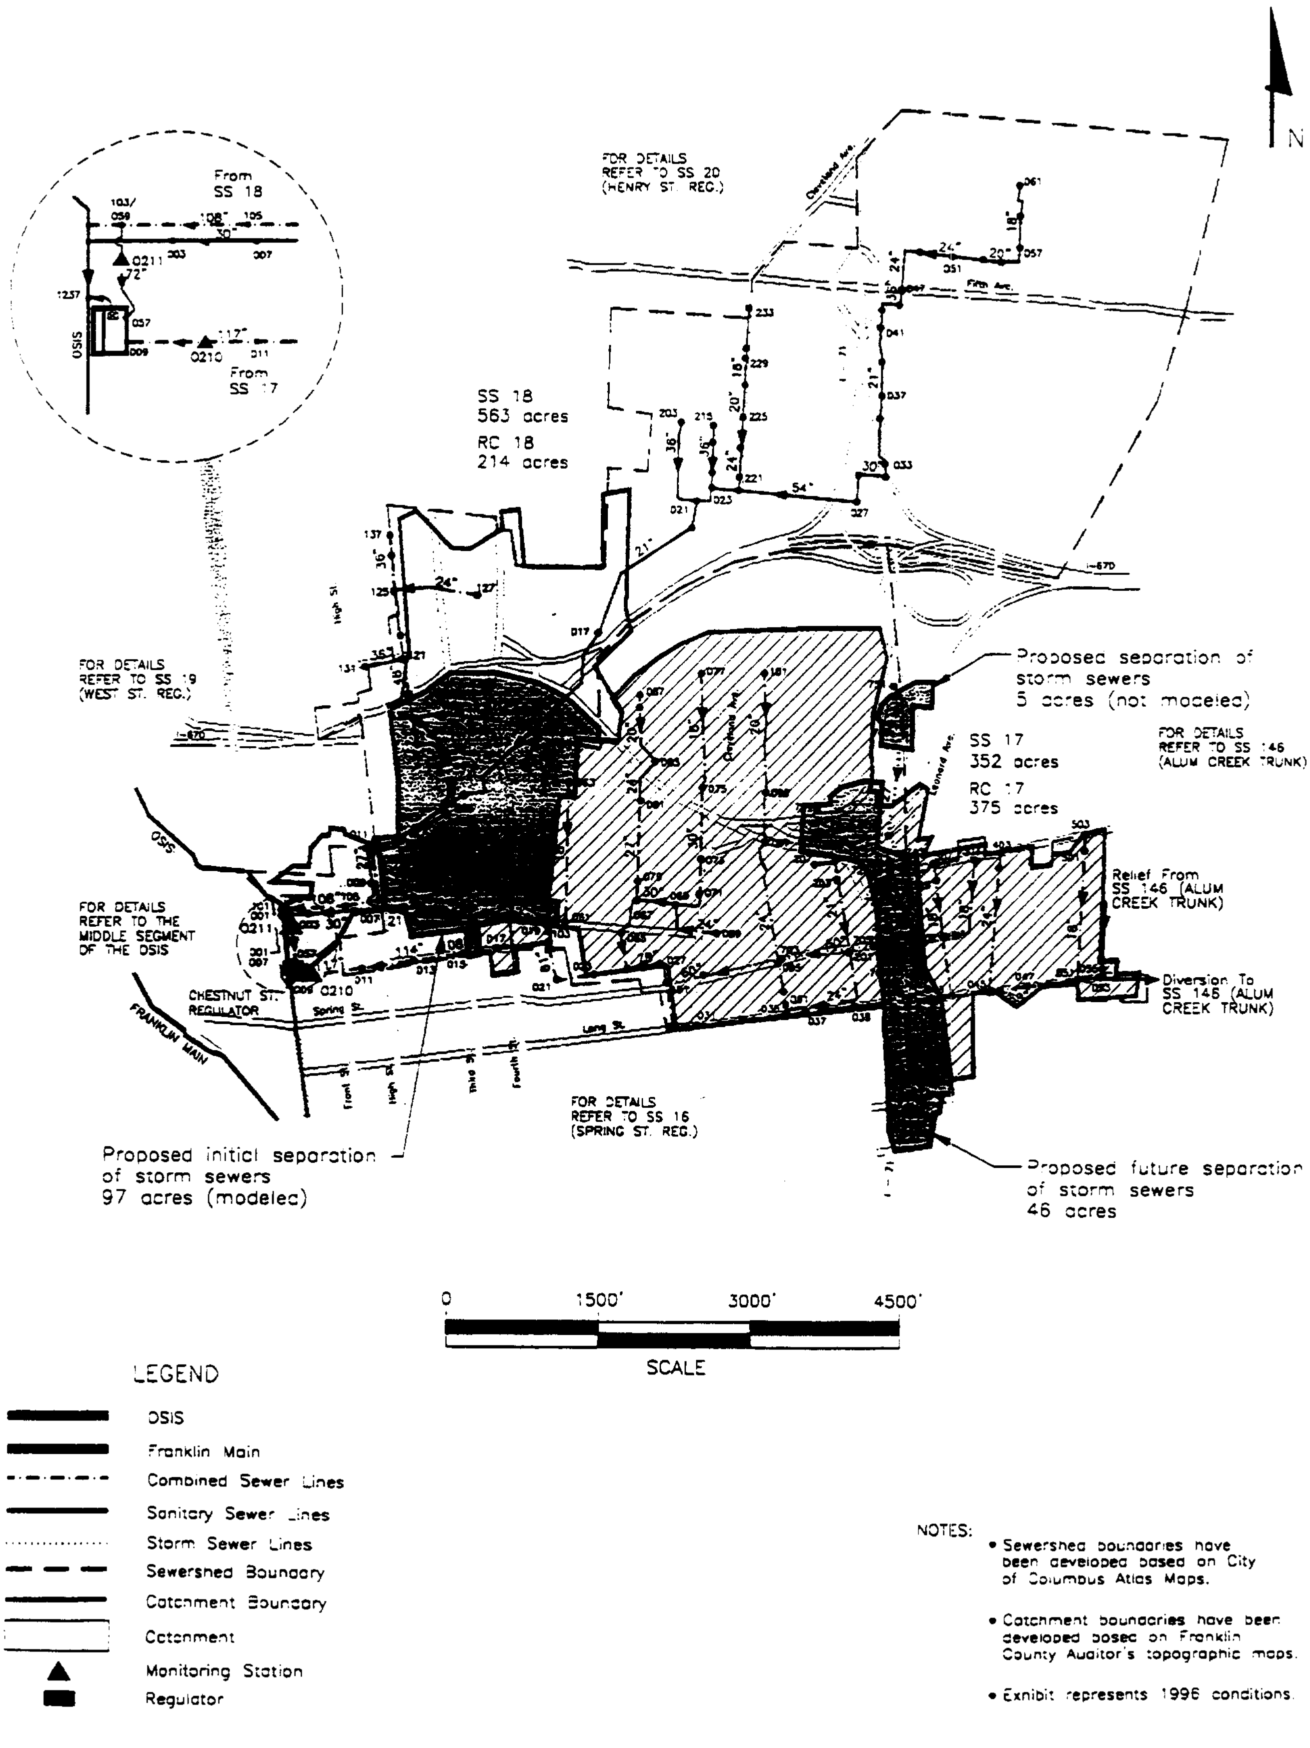

Figure 1. Tributary Runoff Catchment and Sanitary Sewershed to Chestnut Street Regulator

SEPARATION MODEL APPLICATION OBJECTIVES

During the development of the city's Combined Sewer System Operational Plan, the CSCS hydraulic model was used to determine remaining capacity within the city's interceptors. Prompted by questionable record plan information, unknown field conditions (are bulkheads in place, level of debris in chamber, etc.), and unexpected frequency of simulated reverse flow conditions through an upstream regulator, further investigation into the proposed Chestnut Street Separation Project was undertaken. An application of the model was developed to answer the following questions and verify the CSO Study recommendations:

1) *Will the proposed separation improve collection system performance?*

2) *Will the proposed separation negatively impact the streams?*

FLOW MONITORING AND RAINFALL DATA

A comprehensive Flow Monitoring and Rain Gauge Program was developed in conjunction with the CSCS hydraulic model development. This program's objectives are to provide the CSCS team with information on the collection systems hydraulics during dry and wet weather. A network of sixty four (64) flow monitors and thirty nine (39) rain gauges are owned and maintained by the DOSD. The model application was run using flow monitoring data captured during a 2-year storm event as recorded during the July 26, 1995 rain event.

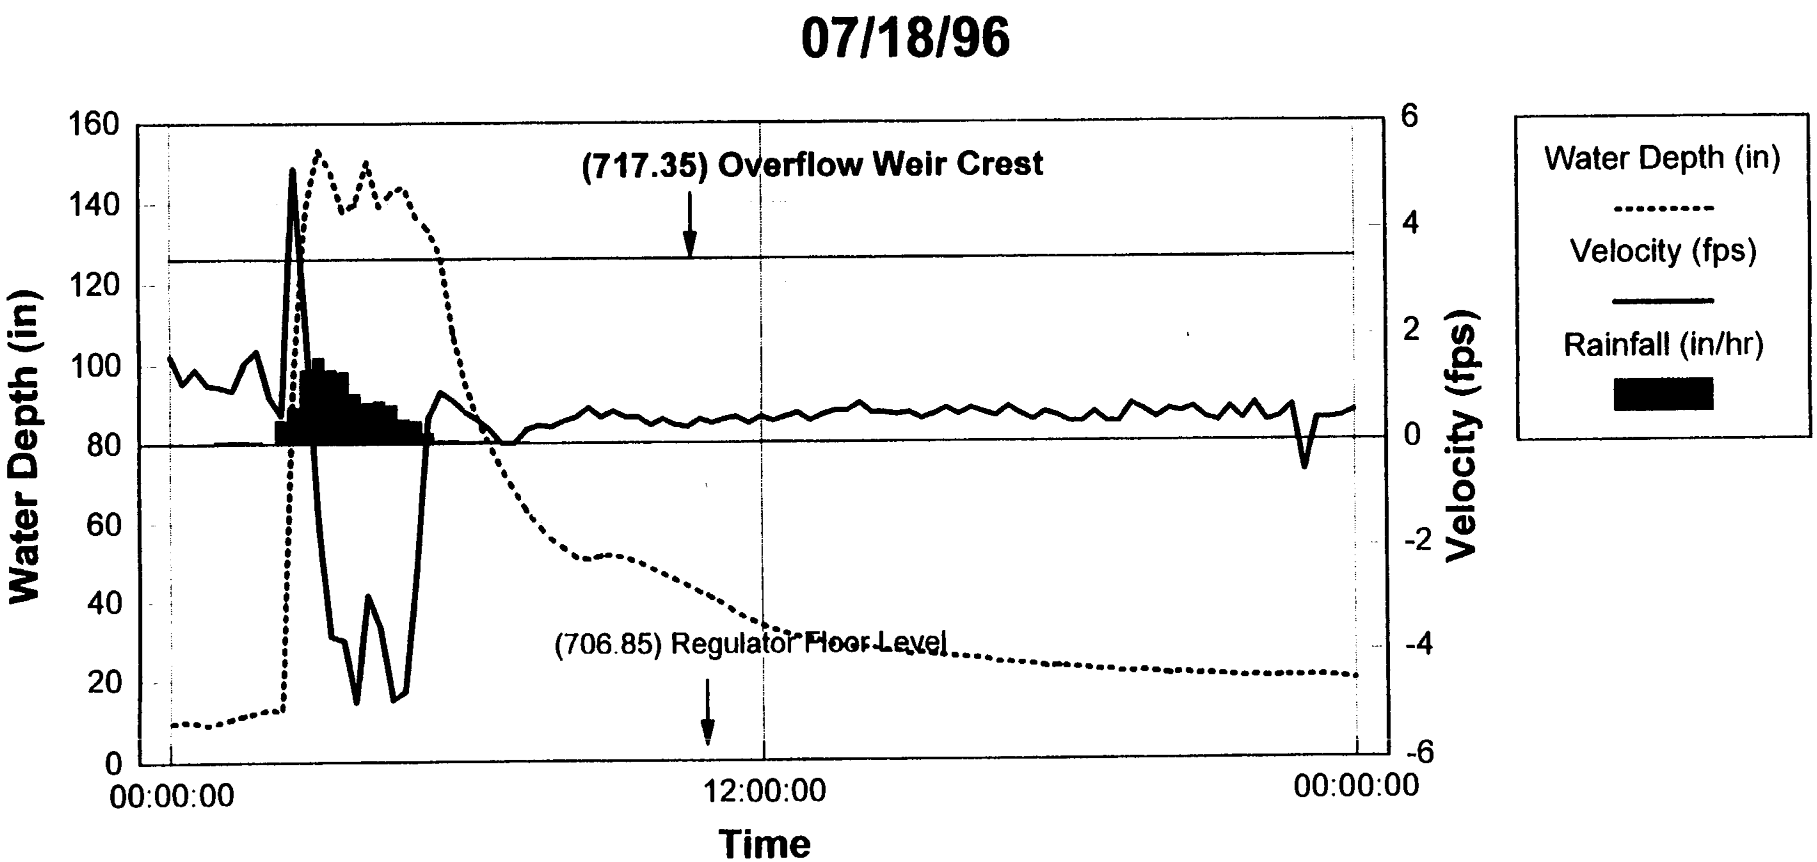
During the initial model application runs, flow data was provided by monitors located within the combined sewer system upstream and downstream of the Chestnut Street Regulator. An additional flow monitor was placed in the OSIS interceptor at a location between the WSST and the Chestnut Street Regulator following the initial model application runs.

HYDRAULIC MODELING EXERCISE

The Columbus Sewer Capacity Study uses historical rainfall events and measured flow data to calibrate the EPA Storm Water Management Model (SWMM) developed for the city of Columbus service area. This model is used to incorporate the collection system's physical description and meteorological data to determine the related hydraulic/hydrologic process. Original design reports were reviewed to determine basis of design criteria to compare to existing system conditions. The collection system is divided into smaller components based on the collection system drainage starting from service connections continuing to the point of interceptor discharge. The same procedure is followed in the runoff catchments (RC) based on topography of streets combined with linkage order of the CSS. All interceptors, including the Olentangy Scioto Intercepter Sewer (OSIS) are modeled using the SWMM EXTRAN block to consider the impact of surcharged conditions.

Initial model runs that were undertaken to evaluate remaining capacity in the OSIS shows that the Hydraulic Grade Line (H.G.L) inside the OSIS is higher than the weir crest elevation of a certain group of regulators. This indicates there may be reverse flow from the OSIS between this group of regulators. In addition, the H.G.L. in the OSIS is found to be below the overflow crest elevation of another group of regulators. This indicates that there may be no reverse flow to this group. To verify the model results, a flow meter was installed at Henry Street Regulator to record water depth and velocity at the intercepting connection. Figure 2 illustrates recorded water depth and velocity during the storm event on July 18, 1996. The recorded data shows that at the beginning of the storm, velocity pattern increases while water depth increases up to a certain time. When the water elevation rose above the weir crest elevation, the velocity pattern dropped and became negative, which indicates reverse flow and confirms the model results.

As shown in Figure 1, the Chestnut Street Regulator tributary area includes 563 acres (227 hectare) within sanitary sewershed (SS) 18, which includes 214 acres (86 hectare) of runoff catchments (RC). The initial proposed separation of 97 acres (39 hectare) of storm and combined sewers from RC 18 (as described in the 1989 CSO Study) would reduce the total RC area to 117 acres (47 hectare). The 108-inch (2700 mm) storm sewer to be removed from the OSIS, the subject of this modeling, has the design capacity to provide gravity storm sewer services to the runoff catchment in both SS 18 (RC = 375 acres) and SS 17 (RC = 214



Total rainfall = 2.9 in
Maximum rainfall intensity = 1.62 in/hr

Figure 2. HENRY Street Regulator Flow Observations at 07/18/96

acres). The second phase in this effort, would provide immediate removal of the 46 acres of Interstate roadway drainage from the tributary flow to the regulator.

The analysis included flow estimates of DWF and wet weather flow (WWF), and were entered as point sources at certain nodes in the collection system. The combined flow was routed in the SWMM EXTRAN. The Chestnut Street Regulator was described in the model as depicted in Figure 3, where a 66 x 66 inch sluice gate controls the flow from the regulator. The gate settings is 33 inches above floor level to allow a 66 x 33 inch opening. The overflow weir crest is set at elevation 717.88.

To investigate the impact of the separation, the RC is reduced to 117 acres in the SWMM RUNOFF model using the same historical rainfall data (7/26/1995- 2 year storm), and using the same parameters for current conditions.

MODELING RESULTS

The modeling results of the proposed initial separation of storm sewers (97 acres) indicate that the maximum computed flow rate in the 108 inch (2700 mm) sewer has dropped from 247 mgd (10.8 m^3/sec) to 200 mgd (8.76 m^3/sec). However, the computed maximum H.G.L. in the OSIS does not show significant change before and after the separation. Figure 4 illustrates a hydraulic profile of the OSIS showing computed maximum water depth and regulator elevations (i.e., weir crest level and floor level).

Table 1 lists all regulators that have been impacted by the separation showing computed overflow volume at each regulator before and after the separation.

The modeling results indicate the total reduction in overflow volume is approximately 0.52 MG (1,968 m^3) (0.42 at WSST and 0.11 at Henry Street Regulator).

Based on these results, the proposed separation is not expected to have a significant reduction in either overflow volume or overflow frequency at WSST for the 2 year storm level.

Table 1. Combined Sewer Overflow Reduction: 2-Year Storm Event

Node Number	Overflow Location	Volume of Overflow				Reduction in Overflow Volume 2 Year Event		
		Before Separation		After Separation				
		(MG)	(m^3)	(MG)	(m^3)	(MG	(m^3)	(%)
1201	Whittier Street Storm Tanks	164.3	621,876	163.9	620,362	0.419	1,586	0.3

FIELD VERIFICATION

Verification of actual field conditions is recommended when the level of certainty of modeling results is critical. During the detailed modeling of the Chestnut Street Regulator, questions were raised as to whether or not the record plans reflected as-built conditions. Specifically, there were two bulkheads shown on the record plans that were to be installed during the final stages of construction. Verification that these bulkheads are in place was performed by the CSCS field crew who also noted the following:

a. Substantial debris was observed within the Chestnut Street Regulator structure during a December, 1996 CSCS field crew site visit. This regulator is extremely difficult for maintenance crews to clean due to location, chamber design, and depth of deposits. During a May, 1997 field crew site visit, it was noted that the regulator structure had been cleaned, with little deposition built up.

b. Deposition was observed to be clogging the 72-inch (1800 mm) diameter storm sewer pipe entering the OSIS within the Chestnut Street Regulator structure during the December, 1996 site visit. During the May, 1997 site visit, this pipe is open and flowing into the OSIS.

c. Recommended locations for flow monitor installations were investigated. Installation and maintenance of proposed flow monitors within the 72-inch by 84-inch (1800 by 2100 mm) connection between the OSIS and the regulator gate may be difficult due to the hazardous flow conditions.

These observations provide very useful information that can support the prediction of reverse flow through the Chestnut Street Regulator and infrequent activation of the overflow weir during high intensity storm events.

In addition to the site visits performed by the CSCS field crew, the Stormwater Management Program currently monitors overflows at all regulators within the CSS. The location of a wooden block initially placed on the weir wall in each regulator is checked on a periodic basis. Historical data collected by the stormwater group do not indicate block movement at the regulators not expected to activate, further supporting the confirmation of model application findings.

FURTHER RECOMMENDATIONS

Based upon the results of the CSCS model application described in this paper, the following recommendations were identified as beneficial to undertake prior to the DOSD proceeding with the proposed Chestnut Street Separation project:

1. Continue the use of the CSCS hydraulic model and flow monitoring program to optimize the performance of all of the regulators by simulating modifications to weir elevations and gate settings. Assuming negligible spatial variation of rainfall, discharge of combined flows during wet weather should occur at the storm tanks until the regulators simultaneously crest their weir elevations.

2. Continue use of the CSCS model to analyze incremental levels of rainfall to determine the receiving stream's level of protection from combined sewer overflows presently provided by the combined sewer system. In addition, determine the level of stream protection at Chestnut Street following separations and optimization of the combined sewer system.

Findings of these two exercises can be used to aid in determining whether or not to proceed with the separation project.

3. If the DOSD proceeds with separation work, implement a flow monitoring program of the Olentangy Scioto Interceptor Sewer, WSST, and Chestnut Street Regulator before and after the construction of separation work to determine separation efficiency.

CONCLUSIONS

The application of the Columbus Sewer Capacity Study hydraulic model, supported by the use of flow monitoring data and field verifications obtained by the CSCS field crew proved to be a very valuable exercise. It successfully demonstrated that it is crucial to consider global impacts as well as local impacts during the decision making process of whether to separate or not separate combined sewer flows. Not only did the preliminary results as stated in this paper indicate that the impact of separation work may provide insignificant improvements in water quality, the results indicate that there may be other improvements that can be made to the system to more effectively spend capital improvement program funds to realize greater benefits to the receiving stream.

ABSTRACT

Creating effective plans to address sanitary sewer overflows requires good understanding of collection system response under a variety of operating conditions. To extend the usefulness of measured data, the Greater Vancouver Sewerage and Drainage District modified SWMM RUNOFF to improve simulation of wet weather flows in sanitary sewers through computer modelling. The addition of an effective infiltration area factor and improvements to tracking head differences between the groundwater stage and pipe tailwater level produced calibrated results that were typically ±15% of measurement. This level of accuracy in simulating immediate and seasonal infiltration and inflow response provides the basis for evaluating a wide range of options that address wet weather issues.

KEYWORDS

SWMM, RUNOFF, infiltration, inflow, sanitary sewer, overflow, computer simulation.

INTRODUCTION

Rainfall-induced infiltration and inflow (I/I) is described as the seepage of percolating rainwater that finds its way into the sanitary sewer system through pipe defects. While rainfall-induced I/I occurs during and some time after the rainfall event, it can result in peak flows that exceed sewer design capacities culminating in sanitary sewer overflows (SSOs). Reactive measures to eliminate SSOs by up-sizing flow conveyance and treatment capacities will often lead to a path of high-cost solutions. Improving one's understanding of I/I and engaging in a thorough assessment of improvement options can provide a set of cost-effective solutions to address SSOs. Computer simulation of I/I is one of several program steps the Greater Vancouver Sewerage and Drainage District (GVS&DD) is undertaking to identify, quantify, and evaluate system improvements.

Objectives of this computer modelling effort included:

- Minimizing discrepancies between measured and simulated I/I under a wide variety of rainfall patterns and antecedent moisture conditions.
- Extrapolation of I/I response to unmonitored areas and to extended durations that cover seasonal variations.
- Overall assessment of existing sewer system performance for light and heavy rainfall years.
- Performance evaluation of options such as increased conveyance, treatment capacity, I/I source reduction, and peak flow storage.

This phase of work focuses on modelling the hydrological process of rainfall, groundwater percolation, and infiltration to sanitary sewers.

Previous I/I Modelling Methods

Various methods of estimating I/I can be categorized as follows:

(i) direct measurement;
(ii) application of unit infiltration rates;
(iii) the multiple unit hydrograph approach; and
(iv) the physically-based approach.

Direct measurement of I/I is required in any program aimed at identifying and quantifying a realistic flow response to rainfall. It is generally the first step to defining the extent of the problem. However, measurement devices generally can not be located everywhere in the collection system and maintained indefinitely given the cost implications. Direct measurement's ability to assess existing response will provide a means of checking indirect methods, but it will not provide estimation of future response or under "what-if" scenarios.

Unit infiltration rates empirically derived from measured data are widely used for design purposes. Its use precludes modelling of a system's hourly or minute-by-minute response to actual rainfall. Unit infiltration rates are typically not correlated to return period storms, but rather represent rules-of-thumb.

Because of its simplicity, the multiple unit hydrograph approach is by far the most often used method to estimate I/I response. For example, the City of Edmonton applied a three unit hydrograph model that describes: fast inflow; fast infiltration; and slow infiltration (Christopher et al., 1996). The City of Alexandria in Virginia applied a two unit hydrograph model to simulate fast and slow I/I components (Oakley and Warren, 1995). The main drawbacks of the multiple unit hydrograph approach are: (i) it does not provide a physical insight to the hydrologic processes, but treats it as a "black-box"; (ii) it generally does not consider the effect of antecedent moisture conditions; and (iii) it assumes processes are linear.

In comparison to multiple unit hydrograph models, there has been limited development in physically-based I/I estimation models. One notable example was the CEMGREF model developed in France for application in rural watersheds (Belhadj et al., 1995). While the CEMGREF model provides a physically-based approach that accounts for hydroclimatic conditions, as well as, surface and subsurface characteristics, the developers have indicated that it does not simulate urban sanitary sewer systems to desirable levels of accuracy.

METHODOLOGY

Since the early 1990's, the GVS&DD has successfully used the RUNOFF module of the Storm Water Management Model (SWMM) to simulate the hydrologic process for several of its combined sewer overflow studies and programs. Early attempts to apply the same approach to sanitary sewer systems highlighted weaknesses in RUNOFF's ability to adequately describe the physical process. While peak flows could be made to match field measurements, simulated storm recessions and nightly low flows differed substantially both during and after storm events. Also noted and confirmed by field measurement was that sanitary discharges account for a substantial portion of the flow depth, even during storm events in sanitary sewers. This effect is much less pronounced in combined sewers.

On the basis of these observations, it appeared that sanitary discharges can effectively 'regulate' groundwater I/I via diurnal fluctuations in the tailwater depth in the sewer. Given that the difference in elevation between the groundwater table and the tailwater depth provides the driving head for infiltration, diurnal variations in the tailwater depth would tend to decrease infiltration potential during sanitary peaks and conversely increase infiltration potential during nightly low flow periods (see Figure 1). To properly account for this physical process, the RUNOFF module would need to deal with dry weather flow inputs for regulating groundwater flow in its subroutines.

Recognizing that sanitary sewers and storm drains typically share the same catchment area in an urban environment, one can describe the area of I/I contribution to the sanitary sewer as a fraction of the total catchment area. Many other factors such as pipe depth, material, age, condition, existing quality of joints, and number of connections also influence the effective area of I/I contribution (see Figure 2). Hence, the idea of introducing an effective I/I contributing area factor, α, a user-defined value as a fraction of the total catchment surface area.

Modifications

Version 4.31 of RUNOFF provided the basis of implementing concepts surrounding input of dry weather flows and application of an effective area factor. The modified version of RUNOFF named v4.31d now provides the option of:

- including 24-hourly, 7-day, or long-term dry weather flows to any given subcatchment
- applying an effective area factor for I/I contributions to any given subcatchment.

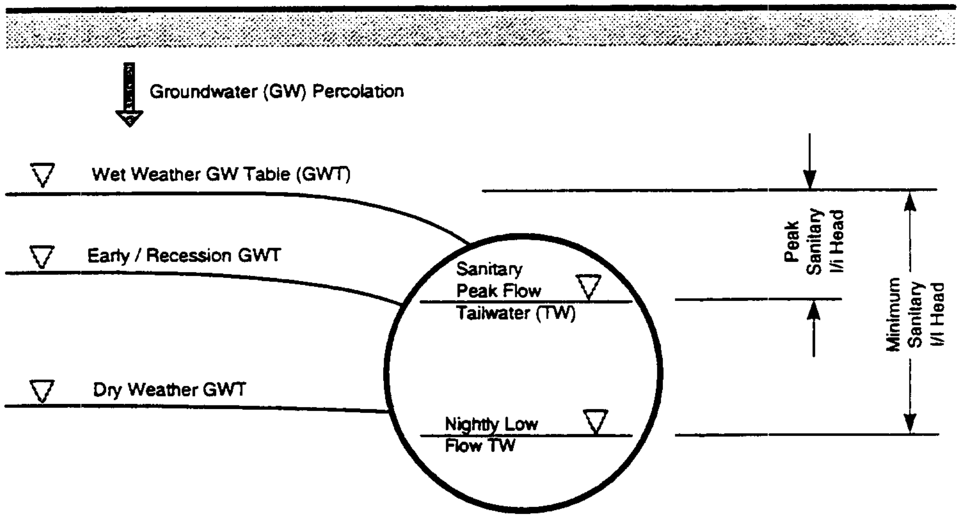

Figure 1. Conceptualization of tailwater effects that tend to decrease I/I potential during sanitary peaks and increase I/I potential during nightly low flows.

Figure 2. Conceptualization of a user-defined effective I/I contributing area factor as a fraction of the total catchment surface.

In addition, the functional form of the groundwater flow equation (GWFLW) was modified slightly to better describe the head difference concept.

The standard version of SWMM RUNOFF uses a groundwater equation to calculate infiltration flow at any given time-step using equation (1) given by the following:

$$I/I = a_1(GWT - PI)^{b_1} - a_2(TW - PI)^{b_2} + a_3(GWT)(TW) \quad (1)$$

where GWT = the water table elevation; PI = pipe invert elevation; TW = the tail water elevation; and a_1, a_2, a_3, b_1, and b_2 = discharge coefficients.

Note that the standard equation does not directly represent the driving head for groundwater infiltration flow given by the difference (GWT - TW). Only in the event if $a_1 = a_2$, $b_1 = b_2$ would equation (1) provide the (GWT - TW) head potential.

The revised groundwater equation is given by equation (2).

$$I/I = a_1(GWT - TW)^{b_1} - a_2(TW - PI)^{b_2} + a_3(GWT)(TW) \quad (2)$$

GVS&DD staff tested modifications to RUNOFF v4.31 on dozens of catchment models which calibrated with generally good results. Figure 3 shows a schematic of the calibration process and revised data flow paths.

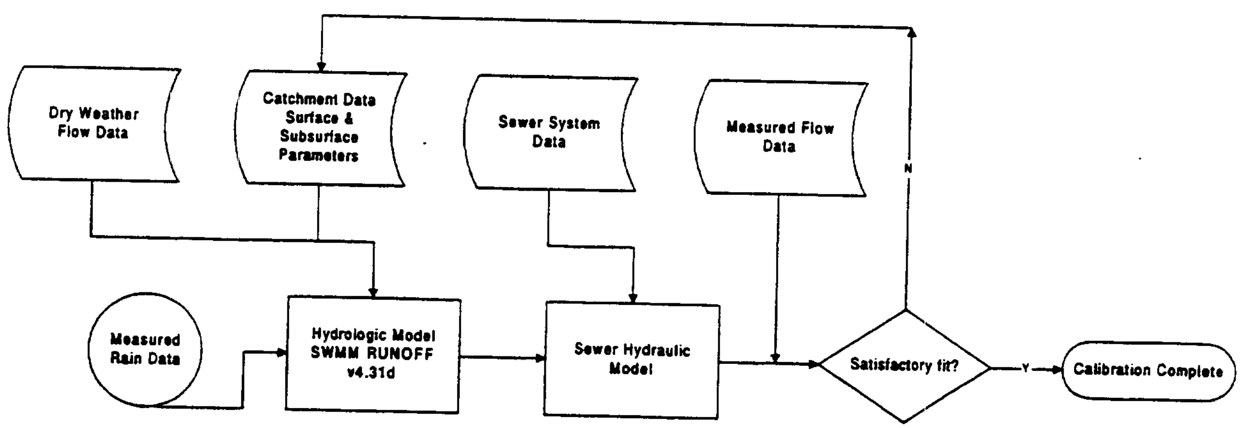

Figure 3. Schematic of the calibration process and data flow paths.

Notes on the Calibration Process

- As shown in Figure 3, dry weather flow data is now an input to the hydrologic model, RUNOFF, rather than its input traditionally into the sewer hydraulic model. All calibrations included hourly dry weather flow patterns for each catchment over a 7-day period.

- Sewer catchments were typically discretized into 50 ha areas. Physical catchment data such as area, average slope, width, capillary suction, hydraulic conductivity, and porosity were estimated either by measurement or interpolated from book values; most parameters with no or little adjustment during calibration. Discharge coefficients and true calibration parameters were used extensively to obtain satisfactory simulated results.

- Historical rain data from 20 tipping bucket gauges distributed over the study area at a density of about one gauge per 2000 ha were used. Recent flow data were available at 44 upper catchment sites to calibrate the hydrologic and hydraulic models.

- RUNOFF's simple hydraulic model was used to calculate the tailwater elevation for each catchment. Only the subsurface flow component was considered in simulating I/I flows. Surface runoff was assumed to discharge into appropriate drainage systems.

- Simulation start-times were set to well ahead of the comparison period to ensure stabilization of ground conditions (e.g., soil moisture; groundwater table) from initial values.

RESULTS

Figure 4 (a) shows an example of simulation results using the standard version of RUNOFF v4.31. It appears that without the modifications, low flows, peak flows, and time to peak flows are not well simulated. The poor fit is likely a function of not correctly balancing the fast and slow I/I responses. In this particular case, there appears to be over-storage of percolated flows resulting in overestimation of I/I as the groundwater equation continues to release water well after the rain storm has ended.

Figure 4 (b) shows the results of including the effective area factor. The prediction of low flows after the storm is improves somewhat, but at the expense of poor fit during peak storm flows.

Adjustment of groundwater equation coefficients, the subsurface hydraulic conductivity, and the field capacity produced the final calibrated result shown in Figure 4 (c). The subsurface hydraulic conductivity was increased to accelerate I/I response so that the time to peak could be better simulated. The overall fit is substantially improved, but with some loss in accuracy during the storm of 27-Dec.

Calibration of the first few catchments took significant effort as parameter sensitivities were explored. Experience grew with each catchment calibrated, providing insight on how to accelerate the calibration process. One simplification made to nearly all models involved reducing the groundwater equation to only the first term with starting coefficients as follows:

Table 1. Default coefficient values in Equation 2.

Parameter	a_1	b_1	a_2	b_2	a_3
Default value	20	0.001	0.0	0.0	0.0

The calibrated value of the effective area factor varied significantly from 5% to 20%.

Once calibrated, the hydrologic model can extend its application to:
- continuous simulations
- estimation of I/I response to any storm (e.g., historical high, low, new data, return-period design storms)
- extrapolation to unmonitored areas (via parameter transference).

As an example, Figure 5 shows two snapshots of a 12-month continuous simulation run, to which only 4 months of measured data exists over the simulation period. Total flows as well as rainfall-induced infiltration and inflow can be determined by year, by season, or by day to assess wet weather performance of the upstream collection system. A review of such statistics for the dozens of calibration points or hundreds of extrapolated and interpolated points will help to identify areas with particularly excessive I/I. The areas can then be prioritized for targeted I/I reduction programs.

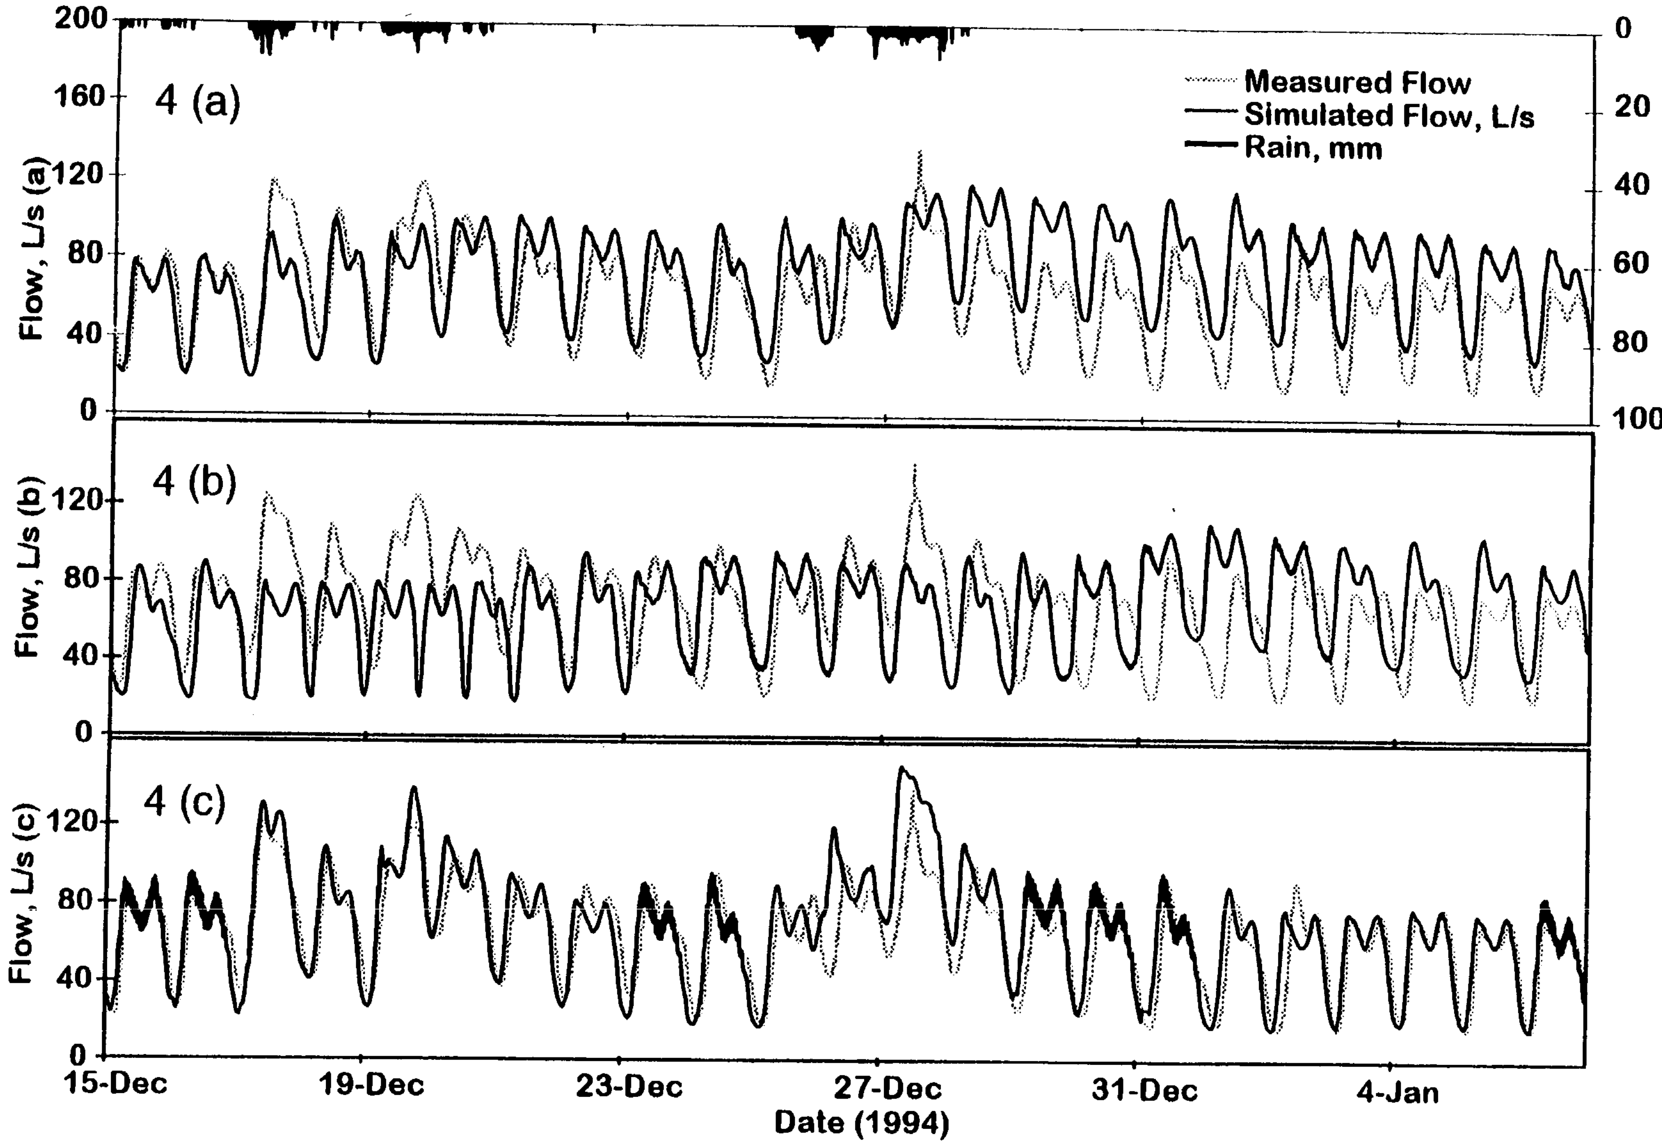

Figure 4. Comparison between standard and modified RUNOFF models. (a) using standard RUNOFF v4.31, (b) with the use of the effective area factor, and (c) with modified RUNOFF that considers tailwater effects of sanitary discharges.

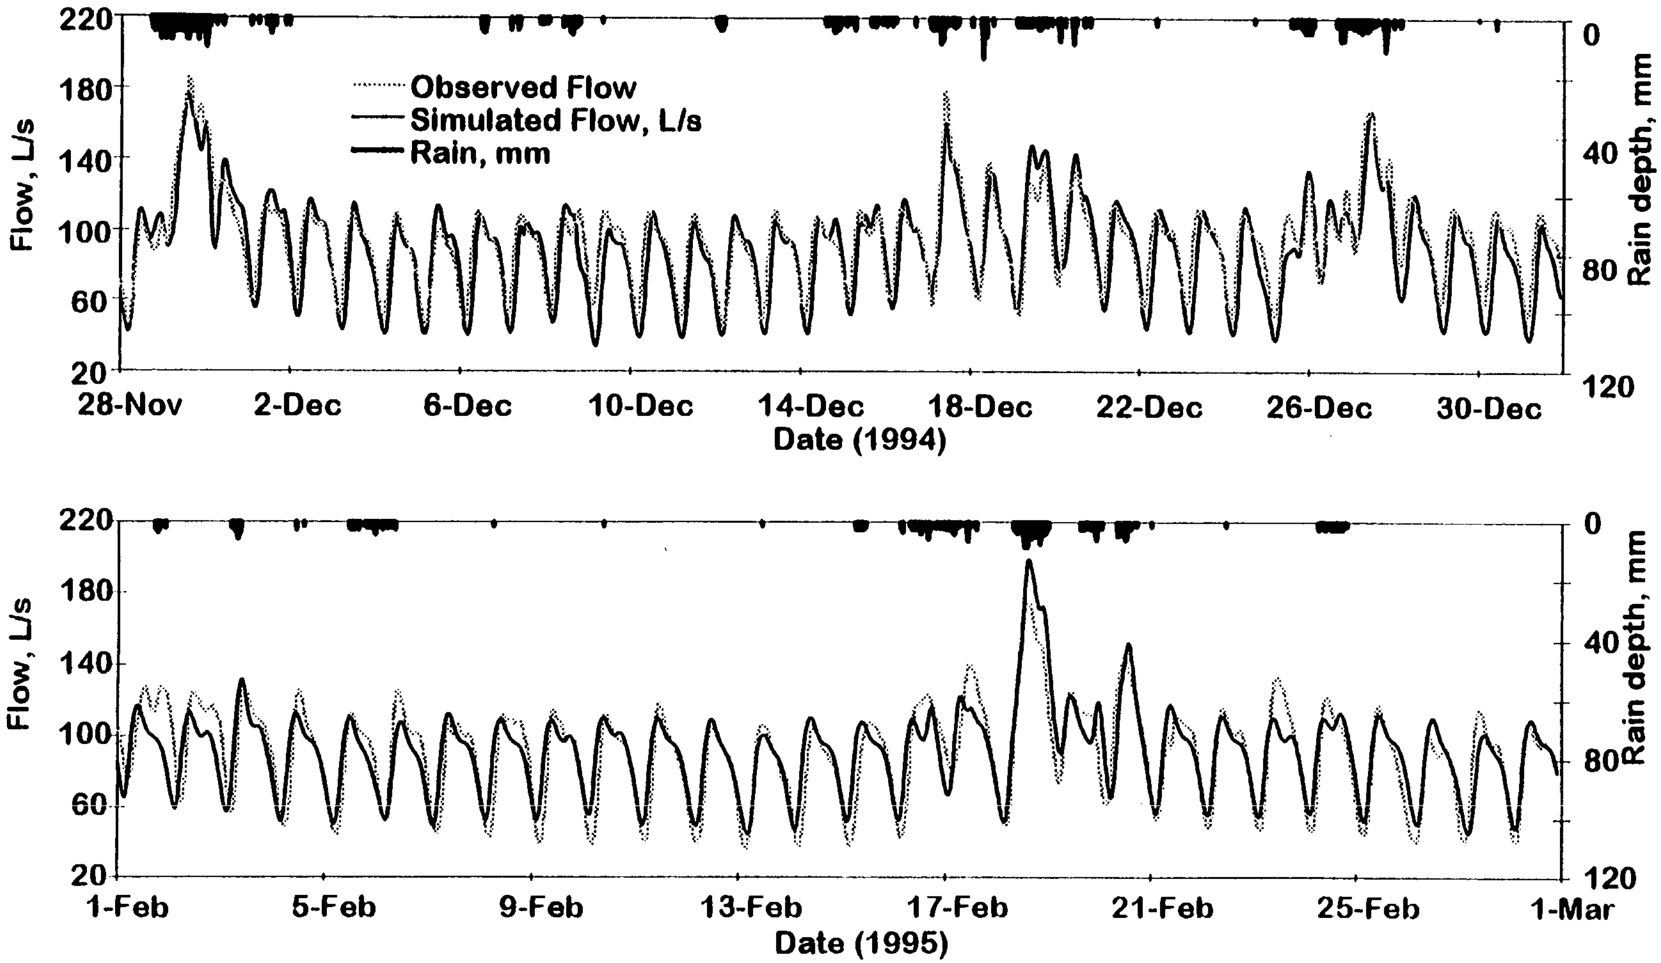

Figure 5. Two snapshots of a 12-month continuous simulation run.

DISCUSSION

In general terms, RUNOFF's subsurface routines can be conceptualized as flow movement in and out of a non-linear reservoir. For the most part, the effective I/I contributing area, the depth of pipe, field capacity and porosity define dimensions of the reservoir. The percolation process and associated parameters such as hydraulic conductivity and moisture content determine the inflow rate into the reservoir. The groundwater equation and its discharge coefficients describe the release rate out of the reservoir.

Catchments characterized by significant I/I, even days after the storm event, can be represented by a large reservoir volume and small discharge coefficients at its outlet. Conversely, catchments with quick I/I response can be represented by a small reservoir volume, large discharge coefficients, and high percolation rates. Using this physically-based conceptualization helps to better understand the I/I process and often leads to highly satisfactory results. As with any other physically-based approach, RUNOFF v4.31d can be readily applied to other geographic areas with starting parameters from known values set for the new study area before calibration begins.

The modifications to RUNOFF have substantially improved its ability to successfully simulate wet weather conditions for a sanitary sewer system. However, simulated results still show some discrepancy from measurement. While there could be a variety of reasons for this, a few are suggested:

- The I/I process is much more complex than can be described by reservoir concepts. RUNOFF is a deterministic one-dimensional model that averages I/I processes over a relatively large catchment. In reality, there exists a wide variation of conditions that can not be described by the simple concepts used in RUNOFF. For example, sewers within a catchment are located at different elevations; the I/I contributing area varies; there are other sources of drainage such as storm sewers, ditches, deep percolation, and evapotranspiration.

- To offer a means of balancing inflow versus infiltration, the original intent was to implement a separate effective area factor for surface and subsurface flow components in RUNOFF. Programming difficulties forced compromise to a single effective area factor for both the surface and subsurface components.

- RUNOFF v4.31d is able to deal with infiltration when the groundwater table is at a higher elevation than the tailwater level in the sewer. However, exfiltration is currently not modelled, should the groundwater table drop below the tailwater elevation.

- In some cases, sewer backwatering occurs which could significantly impact the actual tailwater elevation. RUNOFF's simple hydraulic model is not able to model such effects.

CONCLUSIONS

This paper presents a new approach to infiltration and inflow analysis in separated system. The approach uses a modified version of the SWMM RUNOFF model, which includes the following: (i) addition of an effective area factor to control the I/I contributing area, and (ii) consideration of sanitary discharge influences on the tailwater depth in estimating I/I.

The effective area factor provides a means to control the I/I contributing area and thus the I/I volume. It appears that the rate of I/I release can be adequately controlled using 2 of 5 coefficients in RUNOFF v4.31d's groundwater equation.

Sanitary flow can have a significant influence on I/I contributions through tailwater effects. The presence of sanitary flow increases the tailwater elevation, reducing the driving head differential with respect to the groundwater stage. RUNOFF v4.31d accounts for tailwater fluctuations due to sanitary discharges and rainfall-induced flow components.

Calibrated hydrologic models using the modified version of RUNOFF produced very good results when applied to sanitary sewer systems spanning some 36,000 ha. The GVS&DD uses RUNOFF v4.31d to investigate sewer overflows, address operating and maintenance issues, extrapolate I/I response to unmonitored areas, supplement measured flow data, and evaluate sewer improvement options under a variety of rainfall patterns.

ACKNOWLEDGMENTS

The authors thank Brett Young, M.Sc., P.Eng., for his insight during the conceptualization stage of this project. We recognize Dr. Zhong Ji, Ph.D. for his effort in programming our algorithms into what could be considered the most tinkered FORTRAN source code in history. We also thank the Reid Crowther Consulting team in Seattle for their support.

HISTORICAL PERSPECTIVE

Kenneth A. Pew

Northeast Ohio Regional Sewer District, 3826 Euclid Avenue, Cleveland, Ohio 44115-2504 U.S.A.

ABSTRACT

This presentation provides the historical perspective and background for the nine following presentations regarding various aspects of the Northeast Ohio Regional Sewer District wet weather programs.

KEYWORDS

wastewater, treatment, sewer, combined, overflow, Erie, Cuyahoga

CONDITIONS IN THE LATE 1960s AND EARLY 1970s

Water quality during the late 1960s and early 1970s was definitely impaired. The Cuyahoga River and Lake Erie were polluted by sanitary and industrial wastewater. Numerous oil spills occurred at combined sewer overflows. The Cuyahoga River "burned" in 1969. Beaches were routinely closed. "Help - I'm dying" was painted on a break wall on Lake Erie.

There was also tension among all levels of government. Federal agencies filed litigation against the City of Cleveland for polluting the Cuyahoga River and Lake Erie. State agencies placed a building ban on Cleveland and other communities connected to the Cleveland sewer system. The communities filed litigation against Cleveland over sewer rate inequities. All litigations were consolidated into one case.

NORTHEAST OHIO REGIONAL SEWER DISTRICT

The Northeast Ohio Regional Sewer District was created by the court order ending this case in July, 1972. The District was made responsible for wastewater treatment, interceptor sewers, combined sewer overflow control, industrial waste control, and development of a plan for regional management of wastewater collection and storm drainage.

The court order defined Subdistrict 1 to be Cleveland and Subdistrict 2 to be all other communities. The order then specified that the District would be governed by a seven-member Board of Trustees, appointed as follows:

- Two by the Mayor of Cleveland
- Two by a Suburban Council of Governments
- One by the Commissioners of the County of Cuyahoga
- One by the Subdistrict with the greatest wastewater flow (currently Subdistrict 1)
- One by the Subdistrict with the greatest population (originally Subdistrict 1, but now Subdistrict 2)

The District currently has a 295 square-mile service area, which includes 75 square miles served by combined sewers. The service area encompasses all or part of 53 communities, each responsible for their own local sewer system. The District serves over one million people and treats over 330 million gallons of wastewater per day on average.

The District owns and operates three wastewater treatment plants, six pump stations, 207 miles of interceptor sewers, 467 static combined sewer regulators, and 29 automated combined sewer regulators. The 496 combined sewer regulators discharge to the environment at 126 locations permitted by the National Pollutant Discharge Elimination System. Discharges at these 126 locations impact many receiving waters:

- Lake Erie
- Four streams tributary to Lake Erie
- The Cuyahoga River
- Four streams tributary to the Cuyahoga River
- The Ohio Canal

WET WEATHER PLANT OPERATION

Lewis Debevec Jr.
NORTHEAST OHIO REGIONAL SEWER DISTRICT
3826 Euclid Avenue
Cleveland, OH 44115

ABSTRACT

The creation of the Northeast Ohio Regional Sewer District by court order in 1972 was done to resolve water quality problems that existed in the greater Cleveland area. These problems were due in part to the inability of treatment facilities to treat wet weather flows. Today, the three award winning treatment plants have been exemplary in their day to day operation. Beyond that, they have maintained their permit conditions utilizing strategies to deal with high flows during wet weather conditions. Each plant is unique and this paper explores their uniqueness in handling wet weather operations.

KEYWORDS

wastewater, treatment, wet weather, process, flow

INTRODUCTION

The Northeast Ohio Regional Sewer District operates three-wastewater treatment plants in the Cleveland area. The oldest facility is the Easterly Wastewater Treatment Plant that is located on the east side of Cleveland and discharges into Lake Erie. The largest facility is the Southerly Wastewater Treatment Center located on the south side of the City of Cleveland in Cuyahoga Heights. This facility discharges its treated effluent into the Cuyahoga River. The smallest of the three plants is the Westerly Wastewater Treatment Plant located on the west side of City of Cleveland and discharges its treated effluent into Lake Erie.

EASTERLY WASTEWATER TREATMENT PLANT

The Easterly Treatment Plant is a conventional activated sludge plant with a design dry weather flow of 155 MGD and a wet weather flow of 330 MGD. The plant has no conventional solids handling facilities. The plant pumps it solids through a thirteen- mile pipeline to the Southerly Treatment Plant. The plant's National Pollutant Discharge Elimination System (NPDES) Permit has thirty day limits of 15 milligrams/liter (mg/l) carbonaceous biochemical oxygen demand, 20 mg/l suspended solids and 1.0 mg/l total phosphorus in the effluent.

Process Flow Scheme

The flow enters the plant, as show in Figure 1, through one of three interceptors-Collingwood, Heights-Hilltop or Easterly. When the flow is within the design criteria it receives preliminary treatment consisting of screening, grit removal and comminution. Flow is then measured and given primary treatment. After primary treatment, the flow goes into the activated sludge process in the step feed mode. From the final clarifiers the effluent is disinfected with sodium hypochlorite and dechlorinated with sodium bisulfite. The water elevation in the final clarifiers is lower than the present lake level; therefore, the effluent is pumped by screw pumps up to the lake level.

Wet Weather Flow

In wet weather, when the total plant flow is less than 330 MGD the Collingwood pumps lift all flows less than 100 MGD into the plant and the Heights-Hilltop and Easterly interceptors will flow by gravity into the plant.

When the total plant flow exceeds 330 MGD and the Collingwood flow is greater than 100 MGD the excess flow in the Collingwood interceptor overflows a fixed weir and automatically bypasses the treatment process. This plant receives approximately 0.250 MGD of water plant sludges. When the plant flow is near the bypass level, the wastewater plant has an automatic telephone dialer that sends a call to the water plant and informs them of the impending bypass. The water plants take the necessary action to shutdown their sludge pumping operation.

When the total plant flow exceeds 330 MGD and the Collingwood flow is less than 100 MGD the flow in the Collingwood interceptor is throttled. This is done by shutting down the Collingwood pumps to allow an overflow of the fixed weir and automatically bypass the treatment process. Again, when this occurs, the wastewater plant's automatic telephone dialer sends a call to the water plant and informs them of the impending bypass. The water plants take the necessary action to shutdown their sludge pumping operation.

The wet weather-operating scheme for this plant is to accept the more concentrated sanitary flows and to allow the more dilute sewage to be bypassed. Therefore, the plant will allow the flow from the Collingwood Interceptor to overflow first and then bypass from the Easterly Interceptor. As a last resort, if the flow from the Heights-Hilltop Interceptor exceeds the 330-MGD it will be allowed to bypass.

SOUTHERLY WASTEWATER TREATMENT PLANT

The Southerly Treatment Plant is a conventional two-stage activated sludge plant with a design dry weather flow of 200 MGD and a wet weather flow of 735 MGD. The plant's National Pollutant Discharge Elimination System Permit (NPDES) has thirty day limits of 16 milligrams/liter (mg/l) carbonaceous biochemical oxygen demand, 16 mg/l suspended solids and 1.0 mg/l total phosphorus in the effluent.

Process Flow Scheme

As shown in Figure 2, the flow enters the plant through one of five interceptors-Big Creek, Mill Creek, Cuyahoga Valley, Southwest or Southerly. In addition, sludge from the Easterly treatment plant is pumped into the influent of Southerly. When the flow is within the design criteria it receives preliminary treatment consisting of screening, grit removal. Flow is then measured and given primary treatment. After primary treatment the flow goes into the first-stage activated sludge process currently operated in the step-feed mode. After the first-stage treatment the flow is pumped to the second-stage activated sludge process for nitrogen removal. From the final clarifiers the effluent flows through gravity sand filters. It is then disinfected with sodium hypochlorite and dechlorinated with sodium bisulfite. The plant discharges its treated effluent by gravity to the Cuyahoga River.

Solids handling consists of primary sludge cyclone degritting, gravity thickeners and gravity belt thickeners. A medium-pressure thermal conditioning process to prepare the sludge for dewatering. Centrifuges and vacuum filters dewater the thermally conditioned sludge and incinerators to reduce the volume of sludge. Since the plant receives sludge from the Easterly treatment plant, it must process about twice the amount of sludge that a plant with the same flow would process.

Wet Weather Flow

In wet weather, when the flow to Southerly is less than 175 MGD, the total plant flow will receive preliminary, primary, first-stage, second-stage treatment and filtration. The full flow is disinfected with sodium hypochlorite, dechlorinated with sodium bisulfite, and discharged to the river.

When the flow exceeds 175 MGD, but is less that 400 MGD, the flow receives preliminary and primary treatment. Only 175 MGD of this flow receives first-stage treatment. However, the full flow up to 400 MGD goes to the second-stage and receives secondary treatment. The flow up to 400 MGD can be filtered. The full flow is disinfected with sodium hypochlorite, dechlorinated with sodium bisulfite, and discharged to the river.

When the flow exceeds 400 MGD, but is less than 735 MGD, the flow receives preliminary and primary treatment. The flow exceeding 400 MGD, up to 335 MGD, will receive this degree of treatment. Of the remaining flow, only 175 MGD of this flow receives first-stage treatment. However, the full flow of 400 MGD goes to the second-stage and receives secondary treatment. The flow up to 400 MGD can be filtered. The 400-MGD flow is disinfected with sodium hypochlorite, dechlorinated with sodium bisulfite, and discharged to the river. The portion of the flow above the 400-MGD is discharged to the river.

The wet weather operating scheme for this plant is to provide maximum treatment to the concentrated sanitary flows and reduce the amount of treatment when the flows becomes diluted with rain water. All available tankage in the primary and secondary is used for storm flow retention or flow through.

WESTERLY WASTEWATER TREATMENT PLANT

The Westerly Treatment Plant is a trickling filter/solids contact (TF/SC) biological process plant with a design dry weather flow of 33 MGD and a wet weather flow of 100 MGD. The plant's National Pollutant Discharge Elimination System Permit (NPDES) has thirty day limits of 15 milligrams/liter (mg/l) carbonaceous biochemical oxygen demand, 20 mg/l suspended solids and 1.0 mg/l total phosphorus in the effluent.

Process Flow Scheme

The flow enters the plant through one of two interceptors-Westerly and Northwest. Flows within the design criteria receive preliminary treatment consisting of screening, grit removal and comminution, as shown in Figure 3. Flow is then measured and given primary treatment. After primary treatment, the flow pumped up to one of three trickling filters. Then the flow goes to through the solids contact tanks and to the final clarifiers. From the final clarifiers the effluent is disinfected with sodium hypochlorite, dechlorinated with sodium bisulfite, and discharged into Lake Erie.

The plant processes all biosolids collected from the wastewater. The plant uses gravity thickeners to thicken the solids. The plants centrifuges dewater the solids for the incineration process or in an emergency to transport the solids to an approved landfill.

Wet Weather Flow

In wet weather, when the flow to Westerly is less than 70 MGD the flow receives preliminary, primary and secondary treatment. The full flow is disinfected with sodium hypochlorite, dechlorinated with sodium bisulfite, and discharged to the lake.

When the flow exceeds 70 MGD, but is less that 100 MGD, the flow receives preliminary and primary treatment. Only 70 MGD of this flow receives full secondary treatment. The remainder of the flow up to 100-MGD flows to blend with the secondary treated flow. The full flow is disinfected with sodium hypochlorite, dechlorinated with sodium bisulfite, and discharged to the lake.

When the flow exceeds 100 MGD, but is less than 400 MGD, the flow up to 70 MGD receives preliminary, primary and secondary treatment. The plant will control the flow into the treatment facility by valves in the headworks so that the plant treats 100 MGD. The flow exceeding 100 MGD, up to 300 MGD, will receive preliminary and primary treatment utilizing the Combined Sewer Overflow Treatment Facility (CSOTF). The CSOTF is old Imhoff tanks converted to primary settling tanks with sludge withdrawal provisions. Only the treatment plant flow of 100 MGD is disinfected with sodium hypochlorite, dechlorinated with sodium bisulfite, and discharged to the lake. The portion of the flow above the 100-MGD is also discharged to the lake.

When the flow exceeds 400 MGD, but is less than 1,800 MGD, only 70 MGD of the flow receives preliminary, primary and secondary treatment. Again, the plant controls the flow into the treatment facility by valves in the headworks so that the plant provides preliminary and primary treatment to 100 MGD. The flow exceeding 100 MGD, up to 1,800 MGD, will utilize the Combined Sewer Overflow Treatment Facility (CSOTF). Flows above 300 MGD are bypassed through the center channel to avoid tank flooding. As an added precaution, gates in the CSOTF pump building will also open to protect the catenary bar screens in conjunction with and effluent sluice gates on the influent center channel also open to regulate the flow. At this point, the plant is receiving higher flow rates than can be treated and the system bypasses the process. Only the treatment plant flow of 100 MGD is disinfected with sodium hypochlorite, dechlorinated with sodium bisulfite, and discharged to the lake. The portion of the flow above the 100-MGD is also discharged to the lake.

The wet weather operating scheme for this plant is to provide maximum treatment to the concentrated sanitary flows and reduce the amount of treatment when the flows becomes highly diluted with rain water.

CONCLUSIONS

During wet weather, the three plants are operated to take advantage of all available tankage in the primary and secondary process stream to be used for storm flow retention or flow through. This is evident in the peak wet weather event of February 27, 1997. The design wet weather capacity of the three plants is 1,365 MGD. Table 1 shows the flows handled by each plant on Thursday, February 27, 1997, when heavy rains and snow melt run-off taxed each plant to near capacity. The result was that 86 percent of the total capacity was utilized.

PLANT	FLOW	WW CAPACITY	% of CAPACITY
Easterly -	240 MGD	330 MGD	73%
Southerly -	709 MGD	735 MGD	96%
Westerly -	60.3 MGD	100 MGD	60%
CSOTF -	338.6 MGD	300 MGD	113%
Total =	**1,347.9 MGD**	**1,365 MGD**	**86%**

Advances in Urban Wet Weather Pollution Reduction -- Cleveland 1998 Conference
The Northeast Ohio Regional Sewer District Wet Weather Programs
Session 4 (9:00 am - 12:00 pm)

Daniel M. Hudson
Manager of Systems Operation and Maintenance

In-line Storage of Wet Weather by Real-Time Control (9:30 am - 9:45 am)

Early on the Northeast Ohio Regional Sewer District (District) recognized the need for combined sewer overflow abatement. As early as 1972 the District constructed in-line storage devices that regulated the flow through three combined sewer regulators. The system included twelve rain gauges and twelve sewer level gauges. Monitoring and control was performed with a centrally located minicomputer. Control algorithms were calculated with one central computer and transmitted over dedicated data lines for remote control. The reliability of this system depended on the telephone lines, power service, and computer trustworthiness. By 1990, the District constructed 29 automated regulator, 25 rain gauges, 37 remote level monitors, and 50 remote flow monitors. Majority of the equipment was designed for distributed control with programmable logic controllers (PLC). Personal computers distribute information on a local area network (LAN) through a Supervisory Control and Data Acquisition (SCADA) system. Collection system information, such as wet weather flows, rain intensities, and systems levels, are delivered to the treatment plants in real-time. Plant operators make process control decisions based upon the sewer system data.

Each automated regulator has been constructed at an existing overflow regulator chamber or at a newly constructed chamber that was created by consolidation of several regulators. At each site a hydraulically operated knife gate, plug valve, or in-sewer timber gate controls the amount of flow in the dry weather pipe. Where possible, the size of the dry weather outlet pipe was increased to allow greater flow to be delivered to the interceptor. Fixed weirs were replaced with either an inflatable dam or a hydraulically operated bascule gate. Sewer levels upstream and downstream of the automated regulator are measured with bubbler level sensors. At some automated regulators, interceptor levels remote to the site are telemetered to the local controller. All control equipment is typically contained in a prefabricated underground control vault. The vaults contain support equipment for the automated regulators, including level and flow sensing systems, hydraulic systems, pneumatic systems, motor control panels, uninterruptibal power supplies, and a programmable logic controller.

During the design and construction of the real time control system, consideration was given to controlling the largest amount of combined sewage with the smallest number of automated regulators. The 29 automated regulators eliminated approximately 80 fixed weir regulators. Pipes were constructed that collect water from several regulators and direct the flow to one point where flow could be controlled and storage in the system. The 29 automated regulators control nearly one-quarter of the total flow from the 500 regulators in the Cleveland area. This is equivalent to preventing about 2 MGD of flow from entering the environment untreated every day.

The District's experiences in real time operation and maintenance of a CSO facility are not unusual when compared to other organization with similar systems. Problems with inflatable dams started with the original construction over 20 years ago. Most problems stemmed from the original design and construction. The failure rate of the dams is currently approaching 50 percent total. The majority of the problems with the dam revolves around substandard design and installation. Most of the dams are manufactured with seams. Seam separation is the most common failure mode. Incomplete vulcanization from the original manufacturing process appears to be the major factor for seam separation. The original anchor design was a complicated system of rods, anchors and fabric. Improper installation of anchor bolts and placement of the fabric under the clamping rods has also led to some of the dam failures.

The District has currently replaced six of the original seam-type dams with a seamless design. The new design has proven to be reliable. The seamless dams have been in-service for about five years with no failures. The anchors for the seamless dams are a simple clamp that is mounted to the sewer walls by anchors imbedded in epoxy adhesive.

The annual operating and maintenance cost for each automated regulator annual cost is about $11,000. This includes all of the labor and material expenses required for preventive and breakdown maintenance. Capital cost and the original design and construction cost are not included. Each rain gauge costs about $2,600 per year to operate and maintain. The flow and level monitors cost about $3,000 each per year.

Less then one percent of the total capital expenditures for the District was used for the construction of the in-line storage system. Even with such small capital expenditures, in-line storage of CSO's has proven important in the reduction of overflows and resultant pollution loads to Lake Erie. Experiences at the District have shown that with intelligent design and construction, deliberate management, and maintenance, in-line storage can be environmentally effective and cost efficient.

COMBINED SEWER SYSTEM BEST MANAGEMENT PRACTICES

Robert Gow, Northeast Ohio Regional Sewer District

The Northeast Ohio Regional Sewer District's (District) Wastewater collection System is as diverse as the people who populate the District's two-hundred ninety-five (295) square mile service area.

The District currently owns and/maintains two-hundred and seven (207) miles of intercepting sewers. These interceptors are located primarily within the boundaries of Cuyahoga County. One-hundred fifty-two (152) miles of these sewers are greater than forty-eight (48) inches in diameter, many of which were constructed in deep tunnels. The remaining fifty-five (55) miles of sewers are less than forty-eight (48) inches in diameter and were primarily open trench construction. One-hundred and two (102) miles of interceptors are less than thirty (30) years old and fabricated with reinforced concrete pipe. Brick sewers comprise the remaining one-hundred and five (105) miles of interceptors. These brick sewers range from fifty (50) to over one-hundred (100) years old. The average manhole depth of the old existing interceptors is twenty (20) feet. Whereas, some of the new deep tunnel interceptors exceed two-hundred (200) feet in depth.

The District also maintains four-hundred sixty-seven (467) Combined Sewer Overflows throughout Greater Cleveland. These are the fixed weir-type regulators of which there are four (4) styles in the Cleveland area:

- Perpendicular Weir
- Side Channel Weir
- Leaping Weir
- Relief Pipe

The leaping weir regulator is uncommon throughout the United States and seems to be unique to Cleveland. Historical data also reveals an increased susceptibility for maintenance problems at this type of regulator.

In addition to interceptors and regulators, the District assumes maintenance responsibility for nineteen (19) bar racks, twenty-eight (28) drop pipes, one-hundred twenty-five (125) permitted outfalls, twenty-four (24) miles of storm water outlets from regulators, and other sewer related appurtenances.

The District differs from other sewer authorities in the United States. Unlike other agencies, the District does not maintain the small local sewers. Each community maintains their own sewer system or has entered into a maintenance agreement with the Cuyahoga County Sanitary Engineers.

Inspection and maintenance of the District's Collection System is the responsibility of the Sewer Maintenance and Repair Section. This group includes eight (8) Field Technician Operators, who normally operate the sewer cleaning and inspection equipment, and routinely function as crew leaders also. The operators are supported by sixteen (16) Field Technicians who aide with equipment set-up, traffic control, and assist with actual cleaning and inspection activities. Two (2) supervisors and a manager complement the group. An additional supervisor is slated for later in 1998 (see Table 1).

The Sewer Maintenance Department employs a variety of equipment and vehicles. The following is a list of inspection and cleaning equipment routinely used by the group:

- Three (3) Combination Machines (Jet Vacs)
- One (1) Jet Truck
- Two (2) C.C.T.V. Trucks
- One (1) Easement Machine
- One (1) Manlift System
- Twelve (12) Inspection/Companion Vehicles
- One (1) Set Bucket Machines
- Miscellaneous gas/electric/air/hydraulic power tools

The Sewer Maintenance and Repair Section's goals and priorities are to maintain an unrestricted flow of wastewater to the District's Wastewater Treatment Plants, and to ensure against any dry weather discharges to the environment. These tasks are accomplished through the implementation of an aggressive inspection and maintenance program by skilled and dedicated District personnel.

Regulator maintenance is a priority item at the District. The four-hundred sixty-seven (467) regulators have been compiled into a set of inspection route books based on drainage area, eight by receiving waters or interceptors. The regulators are inspected at least twice per month. Regulators that exhibit a history of maintenance problems have been collected into a set of four (4) trouble-spot route books and are inspected weekly. A routine inspection crew consists of two (2) or three (3) technicians, depending upon the route book being inspected. Normally, three (3) inspection crews are in the field on a daily basis. To further enhance our inspection/maintenance program, a straight jet truck with a two (2) man crew inspects troublesome regulators on a daily basis. Preventive maintenance is performed at each site as necessary.

During the course of the work day, should an inspection crew encounter a blocked regulator, it is immediately reported to a Sewer Maintenance supervisor via two-way radio. The supervisor will then dispatch a jet vac to the site to relieve the blockage. This process has dramatically reduced response time to clean a blocked regulator. Anytime a blocked regulator is discovered by District personnel, the Ohio Environmental Protection Agency is also notified of the dry weather upset condition via fax. A status report follows when the regulator has been cleaned.

During 1997, District personnel inspected sixteen-thousand one-hundred and ninety-eight (16,198) fixed weir regulators (see Table 2). Total and partial blockages were removed at one-thousand six-hundred and forty-nine (1,649) sites (see Table 2). This intensive inspection/maintenance program reduced the number of chronic regulators, those that are blocked more than three (3) times per year, to four (4) (see Table 2). Further, the number of inspections it requires to locate a blockage increased to 265, compared to 87 in 1992 (see Table 2). Response time, the actual time to relieve a blocked regulator from the time it was reported to supervision, has been reduced to a little over an hour. Only a few years ago, a twenty-four (24) hour turnaround was the norm.

Looking to the future, the District will continue to pursue its goal to reduce dry weather overflows by incorporating new technology into the daily routine of sewer maintenance operations. Bar codes, commonly used in grocery/department stores, are now being used by District Sewer Maintenance personnel to inspect regulators. The District initiated a pilot program in early 1998 by which seventy-one (71) regulators are being inspected with the use of bar codes. The bar code system eliminates handwritten inspection/maintenance reports currently being used by the field crews. Bar code readers are downloaded into a computer at the end of each work day. The computer, in turn, logs each inspection and generates an inspection and maintenance report. Thus, increasing the number of yearly regulator inspections.

By years' end, the maintenance department intends to inspect the remaining regulators with the bar code system. Eventually, this program will be expanded to include bar racks, drop pipes and other general sewer maintenance activities.

FIXED WEIR REGULATOR STATISTICS

1. Total Number of Inspections
   1992: 10,867
   1993: 14,270
   1994: 14,359
   1995: 17,686
   1996: 19,723
   1997: 16,189

2. Total Number of Preventive Maintenance Activities
   1992: 1698
   1993: 1804
   1994: 2480
   1995: 2103
   1996: 2205
   1997: 1649

3. Number of Inspections to identify a Dry Weather Overflow
   1992: 87
   1993: 134
   1994: 138
   1995: 230
   1996: 238
   1997: 265

4. Time to Unblock a Regulator
   1993: Approximately 24 hours
   1994: 40% in 24 hrs; 60% less than 2 hours
   1995: 83% in 2 hours
   1996: 87% less than 2 hours; none exceeds 24 hours.
   1997: 1.32 hours

RICHARD J. SWITALSKI

NORTHEAST OHIO REGIONAL SEWER DISTRICT
3826 Euclid Avenue
Cleveland, OH 44115

INTRODUCTION

Like many of the older Metropolitan areas in the country, the wastewater collection system for Greater Cleveland is comprised of both separate sanitary sewers and combined sewers. A master sanitary interceptor plan was initiated in 1966 to minimize pollutant overflows into Lake Erie and tributary streams.

One of the primary goals of the master plan was to intercept separate sanitary sewer flow for priority treatment at the wastewater treatment plants, thereby:

- Reducing separate sanitary overflow (SSOs) into environmentally sensitive urban streams and lakes.
- Reducing flows to the combined sewer areas thereby reducing the volume and frequency of combined sewer overflows (CSOs).

Two interceptor systems were eventually designed and constructed as a result of the master plan. They are the Southwest Interceptor and the Heights/Hilltop Interceptor. Together these two projects consist of 50 miles of interceptor sewers which service over 500,000 people at a cost of $242 million. The first part of this paper will focus on one segment of the aforementioned interceptors, Hilltop Interceptor Contract G, from design through construction.

DESIGN

The design of the Contract G was based on a five year, one hour storm event. Initial design concepts included the consideration of a new surface storage facility consisting of a concrete lined detention tank. However, the concept of a storage-conveyance tunnel proved to be more economical. However, due to the depth of the tunnel, it is feasible to construct additional detention tanks next to the interceptor should the need for expansion be identified in future studies.

OVERFLOW STRUCTURE

The concept for the overflow structure was based on characteristics of a typical detention basin's outfall structures used for surface drainage systems:

1. Control outlet discharge rate by an orifice device.
2. Provide an overflow weir to allow for controlled discharge of flows exceeding the design rate.

However, early in the design stage, it was recognized that to design an outlet control device operating under 105 ft. of a hydrostatic head and discharging into the existing tunnel would require hydraulic modeling. An empirical design approach was considered too risky without guaranteed performance results for the $750,000 structure. The critical issue was to assure stable overflow conditions and still provide acceptable flow characteristics in the shaft and the downstream tunnel.

The design was initiated on a system that would detain incoming flows in the tunnel by controlling the outlet rate through a small diameter pipe (the throttle pipe) at the overflow structure. When the incoming flows exceed the outlet discharge, the water level continues to rise, utilizing the tunnel as a detention tank, until the outlet rate exceeds the inflow rate, at which time the storage in the tunnel is depleted.

From the flow monitoring data which was incorporated into the SWMM program, a hydrograph of the design storm was developed to calculate the size, depth and profile of the tunnel, length and size of the throttle pipe and the volume of the desired storage capacity. Once the system was sized, the data, along with conceptual construction details were sent to the Iowa Institute of Hydraulic Research (IIHR) for modeling. As a result of the IIHR modeling, a smaller diameter throttle pipe was incorporated into the system to decrease its length. A reducer was added to the end of the throttle pipe, in the opposite direction of the flow, with a short larger diameter pipe at the terminus of the throttle pipe to reduce the existing flow velocities.

The IIHR also studied the shape and width of the overflow weir to produce stable flow conditions in the event that the design storm runoff rate is exceeded or the throttle pipe becomes clogged. The modeling concluded that during the worse case conditions, about 4 ft. of flow would over top the weir within the overflow structure shaft. The study also concluded that baffles to control the existing velocities were not needed. The findings from the IIHR modeling were incorporated to finalize the geometry of the full scale structure.

CONTRACT G SYSTEM

When the design of the interceptor was completed, the Contract G system comprised of approximately 11,750 ft. of 132 in diameter storage conveyance tunnel at a slope of 1.00% with 174 ft. of 33 in. diameter throttle piping with reducer and 10 ft. of 36 in. diameter outlet pipe. The system has a peak discharge rate of 145 mgd. (reduced from 285 mgd.) and a storage capacity of 6.5 million gal. The discharge from the throttle pipes and the overflow weir is directly into a downstream tunnel completed under previous contracts. Three access shafts, one deaeration chamber, two work shafts, drop pipe and access adit complete the Contract G system.

ACCESS AND WORK SHAFTS

The NEORSD Maintenance Department has a preference that for large diameter interceptors, the spacing between the access shafts or manholes should not exceed 3,000 ft. This distance is set by the safety equipment reach capacity, such as winches, cables and emergency breathing air packs. Also, at this spacing, ventilation of the system can be accomplished in reasonable time prior to the entry of personnel into the tunnel.

This spacing requirement, at times, positions an access shaft in an area where available land is limited, not available or the surface access shaft covers are in the street and/or roadway with heavy traffic. This was the case on the Contract G requiring the designers to utilize an offset access shaft arrangement. In addition, maintenance access to the tunnel is provided by the NEORSD through the use of a Maintenance Trailer operating from the surface. The trailer has a man-cage which allows personnel to be lowered and picked up directly form the shaft inverts (at tunnel level) and allows for air testing equipment to be lowered to the tunnel level prior to the entry of personnel. The cage can also be used to lower air testing monitors any other safety or support equipment.

CONSTRUCTION

The final bid package consisted of detailed design for shafts and tunnel (final and initial excavation supports), shaft sites, site restorations, details, geotechnical report and other information necessary to complete the package. The contract was bid on in November of 1990 with KM&M, Joint Venture as the successful contractor. The low bid amount was $16,084,517.00.

Shaft excavation utilized a vertical boring machine (VBM) and drill and blast methods. The VBM was developed by the Kassouf Company of Cleveland, Ohio based on designs used in previous NEORSD projects. The machine was capable of excavating downward into the shales and other soft rocks. The two stage cutter head moved rock cuttings toward the center, where they were lifted by a vertical auger to a skip for hoisting to the surface. As the machine excavates downward, the shaft's initial supports were installed from the VBM's platform.

R0024878

The tunnel boring machine (TBM) selected was built by Lovat Tunnel Equipment, Inc. and came equipped with drag cutters and a rear thrust ring requiring ribs and lagging as thrust reaction. The excavation of the main tunnel started on September 6, 1991 and was completed on February 11, 1992. This resulted in a total of 158 calendar mining days (or 162 mining shifts). The following is the summary of the TBM mining record for the project:

Average feet per shift (beginning 9/6/91)		71.60
Average sets of ribs and lagging installed per shaft		17.30
Total footage mined		11,671.96
Total calendar days		158
Total mining shifts		163
Highest footage mined - one shift	11/11/91 (1st shift)	115.70
Highest footage mined - one work day	12/20/91	223.50
Highest footage mined - one work week	12/02/91 thru 12/06/91	931.60

The adits for the access shaft and the deaeration chamber were excavated by a smaller TBM without any trailing gear to avoid drilling and blasting. After the excavation, reinforcing steel was placed in the adits and dearation chamber, followed by the placement of concrete.

The final lining in the tunnel was cast utilizing a 210 ft long form. The average daily placement was 180 ft utilizing with 300 cy. of concrete. The placement started at the upper limit of the tunnel profile. Cleaning of the invert, reinforcement placement and rail removal was performed ahead of the concreting operation. Forms were stripped when concrete lining reached 1,000 psi. After the concrete reached its full strength, contact grouted was employed in the crown area.

For the overflow structure, shaft, and outfall sections of the tunnel (throttle pipe), the final lining concrete mixture contained microsillica. The microsilica additive produced concrete with an average strength of 7,500 psi that was of a higher density and resistant to abrasion.

The throttle pipe consisted of DIP piping, anchored down with reinforcing steel to the final lining and was completely encased in concrete.

CONCLUSIONS

The Contract G proved to be a very successful tunnel project. The geotechnical conditions and initial support type requirements were predicted during the design stage. The construction on the project was authorized to proceed on January 9, 1991 with the completion deadline of June 22, 1993. The actual completion was on December 1, 1993. The delay resulted from a change order requiring the Contractor to dispose of the rock muck saturated with natural oil in the same manner as hazardous waste. The muck was tested and the disposal locations were documented.

The original bid price was $16,084,517. The final cost of the project was $16,225,741. Total extra work on the contract amounted to $905,039 and the total deductions were $763,814, this resulted in a net increase to the contract bid price of 0.88 percent.

BIOFILTERS

INTRODUCTION

Initial flow into portions of the HHI and the SWI began in 1991. When these minor (10 percent of design) flows were diverted into the tunnels several years ago, the District immediately began to receive odor complaints. At first, the problems were relatively minor and were attributed to low flow conditions. District personnel corked certain manhole lids to alleviate local odor problems and the odor complaint issue was considered solved. However, during the summer of 1995, when more flow was introduced into the upstream portion of the system, odors became much more prominent and widespread.

When it was recognized that the odor problems were a direct result of increased flow and that the problem could not be solved by corking manhole lids, the District immediately moved forward to investigate the problem and find a solution. The goal of the investigation was to understand the cause and extent of the tunnel odor release problem, evaluate alternatives to solve the problem, select the appropriate technology and retrofit the system with the most reliable odor control facility possible. Because the probable locations of any odor control facilities would be remote sites in the collection system, the District recognized that one of the most important aspects of the selected treatment system would be operation with minimal operator intervention.

INVESTIGATION

The investigation found that both the HHI and SWI tunnel systems were being pressurized by the eduction of air through the drop shafts. The amount of air educted varied with the quantity of wastewater being dropped and the size and shape of the drop structure. When the wastewater flow down the drop pipe is low, surface tension holds most of the water against the wall of the pipe creating a large central air core . Little air is educted in this case. In fact, if the pressure in the tunnel is high enough, air will overcome the force of the downward draft in the vortex pipe and vent to the atmosphere through the large central air core. However, as the wastewater flow down the vortex shaft increases, friction increases, the central air core becomes smaller and the educted air pressure overrides the pressure in the tunnel. Therefore, as the wastewater flow down the vortex shaft increases, the amount of air being educted also increases.

The surface tension of water is another reason why increased wastewater flow down the vortex shafts causes greater air eduction forces. Under low flow, most of the wastewater falling down a vortex hugs the wall of the pipe. This is the effect of the surface tension of water. The wetted surface of the pipe acts as an anchor and the surface tension between the individual molecules of water act to keep the water from shearing and forming individual droplets.

As the volume of wastewater increases, surface tension forces are not strong enough to hold the water against the surface of the pipe and shear distorts the water surface in the form of wave fronts which travel down the pipe. This wave is the first indication that shear forces, induced by gravity, are overcoming the surface tension because the wave front travels faster down the pipe than the water next to the pipe wall.

When the flow down the vortex pipe becomes large, surface tension forces are only exerted for a short distance from the pipe wall and the rest of the water is in full hydraulic shear. As the droplets shear from the wall they fall like "rain" down whatever may remain of the central air core causing increased surface area upon which friction with the air can act. Under this condition maximum air is being educted down the vortex pipe.

EVALUATION OF ODOR CONTROL ALTERNATIVES

All feasible alternatives were considered for odor treatment or control on the HHI and SWI deep tunnel collection systems. The final recommendation was to employ biofilters.

Biofilters are a type of odor control system that adsorbs/absorbs and oxidizes odorous compounds using microorganisms growing in a soil or compost substrate. Biofilters are successful in treating hydrogen sulfide, ammonia, organic odors and volatile organic compounds from municipal wastewater treatment plants and pump stations, composting facilities, rendering plants, and other solids processing facilities. Odors are absorbed into a thin water film surrounding the substrate particles and also adsorbed directly on to the particles. The sorbed compounds are then metabolized by bacteria and converted to sulfite or sulfate, carbon dioxide, ammonia and water. This oxidation step frees the sorptive sites for additional odorous compounds, thereby continuously regenerating the biofilter.

Biofilters have been used to treat hydrogen sulfide in wastewater collection and treatment systems in the United States since 1959. Their increasing popularity is due to the simplicity of the system, lack of intensive mechanical equipment, and the use of no treatment chemicals. Biofilters have gained acceptance in recent years with more research and full-scale operating experience. The major components of a biofilter system include a fan for transfer of odorous air to the biofilter, a distribution system consisting of a header/lateral piping network and distribution plenum, and the substrate. Usually, biofilters also require an irrigation system and a humidifying system to maintain moisture content of the substrate.

Influent air must be evenly distributed across the entire area of the biofilter for optimal treatment. Failure to achieve uniform distribution may result in localized channeling through the substrate, unequal contaminant loading, odor breakthrough, and development of high headloss with a corresponding drop in airflow. The most basic and commonly used distribution system consists of PVC headers with perforated laterals in a silica stone gravel bed. Some installations have used manufactured blocks to achieve uniform distribution, however, these systems are proprietary and not commonly used.

The biofilters will be conservatively sized using a loading rate of 3 to 4 cfm/sf and a headloss of 6 inches. The depth of the biofilter will be 3 ft and will consist of yard and sludge compost and shredded bark. The treatment bed will be about 85 feet long and 25 feet wide. Maintenance costs will include periodic replacement of the substrate. Capital and O&M will be relatively low, approximately $0.6 million, for one biofilter. Six biofilters are the projected need for the HHI and 5 biofilters on the SWI.

BRICK MASONRY SEWER REHABILITATION USING SLIP LINE METHOD

RODNEY J. DELL'ANDREA, P.E.

THE NORTHEAST OHIO REGIONAL SEWER DISTRICT, CLEVELAND, OH

ABSTRACT

Slip lining circular brick sewers involves inserting a slightly smaller pipe section inside the existing sewer. The annular space left between the new liner pipe and the host sewer is filled with grout. Lateral and side sewer connections generally must be excavated and reconnected to the new liner from the exterior of the existing sewer. The method is most practical for sewers of circular cross section in reaches where there are few existing lateral connections. Slip lining can maintain the structural integrity of the existing brick sewer and improve the hydraulic capacity of the sewer even though the finished diameter has been reduced.

INTRODUCTION

All sewer collection systems require constant maintenance. With time, all structures deteriorate, and circular brick masonry sewers are no exception. The objective of all sewer rehabilitation is to maintain the viability of the conveyance conduit and this is accomplished by (1) ensuring its structural capability, (2) reducing infiltration and inflow (I/I), and (3) controlling exfiltration. The selected rehabilitation method will depend on the rehabilitation objectives and a cost vs. benefits analysis. Most structural rehabilitation methods provide for a reduction in rates of I/I, however, most infiltration control rehabilitation measures have very little impact on enhancing structural integrity. A proper and thorough evaluation of sewer defects is paramount in determining the appropriateness of a given repair method. The selected rehabilitation measure should be chosen for its ability to best correct the cited defects.

CRITERIA FOR REHABILITATION

The structural integrity of a circular brick masonry sewer relies on the support of the surrounding soil. Regardless of its cross section, the crown of a brick masonry sewer is a semicircular arch. This arch behaves as a compression ring supporting vertical loading from above and the lateral loading of the backfill soils at the sides of the sewer. If voids in the backfill material develop near the sewer's springline, lateral support is lost and the sides of the arch can move outward under the weight of the soils above the crown. Void development is associated with soil displacement due to groundwater. Fine granular backfills can be "piped" inside the sewer through cracks, open mortar joints, or poorly made lateral connections. This mechanism will cause the crown to flatten and crack. When vertical deflections of the crown develop and achieve at least a 10% reduction in height, the sewer is considered to be at risk of structural failure. Mortar loss through erosion or sulfite attack from sewer atmospheres can result in displaced or missing bricks which can eventually lead to collapse. Infiltration problems can develop into mineral deposits, deposition of debris in the invert, dropped inverts, and loss of hydraulic capacity. Invert debris can alter flow velocities causing excessive wearing of the invert surface. Cracks, fractures, and holes can allow the undesirable development of exfiltration of sanitary flows to the environment.

THE WESTERLY INTERCEPTOR: A CASE HISTORY

The advance of time has not been kind to the old brick masonry combined sewer known as the Westerly Interceptor owned by the Northeast Ohio Regional Sewer District. The age of the sewer is estimated to be approximately 80 to 100 years old. Several existing conditions, such as periodic surcharging and the proximity of its alignment to a heavily used rail line , have lead to advancing its deteriorated condition beyond its years. In August of 1994, after an unusually heavy rainfall event, a twenty foot long section of 87-inch diameter sewer collapsed forcing emergency cast-in-place concrete repairs totaling upwards of two hundred thousand dollars.

In September of 1995, the District once again paid a contractor to mobilize on an emergency basis to replace a 150 foot long reach of 90-inch brick sewer with reinforced concrete pipe of similar size. This effort resulted in costs totaling more than six hundred thousand dollars. While replacement of damaged or severely deteriorated sewer sections is totally effective in meeting the objectives of sewer rehabilitation, the cost of performing work utilizing replacement methods is staggering. The District's recent experiences with the Westerly Interceptor focused its attention on adopting a preventive maintenance approach. Consultants were hired to study and assess the structural condition of the Westerly Interceptor. The reach of sewer to be evaluated is approximately a 4,000 foot long section located along and parallel to the Conrail railroad tracks beginning at Lake Avenue and continuing in a northeasterly direction to W. 65th Street and Father Caruso Drive on the near west side of the City of Cleveland. Its size ranges from five foot in diameter at the western end to eight foot in diameter at the eastern end.

A sewer stability assessment report prepared by Woodward-Clyde Consultants in July of 1995 arrived at several conclusions after observing defects evident in visual inspections performed specifically for the study, and these are listed as follows:

- Inner brick ring mortar matrix has deteriorated to a point that will promote more rapid ring delamination
- Delamination of the crown brick is decreasing sewer cross section
- Brick loss indicates deterioration of middle brick ring
- Structural integrity of the sewer is being compromised as a result of further mortar matrix deterioration

In May of 1997, the consulting engineering firm, Brown & Caldwell , released the findings of their localized geophysical investigation on the same reach of sewer. Seismic resonance testing (SRT) indicated potential areas of void in the backfill soils surrounding the sewer. Identifying areas containing significant amounts of void within the surrounding backfill provides information about confining earth pressures and the ability of the sewer to capably support or resist the stresses imposed by existing service loadings. Their findings and recommendations are listed as follows:

- The proximity of the interceptor to the railroad tracks and the associated high levels of ground vibration increases the potential for soil migration through existing defects in the sewer and the potential for future collapses
- The general area of the sewer in the region of the 1994 collapse should be strengthened using grout piles or other soil grouting techniques
- Cracks, fractures, and deformations in the sewer reach between manhole(MH)65 to MH60 should be corrected and the soil surrounding the sewer in this region should be strengthened with grout
- Brick sewers with cracks, fractures, and other physical defects are under obvious distress and are subject to catastrophic collapse, especially sewers where surcharging can occur
- Rehabilitation of the sewer only (i.e. relining without adding structure) is insufficient in these areas since the surrounding soils lack the required strength to support the brick sewer

Loss of confining soil pressure, surcharging flows and external vibration loadings (due to heavy rail traffic) continue to add to the distress of the Westerly Interceptor. Loss of mortar due to aggressive sewer atmospheres and external groundwater pressures promotes movement and delamination of brick, leading to further loss of arch compressive strength of the crown. Mortar loss is occurring throughout the entire length of the Interceptor study area to varying degrees and is a function of exposure time to acidic sewer atmospheres and groundwater fluctuations.

SELECTION OF SLIP LINING AS THE REHABILITATION MEASURE

If elimination of significant void development in the backfill soils around the outside of the sewer is a primary objective, then lateral support of the crown arch can be maintained, thus preventing the flattening and cracking of the arch due to vertical loading from the weight of soil above the sewer's crown. Another objective in maintaining the strength of the section would be to mitigate surcharge conditions that occur due to wet weather events. This is significant in areas where voids in the backfill have already developed due to piping diminishing the compressive stress developed within the arch. Steadily increasing internal pressures during surcharging can counteract the dead load compressive stress and cause the brick/mortar matrix of the arch to develop tensile stresses which is very undesirable. The reality is that certain storm events will produce some surcharge conditions somewhere within the system. The practical approach to meet the objective of maintaining strength during these events would be to minimize the internal pressures distributed to the brick/mortar matrix by installing a lining capable of supporting these stresses.

The current Westerly/Walworth Interceptor Rehabilitation project designed by Brown & Caldwell specified the use of a glass fiber reinforced thermosetting resin pipe material to be installed as a slip line within a 1,700 lineal foot reach of the Westerly Interceptor along the Conrail easement. The use of slip line pipe satisfied all project objectives by providing the necessary strength (for both external and internal loading), reduction of inflow and infiltrations, and mitigation of exfiltration of sanitary flow to the environment.

CONSTRUCTION PHASE SLIP LINE ACTIVITIES

To gain access to the sewer for slip lining, two access pits had to be excavated along the alignment. Coordination with the railroad was required during the design of the braced cofferdams and their installation. Within the pits, the crown of the sewer required careful removal from springline to springline for approximately a 21 foot length. Approximately 1150 linear feet of slip line pipe was installed by the contractor from the western most access pit by pulling the pipe material into position from each direction. Approximately 550 linear feet of slip line pipe was pulled into position utilizing the access pit at the eastern end of the project. The contractor, following an approved confined space entry and safety plan of his own development, accessed the sewer to assess existing conditions and make field verifications prior to ordering the slip line material for the project. All dry weather flow was diverted to another combined sewer on a parallel alignment and provisions were made to overpump flows from local side sewer connections.

The sewer was prepared for the installation by pressure washing the existing brick interior surface to remove slime, obstructions, and loose debris and also to enhance bond between the brick and the annular space grout to be pumped in behind the slip line pipe at a later stage. The contractor also took the opportunity to conduct the necessary pre-installation checks and verify cross-sectional tolerances. Two lines of light pipe rails were installed in the invert of the existing brick sewer to a tolerance established by the contractor's survey crews. The rail system was established to hold grade and assist in skidding the slip line pipe along the invert as it was pulled into place. Each twenty foot length of slip line pipe was winched into place by a crawler crane using a special pull ring with the cable running through the barrel of the pipe segment pulling the pipe back toward the cable drum of the crane. As pipe sections were pushed home, each piece was blocked with timber at the springline and crown and one intermediate point each side of crown center. The blocking was positioned to extend across the joint between pipe segments. The installed slip line sections were bulkheaded with concrete at manholes prior to grouting. All existing side sewer connections were reconnected from inside the existing Westerly Interceptor.

Slip line pipe does not require extraordinary strength to withstand external pressure from soil and groundwater, due to its structurally efficient circular shape. The condition critical to the design of the liner segment is the effect of the annular space grouting operation. If blocking is not properly placed, and the liner segment is buoyed upward by the grout, a concentrated load will develop along the crown of the segment, distorting the segment out of round. Additionally, the hydrostatic pressure exerted by the grouting procedure is likely to be greater than the hydrostatic pressure from groundwater, and will be acting on the liner pipe segment before the slip line has the circumferential support of the fully set grout. The contractor elected to use a light weight grout so as to minimize the buoyant force on the pipe segments. He also elected to grout in lifts to control the development of uplift forces. Displaced air and water venting, grout pressure monitoring and grout volume monitoring helped to provide for a successful installation. Grout coverage was verified through hammer soundings and discretionary drilling through the liner into the annular space. Patching was performed with fiberglass resin two-part mix.

CONCLUSIONS

The slip line pipe installed on the Districts Westerly Interceptor project was done so under what could be termed very favorable conditions. Costs were kept in line due to readily accessible sites, a minimum number of existing side sewer or lateral reconnections, and fairly straight reaches of sewer alignment. Unit prices bid for the slip lining of 1,142 L.F. of 84-inch and 87-inch diameter brick sewer with 66-inch inside diameter Hobas Pipe and 572 L.F. of 90-inch and 96-inch diameter brick sewer with 77-inch inside diameter Hobas Pipe were approximately $955.00 per L.F. and $1200.00 per L.F. respectively. These prices compared very favorably to open cut total replacement costs which could have approached several thousand dollars per foot of the same alignment due to the additional braced excavation costs required for work on railroad property.

NORTHEAST OHIO REGIONAL SEWER DISTRICT CSO/WATERSHED PLANNING

Frank P. Greenland, P.E.

Northeast Ohio Regional Sewer District, 3826 Euclid Avenue, Cleveland, Ohio 44115

INTRODUCTION

The Northeast Ohio Regional Sewer District (District) service area contains both combined and separate sewered areas. Facilities planning in the separate sewered areas during the early 1980s resulted in a major separate sanitary interceptor construction program which is nearing completion. Essentially, this construction program has removed the separate sanitary sewer area's contribution to the downstream combined sewer area. Although substantial combined sewer overflow (CSO) reductions have occurred from this effort, significant CSO volumes remain uncontrolled.

The combined sewer system in the District's service area covers the majority of the City of Cleveland and a number of suburban communities. The combined sewer area covers approximately 50,000 acres and contains 125 CSOs. Each of the District's three wastewater treatment plants (WWTP), Easterly, Westerly and Southerly, have tributary combined and separate sewered areas. The District has an NPDES Permit for its CSOs which requires the completion of CSO control plans before 2002. To satisfy this permit requirement, the District has chosen to complete its CSO facilities plans in several phases. The following areas are being addressed:

- Mill Creek Watershed
- Westerly CSO District
- Easterly CSO District
- Doan Brook Watershed
- Southerly CSO District

Figure 1 outlines each of these planning areas.

FACILITIES PLANNING TASKS

In conjunction with or during each facilities planning project, the following tasks have been/are being performed:

- **Dry-Weather Outfall Surveys:** Every outfall within each study area is being located and sampled (if flowing) during dry weather. Outfalls showing appreciable bacterial contamination are being investigated for illicit connections.

- **Interceptor Inspection:** All District interceptors are being televised and internally inspected to assess condition, identify rehabilitation/cleaning needs and to verify flow connectivity.

- **WWTP Wet Weather Capacity Evaluation:** The wet weather capabilities of both the Easterly and Westerly WWTPs have been assessed prior to each applicable CSO facilities plan.

- **Community Sewer Flooding:** An assessment of community sewer flooding areas is being performed during CSO facilities planning. Where possible, coordination of community sewer flooding alleviation projects with CSO control projects is being sought.

- **Stream Flooding:** During both the Mill Creek and Doan Brook Watershed Studies, an analysis of stream flooding was incorporated into each project.

- **Macroinvertebrate Sampling:** Macroinvertebrate sampling programs are being performed to gauge the biological health of various receiving streams.

FACILITIES PLANNING AREAS - OVERVIEW

Mill Creek Watershed

In 1996, the District completed the first of its CSO planning projects in the Mill Creek Watershed area. Mill Creek is a small tributary to the Cuyahoga River and is located within the District's Southerly WWTP service area. The Mill Creek Watershed area contains separate, combined and common trench sewers. Twenty-eight (28) CSOs are located within the watershed and basement flooding is a problem throughout much of the watershed. Common trench separate sewer systems across the District's service area are in the over/under, separate manhole or common manhole/dividing wall arrangement, as shown on Figure 2. The common trench sewer system is particularly troublesome, as study results indicated that bacteria levels from the common trench storm sewers were comparable to CSO bacteria levels. Mill Creek currently does not meet Ohio EPA's primary contract recreation standard during dry and wet weather conditions.

A watershed approach was utilized to identify key dry and wet weather impacts in the study area. Key recommendations or findings of the study were:

- Construction of a storage/conveyance tunnel would serve as the backbone of an integrated approach to solve basin-wide issues, such as basement flooding reduction and CSO control.
- Community projects were needed to relieve wet weather sewer flooding problems.
- Elimination of illicit sanitary connections to storm sewers is needed.
- The high level of impervious area within the watershed (30%) appears to be the primary cause for non-attainment of the Creek's biological use designation.

Construction of the 20 foot diameter Mill Creek tunnel is ongoing. Once completed, CSO volume basin-wide will be reduced by over 90%, CSO frequency will be less than 5 CSOs/year at each Mill Creek CSO location and increased capacity (up to a 5-year storm) will be available to convey separate sanitary sewer flows.

Westerly CSO District

The second CSO planning project is currently ongoing in the Westerly CSO District. This planning area covers approximately 10,000 acres on Cleveland's west side, with 75% of the area served by combined sewers. Common trench sewers serve a large part of the remaining 25% of the service area. A number of the common trench sewer manholes have a removable plate in the invert of the storm sewer. This plate is removed to provide access for maintenance of the sanitary sewer which runs parallel to, but below, the storm sewer. Twenty-six (26) CSOs are located across this service area. Previous CSO control efforts in this area included the installation of 8 hydrobrakes and 8 automated regulators (inflatable rubber dams or hydraulic gates) for in-line storage of combined sewage. A storage/conveyance tunnel, known as the Northwest Interceptor, has been in operation since the 1980s. This tunnel stores CSO flows and releases these flows to a combined sewer overflow treatment facility (CSOTF) located adjacent to the District's Westerly WWTP.

CSOs in the Westerly planning area discharge to Lake Erie, Big Creek, Rocky River and the Cuyahoga River. A public swimming beach is located along Lake Erie within the project area. Due to the large size of the drainage areas of these receiving waters (both the Rocky and Cuyahoga Rivers have significant drainage areas outside of the District's service area), the level of detail in "watershed assessment" is not as great as that employed during the Mill Creek project. The Westerly CSO study is scheduled for completion near the end of 1998. Currently, computer modeling and alternative evaluation activities are ongoing. Key findings of the study to date are:

- Rising Lake Erie levels (near all-time records) have caused backflow of the Cuyahoga River into the District's interceptor system. River inflow control facilitates are under design.

- Numerous invert plates in the common trench system were either missing or misaligned. Computer modeling activities will determine the benefits of invert plate correction.

Easterly CSO District

In early 1998, two CSO facilities planning projects were initiated in the District's Easterly WWTP combined sewer area. The first, known as the Easterly District CSO Study, covers the entire Easterly CSO area. This study area covers approximately 15,000 acres of combined sewer service area and contains forty-six (46) CSOs. CSOs discharge to Lake Erie, the Cuyahoga River and numerous smaller urban streams and culverts. A public swimming beach is located along Lake Erie within the project area. Although the construction of the District's Heights/Hilltop Interceptor will reduce system CSO volumes by a projected 500 million gallons annually, significant CSO volumes will remain. As in other CSO planning areas, a mix of combined, separate and common trench sewers exist in the study area. Project completion is scheduled for 2000.

Doan Brook Watershed

Within the overall Easterly CSO Study area boundary lies the Doan Brook Watershed. The Doan Brook Watershed encompasses a total area of approximately 8,000 acres, with 4100 acres served by combined sewers. Sixteen (16) CSOs are located along Doan Brook. The Doan Brook Watershed Study was initiated in early 1998 and is expected to be completed by 2000. In addition to traditional facilities planning tasks, a comprehensive assessment of watershed problems and pollutant sources will be performed. Analysis of stream flooding characteristics will occur, as flooding exists in the lower portion of the Doan Brook Watershed. A U.S. EPA demonstration grant is funding a portion of this watershed project.

Southerly CSO District

The final District CSO facilities planning study is scheduled to begin in 1999 in the Southerly WWTP combined sewer area. This planning area encompasses approximately 17,000 acres of combined sewer area and contains twenty-five (25) CSOs. The Cuyahoga River and Big Creek receive CSO discharges from the Southerly study area, although each of these receiving waters have large upstream tributary areas.

SUMMARY

The development of CSO control facilities plans across the District's combined sewer service area is an ongoing task scheduled for completion in 2002. A total of five separate studies are being performed to complete the District's long-term planning for CSO control. In certain urban watersheds within the District's service area, detailed watershed assessments are being performed. Each facilities plan will result in the identification of recommended CSO control projects (which is the District's responsibility to implement) and recommended community-based projects (to alleviate flooding). Currently, the District does not have direct jurisdiction over separate storm drainage within its service area. Therefore, required projects to alleviate storm flooding or quality (illicit connections) problems are the responsibility of the applicable affected community. A District program known as the Community Discharge Permit Program is used to manage community-based projects. Details regarding this program can be obtained by referring to the discussion provided by Jeffrey E. Duke.

COMMUNITY DISCHARGE PERMIT PROGRAM

Jeffrey E. Duke, P.E.

Northeast Ohio Regional Sewer District, 3826 Euclid Avenue, Cleveland, Ohio 44115

ABSTRACT

The Community Discharge Permit Program was established as a result of grant conditions for the District's Heights-Hilltop (HHI) and Southwest (SWI) Interceptors. The Community Discharge Permit system is applied to communities serviced by separate sewers areas in the District service area. Two important aspects of the Community Discharge Permit Program are the Performance Objectives, which includes the control of separate sanitary sewer overflows (SSOs) and the establishment of peak flow limitations at designated design storms, and the Community Compliance Plan, which includes required Technical Program projects and reporting on community best management practices.

INTRODUCTION

The Northeast Ohio Regional Sewer District (District) received significant grants from the EPA for the construction of the Southwest Interceptor and Heights-Hilltop Interceptor. Conditions of the grant included the adoption of regulations to monitor flows entering the Interceptor sewers, essentially providing protection of the investment of grant funds into the District's interceptor system. In response to these grant conditions, the District developed Title III - Separate Sanitary Sewer Code of its ***Code of Regulations***. Title III provides a procedure by which the District and each member community served by District facilities can cooperate to control SSOs and peak flows from community sewer systems at the point of connection into sewers owned by the District or another community.

COMMUNITY DISCHARGE PERMIT PROGRAM ITEMS

In 1986, the Community Discharge Permit Program was established to implement Title III and issue Permits to communities serviced by separate sewers. Forty-five (45) communities have been issued Community Discharge Permits. The Community Discharge Permits consist of the following attachments:

- Attachment A - General Conditions
    - ⇒ No Improper Connections
    - ⇒ Identify SSOs
    - ⇒ No new SSOs
    - ⇒ Implement sewer maintenance program (Best Management Practices - BMP)
- Attachment B - Performance Objectives
    - ⇒ Control SSOs to the applicable design storm
    - ⇒ Establish Peak Flow Limitations at design storm
- Attachment C - Community Compliance Plan
    - ⇒ Annual Compliance Report Checklist
    - ⇒ Technical Program Projects
- Attachment D - Outline for Best Management Practice (BMP) Fact Sheet
- Attachment E - Approved Community Compliance Plan

TECHNICAL PROGRAM

Communities that have been issued Permits have been divided into two categories: Priority 1 communities and Priority 2 communities. Priority 1 communities are communities that face mandatory expenditures to construct relief sewer or rehabilitation projects need to achieve Performance Objectives as stated within Attachment B of the Community Discharge Permits. Communities are required to meet established Peak Flow Limitations at points of connection into sewers owned by the District or another community and control SSOs to specified design storms. However, previous sewer system evaluation survey (SSES) studies have found that many existing sewer systems lack the necessary capacity to meet the performance objectives. Therefore, the SSES recommended rehabilitation and relief sewer projects necessary for the communities to meet the established peak flow limitations.

The recommended projects are included in the community's Permit Technical Program. Fourteen communities have been identified as Priority 1 communities with required Technical Program projects. A summary of the completion status of the Technical Program Projects is included in Table 1.

Table 1 **Technical Program Project Statistics**

Total Number of Community Projects	91	
SWI Tributary Area Communities	35	
HHI Tributary Area Communities	56	
Total Number of Community Projects Complete	55	(60.5%)
SWI Tributary Area Communities	23	
HHI Tributary Area Communities	32	

SEPARATE SANITARY SEWER OVERFLOWS

The construction of many of the community technical program projects have resulted in the alleviation of many of the SSOs in the member community sewer system. The Technical Program projects include relief sewers which provide needed capacity to convey the wastewater flows, and rehabilitation projects to reduce infiltration and inflow (I/I) in the sewer system, thus freeing capacity to convey wastewater flows. The District has completed the construction of the SWI and is nearing the completion of the HHI, thus providing capacity for the local sewer system improvement projects. The District is also construction a series of intercommunity relief sewers, to assist in the conveyance of intercommunity flow (flow from 2 or more communities) to District interceptors.

As a result of the completion of several projects, both District and community, several SSOs have been alleviated. A summary of the operational status (alleviated or uncontrolled) status of the SSOs is included in Table 2.

Table 2 **Status of Sanitary Sewer Overflows**

Total Number of Sanitary Sewer Overflows in Permits	187
SWI Tributary Area Communities	74
HHI Tributary Area Communities	113
SSO's Alleviated	39% (73 out of 187)
SSO's Uncontrolled	61% (113 out of 187)
SSO's Alleviated in SWI Tributary Area Communities	51
SSO's Alleviated in HHI Tributary Area Communities	22

A breakdown by community of SSOs in the Community Discharge Permits and the number of required Technical Program projects is included in Table 3.

BEST MANAGEMENT PRACTICES

The alleviation of SSOs in community sewer systems has been an ongoing, and sometimes difficult process. Communities perform Best Management Practices (typically sewer inspection and cleaning) to optimize the performance of the sewer system. Attachment D of the Community Discharge Permit contains a fact sheet outline for community Best Management Practices. The communities are required to identify their community BMP programs.

Table 4 contains a summary of information communities are required to provide regarding their Best Management Practices.

Table 4 **Best Management Practices Fact Sheet Outline**

	Section	Topic	Subtopic
A.	Cleaning	Sewers	Frequency Method Employed Additional Information
		Overflows	Frequency Additional Information
B.	Inspection	Sewers	Frequency Additional Information
		Manholes	Frequency Additional Information
C.	Emergency Contract and Repair Procedures		

The general conditions of the Community Compliance Plan require that each community submit an Annual Compliance Report to provide information on the operation and maintenance of the community's sewer system. An Annual Compliance Report Checklist is sent to the communities to assist in submitting the necessary sewer system information (see Table 5 for additional information).

Table 5 **Typical Questions in the Annual Compliance Report Checklist**

- Has the community met its Technical Program milestone dates for the reporting year?
- Has the community complied with their Best Management Practices for the reporting year?
- Has the community performed any sewer system studies, investigations or monitoring?
- Is the community aware of any new SSOs within the boundaries of the community?
- How much has the community spent on capital improvements to comply with the Permit?
- Have any extensions of service been completed in the last 12 months?
- Are any extensions of service anticipated in the next 12 months?
- Has the community updated is sanitary sewer map during the reporting year?

CONCLUSION

The Community Discharge Permit Program was established to regulate flows from member communities to the environment through SSOs and into facilities owned by the District or another community. Member communities have made significant expenditures to control I/I and alleviate SSOs. As a result, the Permit Program has increased community awareness on the need for BMP to meet the Performance Objectives stated in the Permit.

Current Water Quality Conditions in the Greater Cleveland Area

James F. Weber
Superintendent, EMSC
Northeast Ohio Regional Sewer District

Abstract

The quality of the waters of the Cuyahoga River and Lake Erie in the vicinity of Cleveland, Ohio have been substantially improved over the last two decades. The natural conditions of the river system, with its low seasonal flow and high suspended solids, has contributed to many of its problems. Efforts of the Northeast Ohio Regional Sewer District and other point source dischargers to the river have eliminated virtually all water quality standard violations. Several water quality problems remain. The Northeast Ohio Regional Sewer District will attempt to address the remaining issues in its future planning activities.

KEYWORDS

Cuyahoga River, Lake Erie, wastewater, treatment, water quality

GEOLOGY OF THE GREATER CLEVELAND AREA

The water quality conditions of the Greater Cleveland area may be better understood with some background information of its geology and history. Lake Erie was formed about 20,000 years ago during the last ice age, known as the Wisconsin Stage, when glaciers dug out the Great Lakes. As the glaciers receded, the ground-up rocks, boulders, pebbles, sand and clay; collectively known as glacial till, formed hills to the south of where Cleveland is now located. To the east, the area now known as the Heights are on the westemmost foothills of the Appalachian Mountains. The land to the west is a flat terrain scrapped by the glaciers and covered with a thick layer of clay laid down by glacial lakes as the glaciers receded. A deep river valley separated the Appalachian escarpment (to the east) from the flatland (to the west). This ancient, deep, preglacial valley, filled in with glacial debris, is the current alignment of the main stem of the Cuyahoga River.

The source of the Cuyahoga River is on the Appalachian escarpment. The headwaters of the Cuyahoga River have an elevation of 1,300 feet above sea level and the river has an average fall of about 4 feet per mile. As the river moves southward, from its source towards Akron, it falls at a rate of about 25 feet per mile. This 71 mile-long river drops off the escarpment at the Cuyahoga gorge in a series of waterfalls then turns northward cutting through the aforementioned glacial deposits and carving out the wide, deep Cuyahoga River valley. Borings done in conduction with sewer interceptor projects indicate that clay and silt layers can be as deep as 41 feet below the bed of the river. Sediment transport studies conducted by Heidelberg University state that the Cuyahoga River has the greatest concentrations (time weighted mean concentration) of suspended solids among the eight Lake Erie tributary rivers studied. With rain, the river transports large concentrations of mud and silt. During dry weather the river is remarkably clear, a tribute to the fact that during low flow periods, and about 80% of the river is from sewage treatment plants.

The river and its tributaries drain a small area as far as rivers with big reputations go. The river drains 813 mi^2 (1,300 $kilometers^2$), which includes over 100 cities and townships with two major urban areas; Akron and Cleveland, before its relatively small volume empties into Lake Erie. The average flow of the Cuyahoga River is 1,200 ft^3/sec (36 m^3/s), which is 17% of the flow of Toledo's Maumee River and 0.5% of the flow coming down the Detroit River. Because of this relative small flow and high sediment yield, it did not need much human intervention to cause major pollution problems. Early explorers noted that the river was naturally contaminated, emitting a noxious odor.

HISTORY OF THE CUYAHOGA RIVER

The Cuyahoga River was known to the founding fathers of our Country. Upon a recommendation from Benjamin Franklin in 1765, Thomas Jefferson authorized a fort to be built at the mouth of the Cuyahoga River. As this location was strategically located between the iron ore field of the West and coal mines in the East, the Greater Cleveland area became an early manufacturing center. Major pollution problems of the river can be traced back to the mid 1800's when the City of Cleveland had 20 oil refineries, including the largest refinery in the world. A brochure produced by the Standard Oil Company boasted that its Cleveland refinery used more water than the entire city of Cincinnati. Cleveland also had the world's largest iron-ore receiving port and numerous iron mills along the river. For over a century, the Cuyahoga River was a working river providing both transportation and waste disposal functions.

FIRES ON THE CUYAHOGA RIVER

The first report of a Cuyahoga River fire was in 1902. The river was so polluted with oil and debris that, in 1936, river debris caught fire by a welder's torch and burned for five days! The river burned again in 1952. Even so, the river was not perceived by the public to be polluted. Pollution had another meaning for people in times past. The oil-laden river and dirty smoke emitted by smokestacks were symbols of prosperity. The river was a working river and Lake Erie was thought to provide an infinite source of dilution of the oils and chemicals that were discharged to the river.

By the 1960s, however, Lake Erie and other Great Lakes were showing signs that they could no longer assimilate the massive amount of sanitary and industrial wastewater that was being discharged by the 45 million people living and working around the Great Lakes area. Lake Erie, being the smallest in volume of the Great Lakes, was eutrifying at an alarming rate. It was estimated that half of the bottom of Lake Erie had become anoxic, that is, devoid of oxygen, due to decaying organic material. In the summer of 1969, the Cuyahoga River again caught fire. It was reported in Time Magazine, shortly after this fire, "Some river! Chocolate-brown, oily, bubbling with subsurface gases, it oozes rather than flows." "Anyone who falls into the Cuyahoga does not drown," Cleveland citizens joke grimly, "he decays." The Federal Water Pollution Control Administration noted that the lower Cuyahoga has no visible life, not even lower forms such as leeches and sludge worms. Clearly, this time the fire was not perceived as a symbol of prosperity but a sign of disgrace. The burning of the Cuyahoga River became a national symbol of just how polluted we let our waters become. There was a tremendous ground swell of support and demand from the public to clean up our waterways. Although lasting only 28 minutes, this famous conflagration was one of the banners for the social movement that lead to the Federal Water Pollution Control Act Amendments of 1972.

PROBLEMS IN LAKE ERIE

Lake Erie had its share of problems too: Eutrophication/over enrichment of nutrients, ever increasing algae blooms, malodorous algae mats washing up on beaches and settling to the bottom to decay. This decay caused widespread anoxia in Lake sediments. This, along with over-fishing, was the cause of the extirpation of the prized blue pike. Lake Erie, in the 70's, became the butt of national jokes. There were comments about Lake Erie dying or Lake Erie was dead. Lake Erie never died in the conventional sense. The fact is that the opposite was true. The Lake was becoming too productive. The Lake passed rapidly from Oligotrophic to eutrophic. It changed from a clear lake into the early stages of a swamp, with ever-increasing algae blooms and loss of diversity, including the loss of prize game fish and anaerobic benthic conditions.

The Lake has rebounded. With phosphate reductions in detergents, phosphate control at sewage treatments and upgrades to secondary treatment, the Lake was declared to have passed back to oligotrophic conditions in 1984. Ironically, with the advent of the zebra mussels in the late 80's and early 90's, recently, it has been suggested that perhaps the Lake is too clean to support its excellent walleye and perch fishery.

IMPROVEMENTS IN WATER QUALITY

The improvement in the water quality of Lake Erie is one example of the substantial improvement to area waters. These improvements have been brought about by over a billion dollars of infrastructure improvements and industrial wastewater control by; the NEORSD, the City of Cleveland and area industries. The improvement was so dramatic that AMSA considered the improvements to the water quality of the Cuyahoga River as one the major "Clean Water Success Stories."

The Southerly Wastewater Treatment Plant, situated at about River Mile 10.3, contributes as much as 50% of the total flow in the river during the summertime low flow periods. Consequently, any major change in the character of the plant effluent will have a significant impact on the water quality of the river. Due to industrial waste control and major reconstruction of this treatment facility, substantial reductions in pollutant loading were realized. The following table highlights the reductions in pollutants discharged to the river over time.

Table 1. Southerly WWTP- Percent reductions in pollutant parameters

Parameter	Time period	Percent Reductions
Cadmium	1977 to present	98%
Zinc	1977 to present	95%
Total Metals	1977 to present	92%
Ammonia	1977 to present	97%

Table 2. Cuyahoga River- Water Quality Improvements

Parameter	Time period	Percent Reductions
Ammonia*	1986 to present	89%
Fecal Coliform*	1977 to present	96%
*downstream of Southerly		

There are other notable water quality improvements in the Cuyahoga River. Dissolved Oxygen violations were once very common in the main stem of the Cuyahoga River. There hasn't been a recorded violation since 1988. Metals, including copper, nickel, chrome and zinc, have been reduced by 89% since 1978. These improvements in regional water quality came about by water pollution control programs to reduce pollutants by better transport and treatment. Many of the programs to reduce CSO and SSO flow during wet weather are currently under design so that the impacts will not be seen for some years to come.

The water quality of the Greater Cleveland area has improved dramatically over the last 30 years, i.e., not to suggest that all of the problems have been dispatched. Several major problems still remain. Some of these problems, I suspect, are due to optimistic expectations as much as they are due to point or nonpoint discharges.

- The State of Ohio has chemical and biological standards for assessing compliance with water quality standards. It is a rare event to find a violation of chemical standards. The Ohio EPA and the NEORSD have found that the number of species of fish found in the Cuyahoga River has increased from a low of one or two species in 1984 to a cumulative total of 51 species in recent years. The main stem of the Cuyahoga River still does not meet the State's biological criteria because the Index of Biotic Integrity (IBI) scoring is still too low. That is to say; that the IBI indicates that the Cuyahoga River does not have sufficient populations of certain preferred types of fish, like darters, bass, etc. It may well be that the poor fishery has more to do with geological conditions, soil erosion and bedload movement. These are habitat issues. This is consistent with the State's 305b Report which declared that the major cause for impairment in Ohio is nonpoint source pollution and hydro-modification, not point source discharges.

- Although substantial reductions have been observed, the sediments of the shipping channel are still considered heavily polluted for a number of heavy metals and oxygen demanding parameters.

- The river conveys an enormous amount of tree trunks, root masses, branches, and other woody material from trees that were undermined in the forested area between Cleveland and Akron. This, along with a muddy appearance following a rain event, detracts significantly from the aesthetics of the river and detracts from boating and other recreational uses. Floating debris removal is currently under study by the NEORSD.

- The shipping channel will have several days in the summer time that the DO falls below the dissolved oxygen criterion. This again has much to do with the fact that the shipping channel is dredged to maintain a depth of 26 feet. This depth is too great for the low summer time flows to adequately maintain aeration through its entire depth.

- Most area streams fail to meet the State's biological criteria.

- Bacterial levels in many of the smaller urban streams are impacted with bacteria due to aging separate sewer infrastructure with its many cross connections, breaks, and leaks.

Our own planning studies are indicating that even with the full implementation of the CSO control program, the area waters will still fail to meet all of the water quality standards and solve the above-listed problems. A report issued by Ohio EPA, as part of the 305 planning process, indicates that by the year 2002 only 1.6% of the impacted waters of Ohio are so because of point sources. There is good reason to believe that nonpoint sources are the continuing cause of water quality impairments. These problems transcend the traditional "transport and treat" role of the Northeast Ohio Regional Sewer District. In order to successfully address these remaining issues, the District may expand its traditional function into new areas where it can exert some control over nonpoint issues; restoring urban stream habitat, stormwater and drainage control, and intercommunity flood control.

Northeast Ohio Regional Sewer District, 3826 Euclid Avenue, Cleveland, Ohio 44115-2504 U.S.A.

ABSTRACT

This presentation provides wrap up for the nine preceding presentations regarding various aspects of the Northeast Ohio Regional Sewer District wet weather programs and comment on considerations for the future.

KEYWORDS

sewer, storm, sanitary, combined, overflow

EQUITABLE CHARGES FOR WET WEATHER FLOW

The Northeast Ohio Regional Sewer District rate structure has historically been based on metered water consumption. Over the years, water consumption has decreased. On the other hand, sewer systems have deteriorated and wet weather programs have increased wastewater flows. Water consumption decreased from 55 to 46 billion gallons per year since 1980 (16 percent) while treated wastewater increased from 92 to 122 (33 percent).

COMBINED SEWER OVERFLOW CONTROL

The District is developing Combined Sewer System Long-Term Control Plans on a segmented basis. The current National Pollutant Discharge Elimination System Permit requires all plans to be complete by March, 2002. The Mill Creek plan is complete. The Westerly, Easterly, and Doan Brook plans are currently underway. The Southerly and Big Creek plans will begin next year.

SEPARATE SEWER OVERFLOWS

Many District member communities have separate sewer overflows. Many have been alleviated through the intercommunity relief sewer program. However, many more need to be addressed.

UNITED STATES ENVIRONMENTAL PROTECTION AGENCY PROPOSED STORM WATER PHASE II RULE

Since no District member community meets the 100,000 population criteria for the Storm Water Phase I Rule, no permits have been issued or applied for in the Cleveland metropolitan area. However, many communities will be impacted by the Phase II Rule.

REGIONAL PLAN FOR SEWERAGE AND DRAINAGE

The court order that created the District mandated that "The District shall develop a detailed integrated capital improvement plan for regional management of wastewater collection and storm drainage to identify a capital improvement program for the solution of all intercommunity drainage problems (both storm and sanitary) in the District". Although the District has made substantial progress in the "wastewater collection" area, the "storm drainage" area is still "unfinished business". Work on Phase I of the comprehensive Regional Plan for Sewerage and Drainage began early this year.

INNOVATIVE MULTI-CHAMBERED STORMWATER CONTROL DEVICE FOR CRITICAL SOURCE AREAS

ABSTRACT

This research project is part of a multi-year investigation funded by the U.S. EPA to characterize and treat toxic stormwater contaminants. The first project phase investigated typical toxicant concentrations in stormwater, the origins of these toxicants, and storm and land-use factors that influenced these toxicant concentrations. Nine percent of the eighty-seven stormwater source area samples analyzed were considered extremely toxic. Thirty-two percent of the samples exhibited moderate toxicity, while fifty-nine percent of the samples had no evidence of toxicity. All metallic toxicants analyzed were commonly found in all samples analyzed. Only a small fraction of the organic toxicants analyzed were frequently detected, with 1,3-dichlorobenzene and fluoranthene the most commonly detected organics (present in 23 percent of the samples). Vehicle service and parking area runoff samples had many of the highest observed concentrations of organic toxicants.

The second project phase investigated the control of stormwater toxicants using a variety of conventional bench-scale treatment processes. The most beneficial treatment tests included settling for at least 24 hours (up to 90% reductions), screening and filtering through at least 40 µm screens (up to 70% reductions), and aeration and/or photo-degradation for at least 24 hours (up to 80% reductions). Because many samples exhibited uneven toxicity reductions for the different treatment tests, a treatment train, called the MCTT (multi-chambered treatment train), was designed and constructed for pilot-scale and full-scale testing during the third project phase.

The third project phase included testing of a prototype MCTT). This device, through pilot and initial full-scale testing has been shown to remove more than 90% of many of the stormwater toxicants, in both particulate and dissolved forms. The MCTT is most suitable for use at relatively small and isolated paved critical source areas (gas stations, oil change stores, salvage yards, maintenance yards, etc.) that are about 0.1 to 1.0 ha (0.25 to 2.5 acres) in area. The MCTT is an underground device that has three main chambers: an initial grit chamber with volatile organic removal; a settling chamber with sorbents for the removal of fine sediments and floating hydrocarbons; and a sand/peat filter for the removal of filterable toxicants. A typical MCTT requires between 0.5 and 1.5 percent of the paved drainage area, about 1/3 of the area required for a well-designed wet detention pond.

The pilot-scale MCTT, constructed in Birmingham, AL, was tested over a six-month monitoring period during a variety of rainfall events. Two additional full-scale MCTT units were also constructed and were monitored as part of Wisconsin's 319 grant from the U.S. EPA. During monitoring of 13 storms at a parking facility, the pilot-scale MCTT was found to have the following overall removal rates: 96% for total toxicity, 83% for suspended solids, 60% for COD, 40% for turbidity, 90-100% for heavy metals, 90-100% for the detected semi-volatile organics. The peat filter caused a color increase in the effluent and an overall drop in pH of about one-half unit. Ammonia nitrogen was increased and nitrate-nitrogen had less than 20% removals. The MCTT operated as intended: very effective removal rates for both filtered and particulate stormwater toxicants and suspended solids, but at the expense of increased color, lowered pH, and depressed COD and nitrate removal rates. The full-scale test results substantiate the excellent removals found during the pilot-scale tests, while showing better control of COD and nutrients and less detrimental effects on pH and color.

KEYWORDS

Urban runoff treatment, settling chamber, sand/peat filter, wet weather flows

INTRODUCTION

Runoff from paved parking and storage areas, and especially gas station areas, has been observed to be contaminated with concentrations of many critical pollutants. These paved areas are usually found to contribute most of the toxicant pollutant loadings to stormwater outfalls. Polycyclic aromatic hydrocarbons (PAHs), the most commonly detected toxic organic compounds found in urban runoff, along with heavy metals are mostly associated with automobile use, especially during starting vehicles.

Numerous manufacturers have developed small prefabricated separators to remove oils and solids from runoff. These separators are rarely specifically designed and sized for stormwater discharges, but usually consist of modified grease and oil separators. The solids are intended to settle within these separators, either by free fall or by counter-current or cross-current lamellar separation. Many of these separators have been sold and installed in France, especially along highways (Rupperd 1993). Despite the number of installations, few studies have been carried out in order to assess their efficiency (Aires and Tabuchi 1995). Available results from Fourage (1992), Rupperd (1993) and Legrand, *et al.* (1994) for stormwater treatment show that:

- These devices are usually greatly undersized. They should work reasonable well at flow rates between 20 and 30% of their design hydraulic capacity. For higher flow rates, the flow is very turbulent (Reynolds numbers > 6000) and the removal efficiency is very poor.
- These devices need to be cleaned very frequently. If they are not cleaned, the deposits are scoured during storm events, with negative efficiencies. Currently, the cleaning frequencies are very insufficient and the stormwater pollutant control efficiencies are very limited.
- There are relatively low levels of free-floating oils in most stormwater runoff.

Prefabricated separators could be used for stormwater treatment if the following conditions are respected:

- realistic design hydraulic capacity in terms of maximum flow rates, flow distribution and flow regime;
- realistic solids removal efficiency: the finest and polluted solids will usually not be trapped with a high efficiency because of too high hydraulic velocities;
- frequent cleaning and/or an automatic extraction to assure good overall efficiency;
- specific conception for stormwater that takes into account the solids characteristics, the rapid flow variations, and the maintenance requirements.

METHODOLOGY

The Multi-Chambered Treatment Train (MCTT) was developed to specifically address many of the above concerns. It was developed and tested with specific stormwater conditions in mind, plus it has been tested at several sizes for the removal of stormwater pollutants of concern. Figure 1 shows a general cross-sectional view of a MCTT. It includes a special catchbasin followed by a two chambered tank that is intended to reduce a broad range of toxicants (volatile, particulate, and dissolved). The runoff enters the catchbasin chamber by passing over a flash aerator (small column packing balls with counter-current air flow) to remove highly volatile components. This catchbasin also serves as a grit chamber to remove the largest (fastest settling) particles. The second chamber serves as an enhanced settling chamber to remove smaller particles and has inclined tube or plate settlers to enhance sedimentation. This chamber also contains fine bubble diffusers and sorbent pads to further enhance the removal of floatable hydrocarbons and additional volatile compounds. The water is then pumped to the final chamber at a slow rate to maximize pollutant reductions. The final chamber contains a mixed media (sand and peat) slow filter/ion exchange device, with a filter fabric top layer. The MCTT is typically sized to totally contain all of the runoff from a 6 to 20 mm (0.25 to 0.8 in) rain, depending on interevent time, typical rain size, and rain intensity.

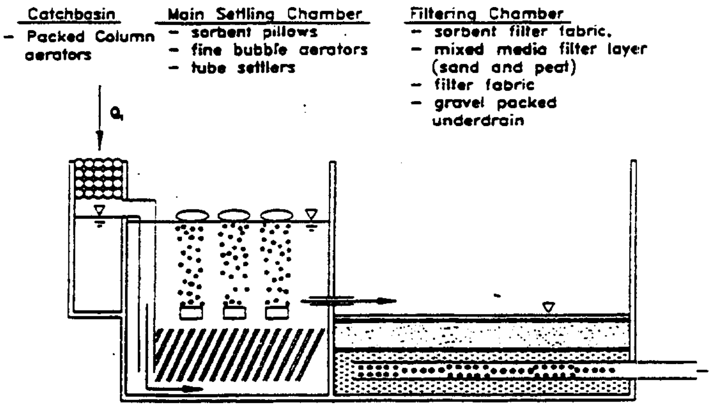

Figure 1. **General Schematic of the Multi-Chambered Treatment Train (MCTT)**

A pilot-scale MCTT was constructed and tested in Birmingham, Alabama, at parking and vehicle service area on the campus of the University of Alabama at Birmingham. The catchbasin/grit chamber is a 25-cm vertical PVC pipe containing about 6 L of 3-cm diameter packing column spheres. The main settling chamber is about 1.3 m^2 in area and 1 m deep which with a 72-hour settling time was expected to result in a median toxicity reduction of about 90%. The filter chamber is about 1.5 m^2 in area and contains 0.5 m of sand and peat directly on 0.15 m of sand over a fine plastic screen and coarse gravel that covers the underdrain. A Gunderboom™ filter fabric also covers the top of the filter media to distribute the water over the filter surface by reducing the water infiltration rate through the filter and to provide additional pollutant capture. During a storm event, runoff from the parking lot is pumped into the catchbasin/grit chamber automatically. During filling, an air pump supplies air to aeration stones located in the main settling chamber. When the settling chamber is full, all pumps and samplers cease. After a quiescent settling period of up to 72 hours, water is pumped through the filter media and discharged. Samples were collected before and after each chamber of the device and were partitioned into dissolved and particulate components before being analyzed for a wide range of toxicants, as listed on Table 1.

RESULTS

Observed Performance of the Pilot-Scale MCTT

Table 2 summarizes some of the significant percentage changes in concentrations of the constituents as they passed through each chamber (settling chamber, filter, and overall) of the MCTT. No data is shown for the catchbasin/grit chamber because of the lack of significant concentration changes observed. Figures 2 and 3 are example plots showing the concentrations of suspended solids and unfiltered zinc as the stormwater passed through the MCTT. The four data locations on these plots correspond to the four sampling locations on the MCTT. The sample location labeled "inlet" is the overall inlet to the MCTT (and the inlet to the catchbasin/grit chamber). The location labeled "catch basin" is the effluent from the catchbasin (and inlet to the main settling chamber). Similarly, the location labeled "settling chamber" is the outlet from the settling chamber (and the inlet to the sand/peat chamber). Finally, the location labeled "peat-sand" is the outlet from the sand/peat chamber (and the outlet from the MCTT). The slopes of the lines indicate the relative removal rates (mg/L reduction) for each individual major unit process in the MCTT. If the lines are all parallel between two sampling locations, then the removal rates are similar. If a line has a positive slope, then a concentration increase occurred. If the lines have close to zero slope, then little removal has occurred (as for the catchbasin/grit chamber for most constituents and samples).

The suspended solids trends (Figure 2) show the significant reductions in suspended solids concentrations through the main settling chamber, with no removal occurring in catchbasin/grit and sand/peat chambers. However, the first storm had a significant increase in suspended solids

Table 1. **Compounds Analyzed during MCTT Pilot-Scale Testing**

Compound Category	Compounds	Testing Methodology (Detection Limits)
Semi-Volatile Organics (BNA Extractable)	Polycyclic Aromatic Hydrocarbons Phthalate Esters Phenols	GC/MSD – particulate and dissolved fractions (1 to 10 μg/L MDL)
Pesticides	Pesticides	GC/ECD – particulate and dissolved fractions (0.01 to 0.1 μg/L MDL)
Heavy Metals	Cadmium Copper Lead Zinc	GFAA – particulate and dissolved fractions (1 to 5 μg/L MDL)
Toxicity	Toxicity Screening Test	Microtox™ - particulate and dissolved fractions
Nutrients	Nitrite + Nitrate Ammonia Phosphate	Ion Chromatography – dissolved fraction (1 mg/L MDL)
Major Ions	Cations (Ca, Mg, K, Na, Li) Anions (Cl, SO_4, F)	Ion Chromatography – dissolved fraction (1 mg/L MDL)
Conventional Pollutants	Chemical Oxygen Demand Color Specific Conductance Hardness Alkalinity pH Turbidity Solids (total, dissolved, suspended, volatile)	
Particle Size	Particle Size Distribution (1 – 128 μm)	Coulter Multisizer IIe

Table 2. **Median Observed Percentage Changes in Constituent Concentrations**

Constituent	Main Settling Chamber	Sand/Peat Chamber	Overall Device
Common Constituents			
Total solids	31%	2.6%	32%
Suspended solids	91	-44	83
Turbidity	50	-150	40
pH	-0.3	6.7	7.9
COD	56	-24	60
Nutrients			
Nitrate	27	-5	14
Ammonia	-155	-7	-400
Toxicants			
Microtox™ (unfiltered)	18	70	96
Microtox™ (filtered)	64	43	98
Lead	89	38	100
Zinc	39	62	91
n-Nitro-di-n-propylamine	82	100	100
Hexachlorobutadiene	72	83	34
Pyrene	100	n/a	100
Bis (2-ethylhexyl) phthalate	99	-190	99

concentration as it passed through the peat due to flushing of fines from the incompletely washed media. This contributed to the negative removals of the filter chamber. For the other monitored storms, removal occurred (although the percent reduction was small). The relative toxicity changes (as measured using the Microtox™ unit) (not shown) indicate significant reductions in toxicity, especially for the moderate and highly toxic samples. No effluent samples were considered toxic (all effluent samples were "non toxic", or causing less than a 20% light reduction after 25 minutes of exposure using the Azur Microtox™ screening toxicity test). Figure 3, for zinc removal, shows significant and large reductions in concentrations, mostly through the main settling chamber (corresponding to the large fraction of stormwater toxicants found in the particulate sample fraction). Zinc also had further important decreases in concentrations in the peat/sand chamber, where removal of the remaining dissolved zinc in the stormwater occurred.

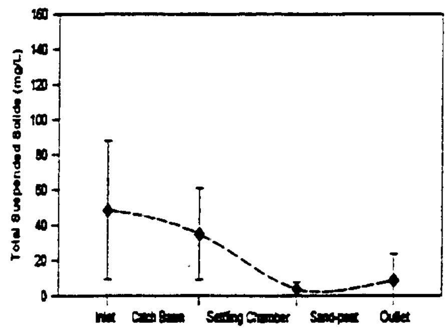

Figure 2. **MCTT Performance for Suspended Solids**

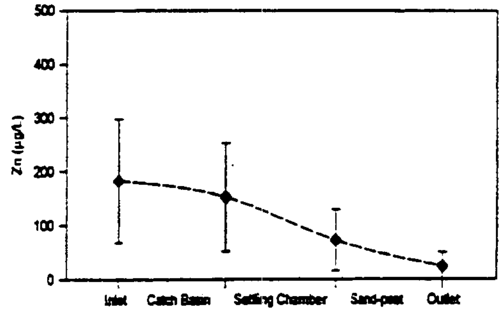

Figure 3. **MCTT Performance for Unfiltered Zinc**

Preliminary Full-Scale MCTT Test Results

Preliminary results from the full-scale tests of the MCTT in Wisconsin (Corsi, Blake, and Bannerman, personal communication) were encouraging and corroborate the high levels of treatment observed during the Birmingham pilot-scale tests. Table 3 shows the treatment levels that have been observed during seven tests in Minocqua (during one year of operation) and 15 tests in Milwaukee (also during one year of operation), compared to the pilot-scale Birmingham test results (13 events). These data indicate high reductions for SS (83 to 98%), COD (60 to 86%), turbidity (40 to 94%), phosphorus (80 to 88%), lead (93 to 96%), zinc (90 to 91%), and for many organic toxicants (generally 65 to 100%). The reductions of dissolved heavy metals (filtered through 0.45 µm filters) were also all greater than 65% during the full-scale tests. None of the organic toxicants were ever observed in effluent water from either full-scale MCTT, even considering the excellent detection limits available at the Wisconsin State Dept. of Hygiene Laboratories that conducted the analyses. The influent organic toxicant concentrations were all less than 5 µg/L and were only found in the unfiltered sample fractions. The Wisconsin MCTT effluent concentrations were also very low for all of the other constituents monitored: <10 mg/L for SS, <0.1 mg/L for phosphorus, <5 µg/L for cadmium and lead, and <20 µg/L for copper and zinc. The pH changes in the Milwaukee MCTT were much less than observed during the Birmingham pilot-scale tests, possibly because of added activated carbon in the final chamber in Milwaukee. Color was also much better controlled in the full-scale Milwaukee MCTT.

DISCUSSION

The Milwaukee installation is at a public works garage and serves about 0.1 ha (0.25 acre) of pavement. This MCTT was designed to withstand very heavy vehicles driving over the unit. The estimated cost was $54,000 (including a $16,000 engineering cost), but the actual cost was $72,000. The high cost was likely due to uncertainties associated with construction of an unknown device by the contractors and because it was a retrofit installation. It therefore had to fit within very tight site layout constraints. As an example, installation problems occurred due to sanitary sewerage not being accurately located as mapped. The Minocqua site was a 1 ha (2.5 acre) newly paved parking area serving a state park and commercial area. It was located in a grassed area and was also a retrofit installation, designed to fit within an existing storm drainage system. The installed cost of this MCTT was about $95,000.

It is anticipated that MCTT costs could be substantially reduced if designed to better integrate with a new drainage system and not installed as a retrofitted stormwater control practice. Plastic tank manufactures have also expressed an interest in preparing pre-fabricated MCTT units that could be sized in a few standard sizes for small critical source areas. It is expected that these pre-fabricated units would be much less expensive and easier to install than the custom-built units tested to date.

Table 3. **Preliminary Performance Information for Full-Scale MCTT Tests, Compared to Birmingham Pilot-Scale MCTT Results (median reductions and median effluent quality)**

	Milwaukee MCTT (15 events)	**Minocqua MCTT (7 events)**	**Birmingham MCTT (13 events)**

Design of the MCTT

__Catchbasin__. Catchbasins have been found to be effective in removing pollutants associated with coarser runoff solids. Moderate reductions in total and suspended solids (up to about 45%, depending on the inflow water rate) have been indicated by prior studies (Lager and Smith 1976, Pitt and Bissonnette 1985). While few pollutants are associated with these coarser solids, their removal decreases maintenance problems of the other chambers. The size of the MCTT catchbasin sump is controlled by three factors: the runoff flow rate, the suspended solids (SS) concentration in the runoff, and the desired frequency at which the catchbasin will be cleaned so as not to sacrifice efficiency.

Main Settling Chamber. The main settling chamber mimics completely mixed settling column bench-scale tests and uses a treatment ratio of depth to time for removal estimates. In addition to plate or tube settlers, the main settling chamber also contains floating sorbent "pillows" to trap floating grease and oil and a fine bubble diffuser. The settling time in the main settling chamber typically ranges from 1 to 3 days.

Peat/Sand Ion Exchange Chamber. Based on literature descriptions of stormwater filtration, especially by the City of Austin (1988), Galli (1990) and Shaver (undated and 1991), earlier UAB bench-scale treatability tests (Pitt, *et al.* 1995), and the preliminary UAB filter media column tests (Clark, *et al.* 1995), it was determined that a mixed media sand and peat "filter" should be used as a polishing unit after the main settling chamber. This unit provides additional toxicant reductions, especially for filtered forms of the organics and metals. The surface hydraulic loading rate of this filter/ion exchange chamber should be between 1.5 and 6 m per day (5 and 20 ft per day). The 50%/50% mixture of the sand and peat should have a depth of 0.5 m (18 in), resting on 0.15 m of sand. The sand used in the testing had the following size: 71% finer than #30 sieve (0.6 mm), 65% finer than #40 sieve (0.425 mm), and 0.5% finer than #50 sieve (0.18 mm). The effective size (D_{10}) of the sand was 0.31 mm and the uniformity coefficient (D_{60}/D_{10}) was 1.45. A filter fabric was used to separate these layers from the gravel and perforated pipe underdrain. In order to facilitate surface spreading of water on top of the media and to prevent channelization, another filter fabric (Gunderboom™) was placed on top of the media.

Example Design

The design of the MCTT is very site specific, since it is highly dependent on local rains (rain depths, rain intensities, and interevent times). A computer model was therefore developed to determine the amount of annual rainfall treated, the toxicity reduction rate for each individual storm, and the overall toxicity reduction associated with a long series of rains for different locations in the U.S. Table 4 gives the simulation results for the sizing of the main settling chamber for 21 cities (rain depths range from 180 mm (7.1 in) (Phoenix) to 1500 mm (60 in) (New Orleans) per year).

Table 4. **MCTT Settling Chamber Sizes (48 hr hold times, except as noted; 1.5 m settling depths)**

City	Annual Rain Depth (mm)	Runoff Capacity (mm) for 70% Toxicant Control	Runoff Capacity (in) for 90% Toxicant Control
Phoenix, AZ	180	6.35 (24 hours)	8.89
Reno, NV	191	5.08 (18 hours)	5.08
Bozeman, MT	325	6.35	10.2
Los Angeles, CA	378	7.62	11.4
Rapid City, SD	414	5.08 (18 hours)	5.59
Minneapolis, MN	671	8.13	2.70
Dallas, TX	749	2.70	24.4
Milwaukee, WI	785	9.14	16.5
Austin, TX	800	5.59 (18 hours)	8.13
St. Louis, MO	861	7.62	12.5
Buffalo, NY	953	8.89	2.70
Seattle, WA	986	6.35	10.2
Newark, NJ	1074	12.2	24.4
Portland, ME	1105	10.7	18.3
Atlanta, GA	1234	14.0	24.1
Birmingham, AL	1384	9.40	13.5
Miami, FL	1463	10.2	18.5
New Orleans, LA	1516	20.3	23.4

The overall range in MCTT size varies by more than three times for the same level of treatment for the different cities. The required size of the main settling chamber generally increases as the annual rain depth increases. However, the interevent period and the rain depth for individual rains determine the specific runoff treatment volume requirement. As an example, Seattle requires a much smaller MCTT than other cities having similar annual total rains because of the small rain depths for each rain. Rapid City requires a smaller MCTT, compared to Los Angeles, because Los Angeles has much larger rains when it does rain. Similarly, Dallas requires an unusually large MCTT because of its high rain intensities and large individual rains, compared to upper Midwest cities that have similar annual rain depths.

In all cases, the most effective holding time is 2 days for 90% toxicant control (for the 1.5 m, 5 ft, settling chamber depth). In most cases, a toxicity removal goal of about 70% in the main settling chamber is probably the most cost effective choice, considering the additional treatment that will be provided in the sand/peat chamber. Figure 4 shows the runoff volume requirements for an MCTT having a 0.6, 1.5, 2.1, or 2.7 m (2, 5, 7, or 9 foot) settling depths in the main settling chamber for Milwaukee, WI. This example shows that the required runoff depth storage capacity increases as the depth of the main settling chamber increases. As an example, for 90% toxicant control at Milwaukee, the storage requirement for a 1.5 m (5 ft) settling depth was shown to be 16.5 mm (0.65 in) on Table 2. Figure 4 indicates that the required storage volume for a 0.6 m (2 ft) settling chamber would only be 14 mm (0.55 in) of runoff, while it would increase to 19 mm (0.75 in) of runoff for a 2.1 m (7 ft) settling depth and to 23 mm (0.9 in) for a 2.7 m (9 ft) settling depth. The greater depths require more time for the stormwater particulates to settle and be trapped in the chamber, while the shallower tanks require a greater surface area. The best tank design for a specific location is based on site specific conditions, especially the presence of subsurface utilities or groundwater and hydraulic grade line requirements. A large surface tank is usually much more expensive, even though the required volume is less, especially if heavy traffic will be traveling over the tank.

A combination of a 48 hour holding time and 11 mm (0.45 in) runoff storage volume would satisfy a 75% treatment goal for Milwaukee conditions, as shown on Figure 3. This 11-mm runoff volume corresponds to a rain depth of about 13 mm (0.51 in) for pavement (Pitt 1987). The 11-mm runoff storage volume corresponds to a live chamber volume of 22 m^3 (770 ft^3) and a surface area of 10 m^2 (110 ft^2) for a 0.2 ha (0.5 acre) paved drainage area. The surface area of the MCTT would therefore be about 0.5 percent of the drainage area. This device would capture and treat about 80% of the annual runoff at a 95% toxicity reduction level, resulting in an annual toxicity reduction of about 75% (0.8 X 0.95). The size of the main settling chamber would need to be greater than this because about 0.7 m (two feet) of "dead" storage must be added to provided for standing water below the outlet orifice (or pump) which would keep the inclined tubes submerged. About a 0.2 m (6 inch) height is also needed below the inclined tubes for the flow distribution system and for long-term storage of fine material that will accumulate.

Additional treatment beyond the 75% level would result in the filter/ion exchange chamber. The pumped effluent from the main settling chamber would be directed towards a mixed peat/sand filter/ion exchange chamber, which must provide a surface hydraulic loading rate of between 1.5 and 6 m per day (5 and 20 ft per day), and have a depth of at least 0.5 m (18 in). In addition to the pumped effluent, any excess runoff after the main settling chamber is full would also be directed towards the filter.

Each of the treatment chambers need to be vented, mosquito proofed, and be easily accessible for maintenance. The device needs to be inspected, the initial catchbasin should be cleaned, and the sorbent pillows should be exchanged, at least every six months. It is expected that the ion exchange media should last from 3 to 5 years before requiring replacement (as determined during our filtration experiments).

CONCLUSIONS

The development and testing of the MCTT showed that the treatment unit provided substantial reductions in stormwater toxicants (both in particulate and filtered phases), and suspended solids. Increases in color and a slight decrease in pH also occurred during the filtration step at the pilot-scale unit. The main settling chamber resulted in substantial reductions in total and dissolved toxicity, lead, zinc, certain organic toxicants, suspended solids, COD, turbidity, and color. The filter/ion exchange unit is also responsible for additional filterable toxicant reductions. However, the catchbasin/grit chamber did not indicate any significant improvements in water quality, although it is an important element in reducing maintenance problems by trapping bulk material. The use of the MCTT is seen to be capable of reducing a broad range of stormwater pollutants that have been shown to cause substantial receiving water problems (Pitt 1995).

ACKNOWLEDGMENTS

This research was mostly funded by the Urban Watershed Management Branch of the U.S. EPA, Edison, New Jersey. Rich Field provided much guidance and assistance during the research. Additional funding was also provided by the U.S. Army-Construction Engineering Research Laboratory in Champaign, Illinois. Rick Scholze's efforts are greatly appreciated. Much of the work reported in this paper was carried out by Brian Robertson as part of his MSCE thesis at the University of Alabama at Birmingham. Additional contributions were also made by the following UAB personnel: Dr. Keith Parmer, Shirley Clark, Olga Mirov, Jay Day, and Holly Ray. Special thanks is also extended to the cities of Minocqua and Milwaukee, the state of Wisconsin, and Region V of the EPA for constructing and monitoring the full-scale MCTT installations. Roger Bannerman and Tom Blake of the Wisconsin Department of Natural Resources along with Steve Corsi of the USGS in Madison were especially instrumental in carrying out these full-scale tests.

ABSTRACT

This paper presents the applicability of four high-rate disinfection technologies for treating combined-sewer overflow (CSO) and sanitary-sewer overflow (SSO). The four technologies are treatment with: ozone (O_3), chlorine dioxide (ClO_2), ultraviolet light irradiation (UV), and high-voltage electron beam irradiation (E-Beam). These high-rate technologies are compared to each other and to conventional chlorination/dechlorination. Utility of increased mixing in concert with any disinfection technology is also discussed.

Disinfection of CSO and SSO is generally practiced to control the discharge of pathogens and indicator microorganisms into receiving waters. Because these overflows are wet weather events, the disinfectant used at a facility for treatment of CSO or SSO should be adaptable to intermittent use. Other considerations include effectiveness, oxidation/disinfection rate, and safety. Since commonly used disinfection by chlorination forms toxic residual byproducts, the newer disinfectants such as ClO_2, O_3, UV, and E-Beam have a far lesser potential to generate toxic byproducts. Since CSO and SSO flow rates and volumes are significantly greater than dry-weather flows, use of high-rate processes requiring less tankage and space is more cost-effective than use of conventional processes.

Comparative effectiveness and cost of high-rate disinfection technologies are supported with data from pilot-scale evaluations conducted primarily on CSO at the 26th Ward Water Pollution Control Plant (WPCP) in New York City.

KEY WORDS

wet-weather flow, combined-sewer overflow, sanitary-sewer overflow, stormwater, disinfection, oxidation, ozonation, chlorination/dechlorination, irradiation, pathogens, indicator microorganisms

INTRODUCTION

The National CSO Control Policy requires disinfection after primary treatment in areas where disinfection is required by local authorities. Conventional municipal sewage disinfection processes generally use chlorine (Cl_2) gas or sodium hypochlorite (NaOCl) due to their rapid oxidation capabilities and relatively low cost. Disinfection of CSO and SSO is generally practiced to control the discharge of pathogens and indicator microorganisms in receiving waters. CSO and SSO have the characteristics of being intermittent and having high flow rate, high suspended solids (SS) content, wide temperature variation, and variable microorganism quality.

Therefore, the disinfectant used at a facility for treatment of CSO and SSO should be adaptable to intermittent use and to treatment of flows of variable quality and quantity. Other considerations include the disinfection effectiveness, oxidation/disinfection rate, and the safety and ease of feeding. Cl_2 and hypochlorite (OCl^-) will react with ammonia (NH_3) to form chloramines and react with phenols to form chlorophenols. These are toxic to aquatic life. The adverse impacts associated with chlorination are among the issues leading to the need for development of alternative methods of disinfection.

Newer disinfection technologies such as ClO_2, O_3, UV, and E-Beam have a far lesser potential to generate toxic byproducts. ClO_2 does not react with NH_3 and completely oxidizes phenols. O_3 is also effective in oxidizing phenols. UV disinfects water and wastewater by altering the genetic material (DNA) in cells so that microorganisms can no longer reproduce. UV disinfection does not generate any toxic byproducts but is affected by high SS content. E-Beam achieves effective pathogen kill, does not generate any toxic byproducts, and is not effected by SS content. Effectiveness of the new disinfection processes needs to be verified by pilot testing on wet-weather flow or on wastewaters with similar characteristics to WWF.

Since CSO and SSO flow rates and volumes are significantly greater than those of dry-weather flows, use of high-rate processes requiring less tankage and space is more cost-effective than use of conventional processes. The need for advanced technologies evolves from the National CSO Control Policy that requires treatment at the existing wastewater treatment plants (WWTPs) and at satellite locations at outfall points during the high flow periods. A similar requirement can be extended to SSO. The objective of these technologies is to secure treatment effectiveness of the plant at the increased throughput, which cannot be accomplished with the use of conventional technologies. High-rate disinfection, i.e., decreased disinfection contact time, can be accomplished by:

- increasing mixing intensity,
- increasing disinfectant concentration,
- using faster-acting oxidants, UV, E-Beam irradiation, and/or
- using combinations of these.

Use of increased mixing with any disinfection technology provides better dispersion of the disinfectant and forces disinfectant contact with a greater number of microorganisms per unit time. The increased rate of collisions decreases the required contact time, which enables a high-rate disinfection (Field *et al.*, 1996).

NEW HIGH-RATE DISINFECTION TECHNOLOGIES

Disinfection processes based on the use of ClO_2, O_3, UV, and E-Beam can accomplish high-rate treatment because they provide greater and faster microbe-killing power than conventional chlorination/dechlorination. E-Beam technology has been in commercial use in other applications, such as food processing and hazardous waste treatment, but is considered new for CSO and SSO. However, chlorination processes, considered here as conventional, can also be optimized to accomplish high-rate treatment. Chlorination, especially when followed by dechlorination, maintains its competitive edge over the newer disinfection technologies (Field and O'Connor, 1997).

ClO_2 - a yellowish gas at room temperature, is an effective disinfectant for the destruction of pathogens and inactivation of viruses. Compared to chlorine, ClO_2 is 10 times more soluble in water, is stable in water solutions, does not react with nitrogenous compounds, is effective over wide pH range, and is effective over longer periods. ClO_2 is generated onsite from sodium chlorate ($NaClO_3$) by solution processes or from sodium chlorite ($NaClO_2$) with the use of Cl_2 gas. A new aqueous UV process generates ClO_2 from $NaClO_2$ directly in UV-light reaction cells. The UV ClO_2 generator is particularly attractive in an urban setting by eliminating the need for transport and handling of Cl_2 gas.

Sequential addition of Cl_2 followed by ClO_2 at intervals of 15-30 seconds enhances high-rate disinfection beyond the expected additive effect. A minimum effective combination of 8 mg/l of Cl_2 followed by 2 mg/l of ClO_2 showed disinfection effectiveness equal to 25 mg/l of Cl_2 or 12 mg/l of ClO_2 when used individually.

O_3 - a gas, is formed by electrical discharges in the presence of oxygen and is a very powerful oxidant and disinfectant. Because O_3 disinfects more rapidly than Cl_2, it requires shorter contact time and requires smaller and less expensive contact chambers. O_3 is highly unstable, must be generated onsite just prior to application, and must be quickly and efficiently contacted with the treated flow. Dosage and contact time requirements depend on the characteristics of the flow but are usually 1-10 mg/l and < 15 minutes. Ozonation produces some byproducts but no chlorinated hydrocarbons and no residual O_3. In general, O_3 systems have relatively high capital and energy costs.

UV - light disinfects flows at the germicidal wavelength of 254 nanometers (ηm) by altering the genetic material (DNA) in cells so that microorganisms can no longer reproduce. In UV disinfection systems, the UV lamps are submerged in either a closed vessel or an open channel. Thin film flows past the UV lamps and for a few seconds the microorganisms are exposed to a dosage of UV energy. UV performance and lamps fouling depend on flow characteristics, such SS concentration and particle size distribution, presence of other UV absorbing compounds, and concentration of microorganisms. Of the various alternatives to conventional chlorination/dechlorination for the disinfection of WWFs, UV has been the most widely tested.

E-Beam - a stream of high-energy electrons is directed into a thin film of water or sludge. The electrons break apart water molecules and form highly reactive species, namely the oxidizing hydroxyl radical ($OH^{\bullet}$), the reducing aqueous electron (e-aq) and hydrogen atom ($H^{\bullet}$). Reactions of these intermediates with contaminants and microorganisms occur at diffusion-limited rates, and the treatment is complete in less than one-tenth of a second. Processes based on the electron beam irradiation principle have been used in the food preparation/packaging industry and for disinfection of wastewater treatment sludges. The E-Beam technology has been demonstrated for treatment of hazardous organic compounds that are either dissolved or suspended in groundwater or wastewater. The E-Beam process has the potential to deactivate a wide range of pathogens in a very short contact time and should penetrate turbid flows with high solids concentration as well. However, testing of this technology for WWF is very limited and there are some concerns with safety and cost (Camp Dresser & Mc Kee and Moffa & Associates, 1998).

Rapid mixing - in combination with any disinfection technology is a critical parameter, particularly when desired contact times are less than 10 minutes. Mixing provides better dispersion of the disinfectant and assures contact of the disinfectant with a greater number of microorganisms per unit time. Mixing can be accomplished by mechanical flash mixers at the point of disinfectant addition, at intermittent points, or by specially designed plug flow contact chambers containing closely spaced, corrugated parallel baffles that create a meandering path for the flow (Glover, G.E., 1973).

PILOT TESTING OF HIGH-RATE DISINFECTION TECHNOLOGIES ON CSO

Project Team

The above described four high-rate disinfection technologies have been recently pilot-tested by the New York City Department of Environmental Protection with contractors Camp, Dresser & McKee (CDM) and Moffa & Associates. For testing of the E-Beam pilot, the above affiliates were joined by the New York Power Authority of New York, NY. In August 1997, CDM entered into a contract with the U.S. Environmental Protection Agency (EPA) for pilot testing of a UV-light generated ClO_2 system, that has not been tested before, and for additional testing of the UV technology as well. The EPA-CDM project will be a part of a much larger pilot program, which will involve all of the above affiliates again (Camp Dresser & Mc Kee and Moffa & Associates, 1997 and 1998).

Pilot Facilities and Operation

The completed pilot testing of ClO_2, O_3, UV, and E-Beam high-rate systems and of a chlorination/dechlorination unit, was performed at the 26th Ward WPCP, which will also be the site for the forthcoming testing of the UV-light generated ClO_2 and UV. The purpose of the pilot study was to evaluate performance of disinfection technologies that are alternative to chlorination/dechlorination for a possible selection to be used as a suitable alternative at the Spring Creek Auxiliary Wastewater Pollution Control Plant (AWPCP), an off-line CSO storage facility.

Pilot testing was designed to subject the selected four disinfection technologies to a wide range of influent quality typical of CSOs and to compare the technologies for their relative effectiveness in decreasing bacteria throughout the range of water quality. Four indicator bacteria were used as a measure of each technology effectiveness: total coliform, fecal coliform, *Escherichia coli (E.coli)*, and enterococcus. Bacteria kills, in terms of log reduction and effluent concentration, were related to the disinfectant dose for each of the technologies. To evaluate performance of technologies, a satisfactory disinfection effectiveness was defined as 3 to 4 log bacterial reduction.

Pilot test runs for ClO_2, O_3, UV, and chlorination/dechlorination were performed from December 17, 1996 through March 12, 1997. The pilot units were located side-by-side for concurrent operation. A total of 16 test runs were performed during both dry and wet weather. The E-Beam pilot testing was performed from February 24, 1997 through March 26, 1997. A total of 20 test runs were performed.

Wastewater flow to the pilot facility was supplied from either the primary settling tank influent or the primary settling tank effluent to assure a wide range of water quality. Wastewater feed and effluent piping was sized to provide a minimum flow velocity of 2 ft/sec to prevent solids deposition. Each pilot system was subjected to the same wastewater to compare the performance of one directly against the other.

The disinfection pilot units used in the study were:

<u>ClO_2</u> The contact /treatment skid was provided by UVD Inc. of Syracuse, NY and included the contact tank, mixer, and residual instrumentation. CDG Technology of New York City, NY provided the onsite ClO_2 generator. The tank was sized to provide a detention time of 5 minutes at 50 gpm.

<u>O_3</u> The O_3 unit was a trailer mounted system manufactured by Aquifine Wedeco Environmental Systems, Inc., (AWES), of Valencia, CA. O_3 was generated onsite and on-demand using 90% pure oxygen and a corona discharge type O_3 generator. The tank was sized to provide a minimum detention time of 10 minutes at 10 gpm.

<u>UV</u> The UV unit was provided by Aquionics, Inc., of Erlanger, KY. The unit was a medium pressure, high-intensity type. Manually controlled flow to the unit varied from 75 to 250 gpm.

<u>E-Beam</u> The E-Beam pilot unit was developed by High Voltage Environmental Applications (HVEA) of Miami, FL. The unit was housed in a trailer equipped with an electric generator to provide the necessary power (500 kV differential) to operate the system. The unit operated at a flow rate of 20 gpm during runs 1 through 4 and 10 gpm during runs 5 through 20.

<u>Chlorination/Dechlorination</u> The unit, provided by UVD Inc., was a skid mounted system consisting of chlorination and dechlorination 250 -gall contact tanks with mixers, chemical tanks with solenoid metering pumps, and residual instrumentation.

Results

<u>Dose-Response Relationships</u>

All technologies achieved bacterial reductions of 3 to 4 logs. ClO_2 , O_3, and chlorination/dechlorination achieved these levels over a full range of wastewater quality tested. UV showed lower effectiveness at SS concentrations above 150 mg/l.

Disinfection doses required to achieve a 4 log reduction of fecal coliform and of fecal coliform effluent concentrations < 1,000 cfu/100 ml, for ClO_2, O_3, UV, and chlorination/dechlorination, were found to be 8 mg/l, 40 mg/l, 55 mWs/cm^2, and 20 mg/l, respectively. The E-Beam did not achieve the 4 log bacterial reduction during any run and the disinfection levels did not appear to be a function of disinfection dose, wastewater quality, or delivery configuration.

Differing sensitivities of bacterial groups to each disinfection treatment

In the case of:

ClO_2 - enterococci showed a greater susceptibility and less variability in concentrations between 6 and 10 mg/l than did fecal coliform

O_3 - there were only minor differences between fecal coliform and enterococci

UV- enterococci showed a greater susceptibility than did fecal coliform and there was less variability in concentration

E-Beam - no trend was observed but effluent fecal coliform and *E.coli* were below the 1,000 cfu/100 ml effluent target for 25% of samples

Chlorine - enterococci showed a greater susceptibility between doses of 16 and 24 mg/l than did fecal coliform

Effect of Wastewater Characteristics on Technology Performance

In case of UV the effect of SS at concentrations > 150 mg/l decreased the disinfections efficiency. However, there is limited data on UV performance at SS concentrations higher than 150 mg/l. The remaining technologies showed no apparent trend of reduced disinfection effectiveness with increased SS concentrations.

Reliability of the Units

The ClO_2, UV, and chlorination/dechlorination units showed a reliable performance. The O_3 pilot was slightly less reliable. The E-Beam unit was not designed for testing of CSO that contains particulate matter. The unit's delivery system was found to be clogging with solids and did not allow for sufficient electron penetration throughout the entire contact area. An increase in energy (dose) did not show increased disinfection efficiency. It is likely that a portion of the wastewater was not treated. As a result, this test did not show the full potential of E-Beam technology for disinfection.

Cost Comparison and Energy Use

In this study the cost comparison of disinfection systems tested was tailored for application to the Spring Creek AWPCP. It appears that chlorination/dechlorination and ClO_2 are most cost effective for this facility. E-Beam, UV, O_3, ClO_2, and chlorination are listed in order of decreasing energy use.

FUTURE NEEDS (Field *et al.*, 1996, Field and O'Connor, 1997)

Pilot Testing

- Pilot testing of improved disinfection technologies, such as the UV-light generated ClO_2 system, on CSO and SSO

- Evaluate the effects of adequate mixing on performance of disinfection technologies
- Develop realistic and thorough cost estimates for new disinfection technologies
- Repeat pilot testing of E-Beam technology with equipment suitable for WWF

Research

- Evaluate byproducts of disinfection for promising technologies
- Evaluate potential for bacterial regrowth following disinfection
- Evaluate development of viral indicators in addition to bacterial indicators for determining disinfection effectiveness
- Evaluate effect of particle occlusion as impairment of disinfection efficiency since microorganisms can be contained or occluded inside larger protective solid particles

ABSTRACT

The Rouge River National Wet Weather Demonstration Project (RPO) is a federally funded initiative with the objective of developing demonstration projects to evaluate a variety of urban nonpoint source pollution (NPS) reduction best management practices (BMPs) for the Rouge River watershed. These demonstrations will in sum improve the quality of storm water runoff to the Rouge River. The function of wetland filtration for water quality improvement has been recognized as one potential BMP.

Wetlands increase storm water detention capacity, increase storm water attenuation, moderate low flows, and improve water quality by removing nutrients, sediments and metals. The goal of this wetland demonstration project was to evaluate the effectiveness of freshwater wetlands in the treatment of storm water. The wetland demonstration project (WETL-1) utilized existing, enhanced, and created wetlands to demonstrate the value and effectiveness of wetlands in treating storm water runoff. Future evaluations will identify pollutants removed by the demonstration wetlands, the efficiency of the removal processes and the effects of sediments on this removal efficiency.

This manuscript summarizes the WETL-1 activities including wetland design, construction, and monitoring required to implement the Rouge River wetlands demonstration project.

KEYWORDS

storm water, wetlands, forested wetlands, runoff treatment, water quality

INTRODUCTION

The Rouge River National Wet Weather Demonstration Project is a federally funded initiative with the objective of developing a wet weather management plan for the Rouge River watershed that will improve water quality. The project includes a variety of demonstration projects which, in sum, will improve the quality of storm water runoff to the Rouge River. The Rouge project includes a variety of demonstrations of urban Nonpoint Source Pollution (NPS) reduction methods known as best management practices (BMP's). These methods include structural controls, source controls, treatment of impoundment sediments, detention basins, public participation and wetland treatment. This report summarizes the activities associated with the WETL-1, wetlands demonstration project.

The Rouge River, located in southeast Michigan, runs through the most densely populated and urbanized land area in the state. It is approximately 465 square miles and includes 48 municipalities in three counties, with a population of 1.5 million people. Pollution is a significant problem throughout the Rouge River Watershed. The State of Michigan Water Resources Commission has indicated that the water quality of the Rouge severely impairs the designated uses of the river, including recreation, water supply, aesthetics, and aquatic organisms.. The demonstration projects, in sum, will improve the quality of storm water runoff to the Rouge River and hopefully reinstate the River' designated uses.

JJR incorporated in association with Tilton & Associates worked together to develop a demonstration project to evaluate whether wetlands can be used as a low cost alternative to treating pollutants from storm water runoff. The alternative is one of the best management practices that the Rouge River Wet Weather Demonstration Project is interested in evaluating. The project is a demonstration of using existing, restored and created freshwater wetlands to control pollution from nonpoint source discharges. Wetlands are known to improve water quality by increasing storm water attenuation, moderating low flows, and removing nutrients, sediments and metals. This demonstration project will compare the pollutant removal effectiveness from storm water for four different types of wetlands systems that occur in the landscape: 1) an existing forested wetland; 2) an existing wetland system that supports a combined forested, emergent and scrub/shrub; 3) a newly created emergent wetland; and, 4) a mature created emergent/shrub/scrub wetland system.

Four wetland areas were identified within the City of Inkster, north of Michigan Avenue between Inkster and Henry Ruff Roads. The design of the wetland projects as storm water pollution control sites incorporated features that allows for the manipulation of storm water flow, quantity and duration, and provides direct comparison of the effectiveness of pollution control in each of the wetland types. The contributing storm sewer drainage for each site was defined and modeled so that the effect of a given wetland area on water quality and quantity can be determined. Design criteria were developed from the modeled hydrological data in combination with characteristics of the available treatment area. Common elements of the design included the incorporation of a sediment forebay to filter the large particles before the storm water enters the wetland system; treatment of "first flush" for most storm events; engineered discharge outlets to the Rouge River with monitoring capabilities; and intermediate monitoring points where applicable..

METHODOLOGY

Although past storm water management designs utilized natural wetlands to treat storm water, regulatory agencies discouraged this approach. This position is primarily a function of jurisdictional policy implemented against poorly designed systems that have traditionally impaired the functional uses of natural wetlands. There is a lack of research on the quantity and quality of storm water that natural wetlands are capable of treating without being negatively impacted. Constructed wetlands in contrast, are being built specifically for treating point source discharges and storm water runoff. Consequently there is no intention of replicating ecological functions other than water quality treatment. Only a few examples of wetland BMP's occur in the Rouge River watershed.

The RPO included a demonstration of nonpoint source control from the use of existing, restored and created freshwater wetlands (WETL-1). The overall nonpoint source pollution (NPS) control strategy of WETL-1 has been documented in various publications available at the Rouge Project Office (RPO). The strategy consisted of demonstrating: 1) a site selection process that emphasizes the potential for integrated solutions, *"Selection of Appropriate Wetland Nonpoint Source Pollution Abatement Locations"* (RPO-NPS-TM36.00); 2) a basis for design development that accounts for wetland habitat protection and water quality improvement goals, *"Conceptual Design of Wetland Management Systems"* (RPO-NPS-TM37.00); 3) biological and water quality monitoring program unique to wetland habitats, *"Wetland Biological Monitoring Program"* (RPO-NPS-TPM48); 4) the operation and maintenance program for the wetland systems "*Operation and Maintenance Manual Nonpoint Work Plan (WETL-1), Task No. 3* (RPO-

NPS-TPM37.00). The current status of the wetland project of the RPO is that site selection, design development, monitoring plans and construction documents have been completed. Construction of the wetland projects was virtually completed in November 1996 and preliminary water quality monitoring data is now becoming available.

The intent of the WETL-1 project was to increase storm water detention capacity by utilizing wetlands in the Rouge River watershed. Wetlands increase storm water attenuation, moderate low flows, and improve water quality by removing nutrients, sediments and metals. The future goal of this demonstration project is to evaluate the effectiveness of the demonstration wetlands in the treatment of storm water. This evaluation will include identification of pollutants removed by the demonstration wetlands, the efficiency of the removal processes and the effects of sediments on this removal efficiency. Ultimately, the demonstration project will compare the pollutant removal effectiveness of different types of wetlands:

- An existing forested wetland;
- A mixed forested, open water and scrub wetland system;
- Newly created emergent wetland; and,
- A mature created emergent/shrub/scrub wetland system.

The basis for design of NPS control wetlands, regardless of whether the wetlands are existing, restored or created, presents an integrated approach that accounts for wetland ecology, wetland hydrology, water quality considerations, watershed characteristics and surrounding land use. Utilizing these guiding principles, a selection process was initiated to identify appropriate sites for wetland demonstration projects.

Site Selection Process

As part of this project, an extensive investigation was completed to identify and select appropriate wetland sites in the watershed where pollution abatement was feasible and prudent. The investigation included collecting relevant information to aid in the search for targeted wetland sites. The information included Michigan Resource Information System (MIRIS) maps, National Wetlands Inventory maps, soil maps, aerial photography, land use maps, recreation maps, Wayne County Rouge Program Office (RPO) Geographic Information System (GIS) mapping of storm water discharges, and existing and historical drainage maps. Utilizing this information, potential sites were field surveyed. The sites included existing constructed wetlands, naturally occurring wetlands, potential Combined Sewer Overflow (CSO) sites for constructing new wetlands, and sites draining approximately 100 acres where wetlands could be restored.

This investigation also included a review of the existing information on site specific wetland ecology, wetland ecosystem processes, and the use of specific wetland sites for the control of storm water. A review of the wetland types and existing plant communities existing in the watershed identified four wetland types: forested wetlands, wet meadows, scrub-shrub and shallow water wetlands. These Rouge River wetland types periodically flood with nutrient-enriched waters.

A total of 25 sites (9 constructed, 13 existing, and 3 CSO) were considered as potential nonpoint source abatement locations. Five Areas were selected (3 existing and 2 constructed wetlands) as prudent and feasible for further consideration. Technical Memorandum, *"Selection of Appropriate Wetland Nonpoint Source Pollution Abatement Locations"* *(RPO-NPS-TM36.00)* is available from the Rouge Program Office for review. These Areas are located within the City of Inkster, north of Michigan Avenue between Inkster and Henry Ruff Roads. A created wetland built approximately eight years ago in West Bloomfield Township has also been selected to evaluate and compare its effectiveness with newly created wetlands.

Wetland Design Development

The design of the wetland projects as NPS control sites incorporated features that allows manipulation of storm water flow quantity and duration, and allows for the direct comparison of the effectiveness of NPS control in existing and created wetlands receiving storm water runoff from a single watershed. Design criteria for each of the wetland areas were developed from modeled hydrological data in combination with characteristics of the available treatment area. The wetland creation and enhancement areas contain similar design elements that provide comparable experimental data which can be related to known design parameters. These elements include the incorporation of a sediment forebay to filter the large particles before the storm water enters the wetland system; treatment of "first flush" for most storm events; designed discharge outlets to the Rouge River with monitoring capabilities; and, intermediate monitoring points where applicable. The contributing storm sewer area for each area has been defined and modeled so that the effect of a given wetland area on water quality and quantity can be determined. The influence of directly adjacent land is assumed to be negligible.

Design Characteristics of Wetland Area 1. Wetland Area 1 is designed to demonstrate the efficiency of storm water treatment by a newly created emergent wetland. Approximately 3.0 acres of emergent wetland was designed and constructed to receive storm water from an approximately 48 acre older residential neighborhood. Storm water from the storm sewer area was being discharged through a short swale directly connected to the Rouge River. The design elements of Area 1 includes a sediment forebay, designed to capture the storm water flowing from the existing 42-inch storm. All of the storm water from each rain event is directed to the wetland system via the sediment forebay and a vegetated swale.

Soil boring information was acquired to document and test wetland creation designs with varying soil types. Area 1 was evaluated to determine the need for a clay liner in sandy soils, soil fertility, soils in direct contact with ground water, etc. An outlet structure was designed that included a manhole for the installation of water quality and flow monitoring equipment. Manipulation of flow rates and retention periods may be discontinued at the end of the demonstration period. The wetland area however has been designed to be sustained by the contributions from the existing storm sewer area. This area will continue function as an emergent wetland after completion of the demonstration project

Design Characteristics of Wetland Area 2. Among the demonstration sites the project selected two forested wetlands. These were selected to demonstrate the effectiveness of this type of wetland in controlling NPS control. The majority of the existing wetland habitat in the Rouge River watershed is forested and forested wetlands are common in certain parts of the world. The demonstration of the effectiveness of forested freshwater wetlands in control of NPS pollution is critical to the long-term implementation of a wetland component in a comprehensive NPS management strategy. Forested wetlands, as NPS control sites have not been widely studied, although emergent and open water systems have been studied and are utilized much more frequently. One of the more frequent negative environmental impacts of the use of forested wetlands is flooding and destruction of tree species and subsequent loss of forested wetland habitat. The site selection methodology and basis for design of the forested wetland basins were adapted to account for the sensitive nature of these wetlands and the hydrologic impacts of using forested wetlands will be assessed. Demonstrating the use of forested wetlands as effective NPS control sites and, perhaps more importantly, demonstrating the design elements necessary to protect forested wetland habitat from adverse impacts associated with NPS control is one benefit of the demonstration project.

Wetland Area 2 is proposed to demonstrate the efficiency of storm water treatment by an existing forested wetland. Approximately 3.0 acres of forested wetland has been enclosed by small berms designed to retain a specified amount of storm water from the storm sewer area. Storm water from approximately 165 acres of mixed land use has historically been discharged directly to the Rouge River via a 60-inch pipe. Area 2 wetland utilizes a lift station to deliver a specified portion of the storm water from the storm sewer to the wetland. Storm water is transported to the wetland area from the storm sewer via an underground pipe into a catch basin designed to function as a sediment forebay. Both the pipe and catch basin are constructed in an upland area. The wetland area is enclosed by a berm along the northern boundary of the site to isolate it to a known and measurable area. This berm runs parallel to the Rouge River and is set at an elevation of 610 which will be crested by 100 year flood waters from the Rouge River.

This wetland previously discharged water to the Rouge River at one location situated at the far eastern point of the site. Overflow from wetland Area 2 will continue to discharge from this location. The outlet has been modified to control the outflow rate and allow for monitoring activities. Minor grade modifications were necessary for the installation of a weir and valve to control outlet flow levels. The low point of the weir has been set to retain water within the wetland and slowly release it to the Rouge River.

Design Characteristics of Wetland Area 3. Area 3, is also located south of the Rouge River between Inkster and Middlebelt Roads, approximately 1,800 feet west of Area 2. The entire site is within the 100 year floodplain of the Rouge River. The site is bisected by an 80 foot long channel which currently conveys storm water runoff from the 183 acre, residential and commercial watershed directly to the Rouge River. The ditch has partially filled with sediments resulting in some storm water flow being diverted to the wetlands on the east and west sides of the ditch. The 4.7 acre wetland on the east side of the ditch contains forested/scrub/shrub/emergent and open water communities. Existing vegetation includes willow, cattail, water plantain, elm, cottonwood, sedges, rushes and snags. Water discharges from this wetland to the river through a shallow swale along the site's eastern river bank.

Approximately 2.4 acres of emergent/scrub/shrub wetland are located along the west side of the ditch. This wetland also receives storm water from the existing sewer line due to the clogged ditch. This wetland contains primarily willow, dogwood and cattail. While no detailed hydrogeologic data has been collected, moderate base flow in the ditch indicates groundwater may also contribute to the wetland hydrology.

Wetland Area 3 contains two separate treatment areas, 3-East and 3-West. A sediment forebay is located at the inflow of each wetland area. Three outlets were constructed in this basin to direct first flush and small storm event flow to wetlands 3-East and 3-West, and overflow from larger storms is discharged directly to the Rouge River through an existing swale.

Wetland Area 3-East is an existing wetland system that supports forested, emergent, scrub/shrub, and open water systems. The objective of the design is to enhanced the flow through this wetland to utilize each of the wetland types in the treatment of storm water. The designated area is enclosed by eighteen inch berms. Storm water flow from the sediment forebay is discharged into the existing wetland. A containment berm was constructed along the northern portion of the wetland area. Within the wetland the flow achieves a maximum flow length ratio and utilizes various wetland types in the treatment train. Berms do not impede the 100 year flood flow from the Rouge River flood conditions. Area 3-East drains to the Rouge River at a low point located along the eastern boundary. Overflow from this area will continue to discharge from this location. The outlet has been modified to control the flow rate and allow for monitoring activities

Wetland Area 3-West contains an emergent and scrub/shrub wetlands created within a former upland area. The created wetland was apportioned into two areas; one and two acre wetland cells. Flow from the sediment forebay is released directly into this one acre wetland. The succeeding wetland is approximately two acres in size. This sizing allows for an assessment of water quality treatment from specified areas of created wetland. The water flows through this two tier system to an outlet to the Rouge River. This outlet is located at a naturally occurring low point within the forested wetland along the River's banks. A controlled outlet structure was installed at the outlet point to control retention time, water depth and allow for monitoring activities. These wetlands are created in conjunction with wetland mitigation; therefore, they are designed to function as wetlands with minor modifications, if any, after the demonstration is completed.

Construction of the Wetland Project. Construction documents and specifications for the construction of these projects were completed in November 1995. Bidding and award of the projects allowed construction to begin in February, 1996. Construction was substantially complete in November 1996. The construction schedule for these projects was extended by approximately five months. Various reasons accounted for project delays including; spring flooding of the Rouge River, vandalism of power supply panels, delays in equipment orders, unknown utilities encountered and land owner disputes. The operation and maintenance of this wetland demonstration project requires regular inspections of earthwork, landscaping, structural components and other aspects of distribution system. The construction contractor as part of the contract has provided this task. An *Operation and Maintenance Manual* (RPO-NPS-TPM37.00) was prepared for the wetland projects. A written summary of Operations and Maintenance activities is provided on an annual basis.

RESULTS

Initial data results are now being reported. The following tables represent the average of six wet weather events collected from September 1996 to September 1997: Table 1) West Bloomfield Wetland, a mature created wetland; Table 2) Wetland Area 2, forested wetland and Table 3) Wetland Area 3 East, a mixed community wetland. The results indicate that nearly every measured pollutant of storm water was significantly reduced through the wetland treatment system. Nitrate and nitrite nitrogen removal percentages ranged from 22 to 53 percent; Total Phosphorus removal efficiency ranged from 11 to 43 percent; Total Suspended Solids were reduced from 63 percent up to 86 percent; and heavy metals removal percentages were reported from 10 percent to 73 percent reduction. In a few cases some parameters increased, most notably ammonia nitrogen, total kjeldahl nitrogen and orthophosphate. The averages for these parameters were elevated primarily due to late summer sampling events when plant die-off and decomposition skewed the results. The summary of the results reported thus far are typical of what has been reported in the literature for wastewater treatment wetlands (Hammer and Kadlec, 1983). All of the wetlands will continue to be monitored for the next five years including the forested and enhanced wetland systems. The results will be tabulated and published through the Rouge Program Office and will be presented on the Internet Web Page at the RPO.

DISCUSSION

The use of wetlands for wastewater treatment has been researched for approximately twenty years. The results of this body of information define the effectiveness of wetlands in pollutant removal efficiency in wastewater treatment systems. However, this information may not be directly applied to the use of wetlands for nonpoint source treatment systems. Specifically, the two systems are different in hydrology, pollutant loading, pollutant characteristics, and operation and maintenance practices. Wastewater treatment wetlands tend to receive a constant flow of water whereas storm water systems receive pulse loading of storm water with inconsistent pollutant levels. Typical pollutant removal rates reported in the literature for wastewater systems include: 75-93 percent for Total Suspended Solids; 70-90 percent for BOD; 30-50 percent for total phosphorus; and 75-95 percent for total nitrogen.

Under the Clean Water Act, the EPA has responsibilities for wetland protection and specifically for regulation of discharge of waterborne pollutants (Section 401 and 402). The use of natural wetlands has been a source of controversy for receiving storm water runoff. The EPA does not support the use of natural wetlands for treating storm water due to the potential ecological and environmental degradation of the wetland. This position is primarily a function of jurisdictional policy implemented against poorly designed systems that have traditional impaired the functional uses of natural wetlands. There is a lack of research on the quantity and quality of storm water that natural wetlands are capable of treating without being negatively impacted. The use of natural wetlands in treating storm water may be considered, particularly in an urban setting if; 1) other treatment options are limited; 2) the existing wetland has been disturbed or degraded thereby limiting its plant and animal diversity; 3) the existing wetland is small, isolated, and incidental compared to the watershed area; or 4) the existing wetland could be enhanced by increasing the amount of flow and increasing its biodiversity.

This project has only begun to evaluate the effectiveness of freshwater wetlands in treating storm water runoff. To date only a limited number of sampling events have occurred and in the case of Wetland 3 West, a newly created wetland, sampling will begin in the spring of 1998. Future evaluations will quantify the pollutants removed by the demonstration wetlands, the efficiency of the removal processes, direct comparisons of pollutant removal efficiencies for different wetland types and the effects of sediments on this removal efficiency. Biological monitoring running concurrent with the water quality monitoring will closely monitor the wetland ecosystem as the project progresses. In addition, tissue analysis is being proposed on aquatic organisms to determine if bioaccumulation of heavy metals should be of concern in wetland treatment systems.

CONCLUSIONS

The initial results look promising as the natural wetlands and created wetlands are removing a significant amount of pollutant loading that would otherwise be discharged to the Rouge River. Future strategies that would consider the incorporation wetland treatment systems into a storm water management plan should be seriously considered.

Assessments of the benefits relative to these wetland systems will be provided on an annual basis for five years in separate biological and water quality monitoring report. Three annual biological monitoring reports, RPO-NPS-TPM48.00, RPO-NPS-TPM48.01 and RPO-NPS-TPM48.02 (pending) have been prepared to develop baseline information. Direct assessment of pollutant removals started in the spring of 1997 when the wetland water quality-monitoring program was implemented and initial data results reported. Preliminary assessments indicate that the hydrology of the existing forested wetlands has been slightly modified during the study. In anticipation of this altered hydrology a tree survey was completed as part of the biological monitoring report. All trees greater than six inches were surveyed using GPS technology. The trees identified exhibit a wide range of tolerance to inundation. Therefore, it is not anticipated that the altered hydrology will greatly affect the wetland areas. The volume of water flowing through the systems is being monitored and controlled so as not to be significantly different from the pre-construction condition. The wetlands will continue to be monitored closely to ensure the existing function and structure are not impaired.

ACKNOWLEDGMENTS

We would like to thank representatives from Wayne County Department of the Environment, Rouge Program Office staff, and the U.S EPA for their assistance in the implementation of this wetland demonstration project. The Rouge River National Wet Weather Demonstration Project is funded, in part, by the United States Environmental Protection Agency (EPA) Grant #X995743-01, #X995743-01, #995743-03 and #C995743-01. The views expressed by the authors are their own and do not necessary reflect those of EPA.

Costs associated with the construction and monitoring of the existing wetland projects were borne by money made available through Rouge River Demonstration Funds as approved by the EPA Region V, MDEQ, and Wayne County. In addition to the two forested wetland areas, two created wetlands were developed under grant money designated for wetland creation within the Rouge River watershed. The money was designated under an MDEQ permit which required Waste Management of Michigan, Inc. (WMI) to provide Wayne County a grant to create wetlands within the Rouge River watershed for the purpose of providing water quality improvement to the Rouge River (RPO-NPS-TM35.00).The created wetlands have been designed to function in perpetuity and will be monitored as required by MDEQ. In addition to monitoring the success of the wetland creation, all of the wetlands are monitored for water quality improvement by the RPO.

ABSTRACT

The New York City Department of Environmental Protection (DEP) has conducted a study to analyze the feasibility of utilizing supplemental aeration in conjunction with a combined sewer overflow (CSO) facility proposed at Paerdegat Basin, Brooklyn, NY. The goal of the study was to determine the overall cost effectiveness of limiting the amount of conventional CSO storage required, and supplementing dissolved oxygen levels within Paerdegat Basin through either in-stream or side-stream aeration.

Unlike existing current uses of aeration to supplement dissolved oxygen levels in water bodies, this study considered the technical aspects of implementing aeration within a marine environment in a narrow man-made tributary extending over a mile inland from Jamaica Bay.

In addition, original computer models and water quality projections developed for the proposed Paerdegat Basin Water Quality Facility plan were updated and run for varying levels of CSO abatement supplemented with aeration. Specifically, aeration modeling was based on the USEPAs aeration design theory, with consideration given to calculation of oxygen transfer efficiency based on receiving water conditions. Additionally, a fine-grid water quality model was developed to represent conditions within Paerdegat Basin, and assist in the design of an aeration distribution system.

Considering CSO controls and supplemental aeration analyzed in this study, a recommendation for attainment of water quality dissolved oxygen standards in Paerdegat Basin was developed.

KEY WORDS: Combined Sewer Overflows, Water Quality Standards, Water Quality Modeling, Dissolved Oxygen, Aeration

INTRODUCTION

Studies conducted by the New York City Department of Environmental Protection (NYCDEP) in the late 1970's showed that Paerdegat Basin, located in southeastern Brooklyn, New York, was severely impacted by degraded water quality conditions. Combined sewer overflows (CSOs) were identified as a major source of the pollution entering Paerdegat Basin, contributing to significant violations in the New York State Department of Environmental Conservation (NYSDEC) state water quality standards for dissolved oxygen (DO), coliforms, floatables and settleable solids.

The Paerdegat Basin Water Quality Facility Plan (September, 1991), as developed, included the reduction of CSO impacts through the maximized use of existing facilities (sewers, interceptors, and water pollution control plants (WPCPs)), and construction of a 30 million gallon (MG) off-line CSO retention tank. The resulting CSO retention facility had a capacity (in-line and off-line storage) of 50 MG.

The original CSO plan had an estimated construction cost of approximately $200M (million) and resulted in significant water quality improvements in Paerdegat Basin. Model projections indicated up to an 80% reduction in biochemical oxygen demand and suspended solids discharged. Total coliform levels would be similarly reduced by 95%. Based on these performance levels, it was projected that required DO levels would be met throughout Paerdegat Basin, except at the head end where they were projected to drop to 3.0 mg/L about 1% of the time as a result of heavy rainfall conditions. At all other times, DO levels were above the NYSDEC standard of 4.0 mg/L.

Subsequent to development of the Paerdegat Basin Facility Plan, an alternative proposal was presented by the NYCDEP in the Jamaica Bay Comprehensive Watershed Management Plan (December 1993). This alternative proposal asserted that similar water quality improvements in Paerdegat Basin could be achieved through the volumetric reduction of CSO storage capacity, while simultaneously supplementing the reduced storage volume with aeration. The proposed system was to fully comply with dissolved oxygen standards in Paerdegat Basin.

The goal of investigating supplemental aeration for Paerdegat Basin was to evaluate the technical feasibility of using aeration technologies to supplement a reduction in CSO retention volume. This paper describes the engineering evaluation that was conducted to evaluate the feasibility of applying various aeration alternatives to a revised CSO facility design at Paerdegat Basin. It was concluded from this evaluation that the reduction of CSO retention volume can be supplemented with aeration to maintain adequate levels of dissolved oxygen in the basin, and potentially reduce overall project costs.

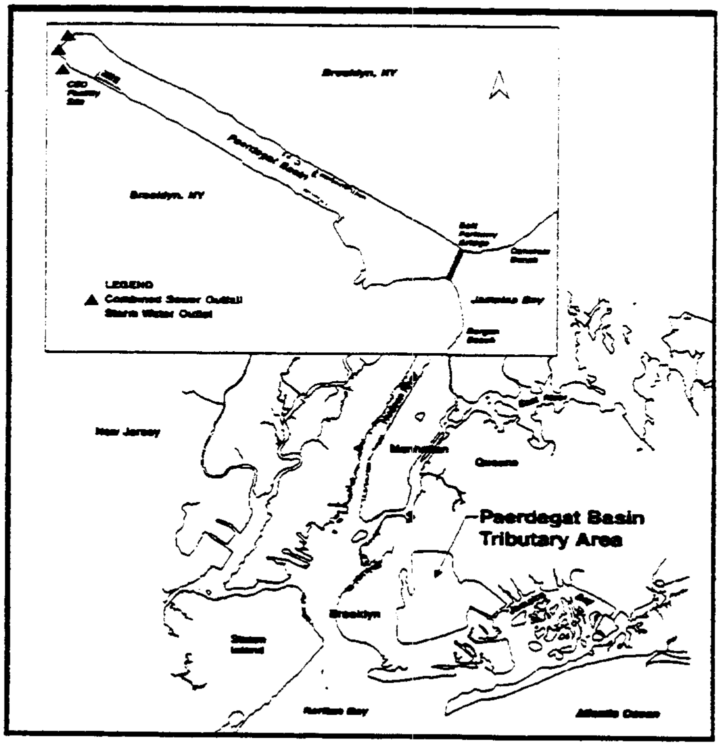

Figure 1 - Location Plan

Project Area

Paerdegat Basin is a rectangular, dead-end channel approximately 6,600 feet long, 450 feet wide at points, and varying from 1 to 16 feet in depth depending on tidal conditions. The basin is located in southeastern Brooklyn, New York and receives combined sewer overflows (CSO's) from a drainage area of approximately 6,000 acres. The basin receiving waters have been designated Class I by the NYSDEC where fishing and secondary contact recreation is its' best intended use. The NYSDEC enforces a dissolved oxygen standard of never less than 4.0 mg/L in Paerdegat Basin.

Paerdegat Basin is tributary to the larger Jamaica Bay situated to the east, where the waters are designated by NYSDEC as Class SB. Class SB waters have a higher DO standard which is never less than 5.0 mg/L. Figure 1 shows the general location of Paerdegat Basin, its proximity to Jamaica Bay, and the contributing drainage area.

METHODOLOGY

Discussion of Aeration Technologies

Several systems are currently available for the artificial aeration of natural water bodies with low DO levels such as Paerdegat Basin. Systems including direct in-stream aeration through the use of shore-mounted blowers, air distribution piping and a network of bottom-mounted diffusers were considered. Additionally, side-stream aeration systems where low DO water is pumped to a shore-side aeration tank and aerated by forced air diffusion (such as used in water treatment processes), or a cascade system were considered. Technology reviews of alternative applications currently available for aeration, including systems utilizing pure oxygen injection or ozonation were also considered.

One of the major engineering obstacles facing successful aeration of a large body of water such as Paerdegat Basin involves not only the direct application of a sufficient quantity of oxygen into the water, but also completely distributing it throughout the water column. This task was further complicated by the relatively stagnant waters of Paerdegat Basin, where complete flushing of the basin has been estimated to occur only once during a period of fourteen (14) tidal cycles.

Preliminary Evaluation of Aeration Technologies

Each of the aeration technologies identified below was subjected to a preliminary screening process. Each technology was evaluated with consideration given to cost, technological constraints, siting issues, environmental issues, community concerns, operation and maintenance, permitting, and other issues.

Aeration technologies reviewed included:

1. In-stream mechanical aeration;
2. In-stream natural aeration;
3. In-stream forced air diffusion;
4. Side-stream forced air diffusion;
5. Side-stream cascade aeration;
6. Side-stream aeration with pure oxygen, and
7. Ozonation.

In-Stream Mechanical Aeration

An in-stream mechanical aeration system consists of equipment placed on the water surface that is designed to mechanically agitate the water column. Mechanical surface aerators are conceptually one of the simplest aeration equipment presently available, which is one of their advantages over other technologies. They consist of a submerged or partially submerged impeller attached to a motor that is either anchored to the basin bottom or fixed on platforms/structures. The impellers agitate the water column vigorously while simultaneously entraining air into the water. In some cases, surface aerators are equipped with submerged draft tubes that enhance mixing by bringing liquid from the bottom of the water column up through the tube and into the aerator's impeller. It is worth noting that draft tubes are normally used where the depth exceeds 15 ft.

Another type of mechanical surface aerator is the motor-driven propeller aspirator consisting of an electric-driven propeller submerged at the end of a hollow shaft. The action of the propeller rotation draws air from the atmosphere through the shaft. Combined air velocity and propeller action creates turbulence forming small bubbles that diffuse oxygen into the water column. This type of aerator can also be floating or permanently platform mounted.

Both of the above types of in-stream mechanical aerators would require shore-side construction to locate the electric service and house the control equipment. Power to the units can be either floating or bottom run. In addition, a pullout station equipped with a crane to remove the surface aerators, and provisions to load and off-load trucks for transport to a storage/maintenance facility could also be provided.

The advantages of using mechanical surface aerators over other types of aeration for Paerdegat Basin is that they are relatively simple to operate, and have a good maintenance record. They can also be taken off-line easily and spare units activated if necessary. They also have the capability of operating under changing process conditions and have excellent mixing action.

Disadvantages include the mooring system requirements, the shore-side support facility required, the power distribution to the individual units, and the impact on the basin's accessibility for recreational boaters. The impact on basin's accessibility resulting from the floating units is considered a major disadvantage to the ultimate goal of the water quality restoration of Paerdegat Basin and its use as a passive recreational water body. As a result, the use of mechanical aerators for in-stream mechanical aeration at Paerdegat Basin was not further developed.

In-Stream Natural Aeration

An in-stream natural aeration system is a relatively simple system utilizing coarse bubble technology. Airflow to the basin is distributed through a series of perforated hoses and/or pipes located on the basin bottom, and attached to a shore-side air supply system. Aeration is accomplished without the use of diffusers and is employed generally for mixing stratified water bodies. During the mixing process, bottom layers having low DO levels are brought to the surface and mixed with higher DO waters. At the surface, reaeration occurs by direct transfer from the atmosphere. Bubbles rising through the water column also transfer oxygen to the water body, as well as aid in transporting the low DO water layer to the surface. Oxygen transfer in this manner is more efficient however, in water bodies with greater depth.

In-stream natural aeration systems have been used primarily in lakes and water supply reservoirs for mixing purposes. Because these systems are designed primarily for mixing, they tend to be of smaller capacities. Additionally, aeration is primarily accomplished by vertical mixing actions in a stratified water body. Direct diffusion of air is a secondary transfer mechanism in this application, and is typically more effective at greater depths. Paerdegat Basin is considered a shallow water body without much stratification, and is therefore not a good candidate for natural aeration technology.

In-Stream Forced Air Diffusion

An in-stream forced air diffusion system would consist of equipment typically located on the bottom of the water body, designed to diffuse air up through the water column thereby accomplishing oxygen transfer. The complete diffused air system would consist of porous or non-porous submerged diffusers, headers, air mains, and the blower and appurtenances through which the air passes.

While the most common materials of construction for the diffuser is ceramic, many types of materials have been utilized. Porous diffusers also come in many types, such as plates, tubes, domes and discs. Plates, domes and disc diffusers are normally installed in a total floor configuration, but they also have been placed along the perimeter of tanks or basins to generate a single or double roll pattern. Disc and domes are normally arranged in a grid pattern with variable spacing. Generally, full floor coverage is the most efficient diffused aeration configuration.

Non-porous diffusers are available in a wide variety of shapes and materials and have larger orifices than porous devices. Non-porous diffusers can vary from simple holes drilled in piping to specially designed openings in metal or plastic devices. Typical system layouts for non-porous diffusers are similar to those of porous diffuser systems.

Oxygen transfer to the water column is much greater with a decrease in the bubble size. Therefore, fine bubble diffusers generally have the highest oxygen transfer efficiency. There are times when actual field and/or process conditions preclude the use of fine bubble technology, and medium and coarse bubble diffusers are used. While fine-bubble diffusers are more efficient at the transfer of oxygen to water, they could potentially prove problematic (i.e. clogging) in Paerdegat Basin due to the solids and sediment in the basin. Therefore, coarse bubble technology was considered for this particular technology, and all other technologies that were subsequently analyzed.

Side-Stream Forced Air Diffusion

A side-stream forced air system would require construction of a side-stream aeration tank adjacent to Paerdegat Basin. Under this scenario, porous or non-porous diffusers would be utilized to transfer oxygen into the water column.

A side-stream aeration tank would be constructed of reinforced concrete and could be either open to the atmosphere, or covered to control potential volatile organic compounds (VOC) emissions. Air would be transferred to the flow within the side-stream aeration tank via porous and/or non-porous diffusers. The actual choice of diffuser would impact the side-stream aeration tank's configuration and geometry.

Implementation of this type of aeration system would also require construction of an inlet pumping station consisting of instrumentation and mechanical controls, influent channels, mechanical bar screens and screening handling/disposal, isolation gates, and distribution channels to the aeration tanks. The air supply system would consist of centrifugal blowers housed in a blower building, air discharge manifolds, and air supply piping, all located adjacent to the aeration tank.

The advantages of using a side-stream forced air diffusion system for Paerdegat Basin is that it is a proven efficient means of supplying and transferring oxygen to a liquid. The entire system would be land-based making maintenance and operation easier over previously discussed in-stream systems.

Disadvantages of the side-stream forced air diffusion system is that it would require extensive structures be built along the basin, and also requires both pumping and air supply systems be operated and maintained. It will also require an outfall to distribute the aerated flow back to the head of the basin.

Side-Stream Cascade Aeration

A side-stream cascade aeration system would consist of pumping water from Paerdegat Basin to a series of elevated on-shore shallow pools that are linked by cascades. Discharge of aerated flows would also be through an outfall structure/piping back to the basin.

The on-shore pools would be constructed at an elevation that would allow water from the first pool to flow into a series of progressively lower pools, eventually discharging back to the basin. The pools would be relatively shallow and constructed of reinforced concrete, with flow discharging from each pool via a series of weirs. Aeration would occur as a result of the free fall over the weirs and the resulting turbulence of flow in the next pool. A rough spillway surface could also be designed to further enhance the aeration rate.

Either screw or centrifugal pumps would be used to pump the water to the cascade pools. Screw pumps have an added advantage in that the design of the open screw also allows simultaneous aeration of the flow during transport. An intake structure is required and would be constructed of reinforced concrete. The facility would also include a bar screen, screenings handling and disposal, a series of isolation gates, and distribution piping to the cascades. The pump station would include multiple units to pump the range of flows as process conditions dictate.

As discussed above, use of any of the side-stream alternatives will require the use of an outfall system to return the aerated flows to the basin. The discharge could be from a single point or through a manifold system to provide effective mixing.

Side-Stream Aeration Utilizing Pure Oxygen/Ozonation

A pure oxygen system is complex both mechanically and operationally requiring a specially trained operations staff. A backup liquid oxygen facility would require liquid oxygen supplies be periodically trucked onto the site. A pure oxygen system is also a highly energy-intensive system.

Ozone is also a strong oxidizer and therefore, is very corrosive. Special consideration must be given to all components and tanks used in an ozone system.

In light of these issues, a side-stream aeration system utilizing forced pure oxygen or ozone generation is not recommended for usage at Paerdegat Basin.

Aeration System Design Conditions

The selection of a supplemental aeration technology for Paerdegat Basin was dependent on many varied factors. These factors include the quantity of aeration required, technical characteristics of aeration equipment and the physical and environmental parameters of Paerdegat Basin.

During this evaluation, a range of CSO retention volumes (combined volumes of both in-line and off-line storage) were evaluated in conjunction with aeration. It was found that to reasonably improve the DO levels throughout Paerdegat Basin, a CSO volume reduction of 10 MG (for a total in-line and off-line combined sewer storage of 40 MG) coupled with the addition of 20,000 lbs/day of oxygen (O_2) was necessary. Assuming that water entering the basin is at 90 percent (%) of saturation, or 6.3 mg/L (temperature dependant), each technology was sized appropriately to deliver the required 20,000 lbs/day of O_2.

Water Quality Modeling

An existing three-dimensional water quality model originally developed for Paerdegat Basin was modified to provide a finer spatial modeling grid at the headwaters of the basin, while also allowing evaluation of the impacts of distributing aerated flows to the basin. The original receiving water quality model utilized during preliminary design of the Paerdegat Basin facility was developed using a six-layer model adapted for existing conditions found in the basin. The original model considered the basin in segments spanning the entire width of the basin extending from the bulkhead located at the farthest upstream reach, out into Jamaica Bay. Each segment averaged approximately 500 feet in length towards the head end, becoming larger as it approached Jamaica Bay. The model also included CSO loading and the interaction between the water column and the underlying basin sediments.

The original model was re-developed to include a finer-grid layout at the head end of the basin. The first 1200 feet of the waterway was subdivided into 100-by 100-foot boxes, with 10 layers in the vertical plane. These modifications allowed detailed evaluation of the receiving waters throughout the head end of Paerdegat Basin, and provided insight into the most cost-effective aeration distribution layout.

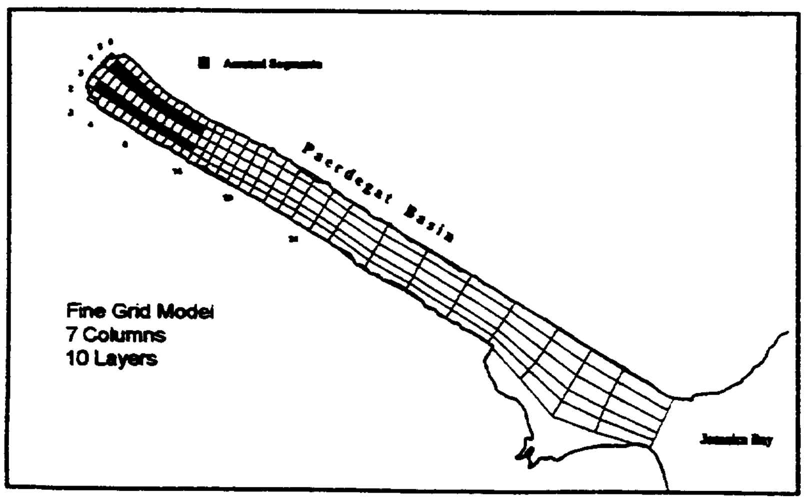

Figure 2 - In-Stream Aeration Model Configuration

Improvements to the DO levels were modeled for changing aeration configurations (both in-stream and side-stream) within the basin. Refinement of the model in this way allowed detailed analysis of aeration impacts on the water quality in distinct model segments of the receiving waters of the basin.

Various configurations were developed for evaluation of aeration layouts during the modeling process. Initial runs for the in-stream alternative included aeration of the entire head-end of the basin from shore to shore, and from the existing bulkhead to roughly 1,150 feet out (maintaining the aeration grid approximately 100 feet from the shoreline). A second alternative aerated two (2) strips 100 feet wide, again from the bulkhead at the head end, to 1,150 feet down the length of the basin. The final configuration maintained the two (2), 100 foot wide rows of aeration out to 1,150 feet from the bulkhead, but maintained a 100 foot distance off the bulkhead (see Figure 2). Modeling showed that sufficient mixing and aeration was obtained in this configuration while minimizing the number of diffusers required.

While the in-stream aeration problem centered on an economical location of the aeration grid within the basin, the concern with side-stream aeration proved to be where the basin water was withdrawn, and ultimately, where it was replaced. Several different configurations were examined including withdrawal at the side of the basin nearest the aeration facility, and replacement back to the headwaters where the DO deficit is the greatest. Numerous scenarios were examined in which the aerated water was pumped back to the head end in different locations. Ultimately, it was determined that to reasonably maintain acceptable DO, it was necessary to return the flow through outfalls and diffusers to three (3) model segments located just off the bulkhead (see Figure 3).

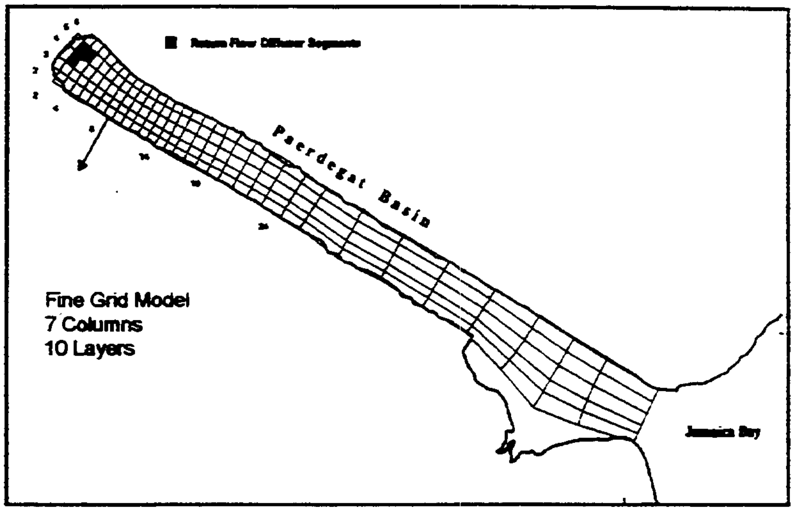

Figure 3 - Side-Stream Aeration Model Configuration

RESULTS

Evaluation of each of the aeration alternatives described above resulted in the selection of three (3) technologies for further development. Specifically, in-stream forced air diffusion, side-stream forced air diffusion, and side-stream cascade aeration. Each of these three (3) technologies was further designed based on several design criteria developed for the project. As mentioned previously, the NYSDEC water quality standard for Paerdegat Basin is never less than 4.0 mg/L. Further consideration was given to interim Long Island Sound Study standards of never less than 2.0 mg/L. In order to reasonably improve DO conditions in Paerdegat Basin with these goals in mind, a range of CSO retention volumes (combined volumes of in-line and off-line storage) were evaluated in conjunction with aeration. The combination of

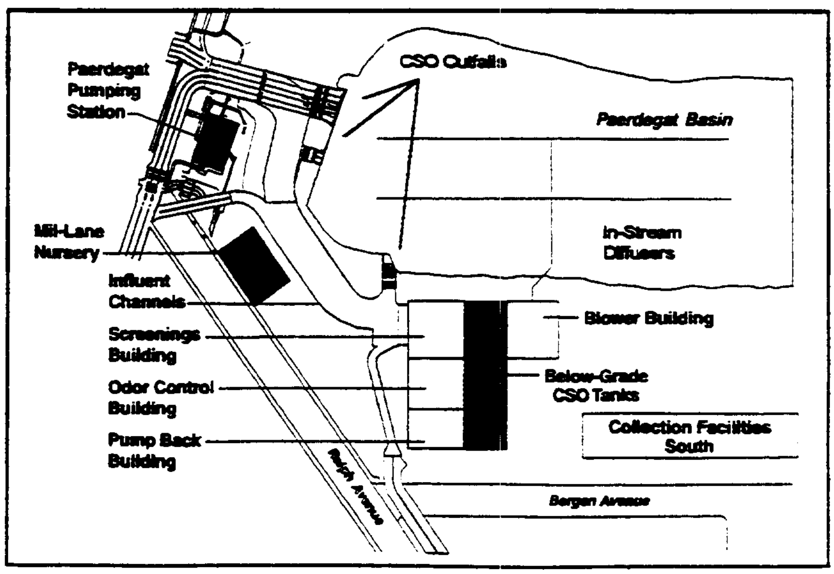

Figure 4 - In-Stream Aeration Site Plan

CSO volume reduction to 40MG with the addition of 20,000 lbs/day of oxygen (O_2) would be necessary to produce desired results in the basin. Each of the following technologies were further designed to supply the required amount of oxygen to the water body as discussed below.

In-Stream Forced Air Diffusion

Designing a coarse bubble aeration system to deliver 20,000 lbs/day of O_2 was the process criteria used to size the blowers, manifolds, headers, air distribution piping, and ultimately the diffusers. It was found that using four (4), 300 Hp centrifugal blowers during operation would be sufficient to deliver 29,400 standard cubic feet per minute (scfm) through 1,470 stainless steel coarse bubble tube diffusers, each with a capacity of 20 scfm, and located at the basin's bottom. The conceptual layout of the diffusers in the basin is shown in Figure 4.

Life cycle costs assumed the projects' useful life to be 20 years, with a yearly inflation rate of 3.4%. It was also assumed that some of the costs such as the availability of power, dewatering, geotechnical considerations, and dredging were already included in the cost of construction of the CSO retention facility.

Capital costs associated with the in-stream forced air diffusion technology were in the range of $11.8M, while operation and maintenance (O&M) costs were $0.67M. The resulting present worth cost was approximately $16.9M (see Figure 6).

Side-Stream Forced Air Diffusion

Design of the side-stream aeration tanks (see Figure 5) allowed the use of reduced process airflow rates compared to the in-stream option. This was in part due to the fact that the sidewall depth of the tank was now controllable. The average depth of Paerdegat Basin after construction of the CSO retention facility and final dredging would be roughly 12 feet at mean tide. The depth of the side-stream aeration tank was set at 20 feet to allow more efficient transfer of O_2 to the water column. Therefore, the required blower capacity was reduced considerably, requiring only 17,000 scfm capacity rather than 29,400 scfm. The resulting number of coarse bubble tube diffusers was also reduced to 850, again each having a capacity of 20 scfm and mounted at the bottom of the tanks. Process air requirements dictated that five (5) blowers, each 200 Hp, be capable of delivering 17,000 scfm of air to the tanks.

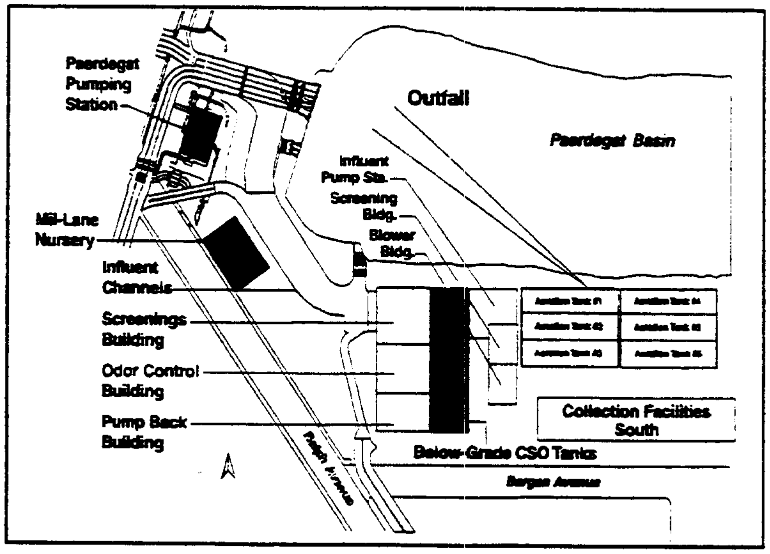

Figure 5 - Side-Stream Aeration Site Plan

Cost Comparison

	In-Stream Forced Air Diffusion	Side-Stream Forced Air Diffusion	Side-Stream Aeration Utilizing Cascades
◆ Capital Cost	$11,880,000	$38,730,00	$24,550,000
◆ O & M Cost	$667,000	$1,480,000	$1,170,000
◆ PRESENT WORTH OF CAPITAL & O & M	$16,900,00	$48,144,000	$32,950,000

Figure 6 – Aeration Technology Cost Comparison

A flow rate of 430 MGD, and hydraulic detention time of approximately 30 minutes, required that 4 aeration tanks be constructed, each measuring 200 feet by 50 feet by 20 feet deep. Pumping requirements of 430 MGD were met with four (4) pumps each with a capacity of 110 MGD. The aerated flows would be returned to the basin through 2-10 foot diameter submerged outfalls.

Capital costs associated with the side-stream forced air diffusion technology were in the range of $38.7M, while operation and maintenance (O&M) costs were $1.5M. The resulting present worth cost was approximately $48.1M (see Figure 6).

Side-Stream Cascade Aeration

Similar to the side-stream forced air diffusion alternative, the cascade system (see Figure 7) would also be required to pump 430 MGD from the basin to the cascades. Six (6) open screw pumps were chosen that were 40 feet in length, set at a 30-degree angle to horizontal, roughly 8 to 10 feet in diameter, and powered by a 420 HP electric motor mounted at the top of each screw. The cascades were designed to drop the flow over 18 feet, and required a weir length of 235 feet. This alternative would also require the construction of 2-10 foot diameter submerged outfalls to return the flow to the basin.

Capital costs associated with the side-stream cascade technology were $24.5M, while operation and maintenance (O&M) costs were $1.2M. The resulting present worth cost was approximately $32.9M (see Figure 6).

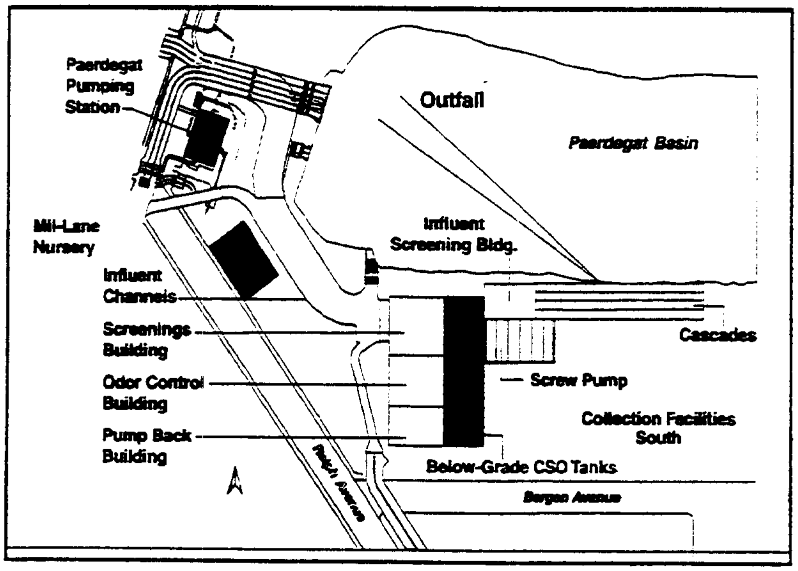

Figure 7 – Side Stream Cascade Aeration Site Plan

Discussion

While all three (3) of the aeration technologies for which additional design was evaluated have demonstrated their ability to improve low DO conditions existing in Paerdegat Basin during the summer months, each has distinct advantages and disadvantages.

Specifically, while the in-stream forced air alternative was demonstrated to be the least costly, the issues of permanent construction and continued maintenance within the waterway remains a disadvantage. In-basin maintenance would require either removal of the affected component, or the use of dive teams to locate and correct any problems. Other operational concerns center on the ability to keep the diffusers clean throughout the year. Expected increases in solids loading to the basin as a result of a reduced capacity CSO facility increases concerns of siltation and subsequent clogging of the diffusers. It is expected that the in-stream system will be operated during the off-season at a reduced air flow rate to lessen the impacts of clogging. However, the added expenses and continuous maintenance required throughout the year is another consideration.

Side-stream forced air diffusion lends to an easier air distribution system and diffuser network to both operate and maintain. All the equipment required for the operation is located on-shore, and as with aeration tanks located at WPCPs, an aeration tank can simply be taken off-line periodically for routine maintenance of the equipment. Another concern of relative significance is the cost of operation of the facility. Not only are there the operational costs associated with the aeration system, but there is the additional cost of pumping flow rates in excess of 400 MGD.

Side-stream cascade aeration appears to be the simplest system to both operate and maintain. Essentially, the only equipment requiring maintenance would be pumping and screening equipment. One drawback however, remains the extensive shore-side construction required.

A common disadvantage to both the side-stream alternatives involves the construction of a large outfall pipe to return the aerated flows back to Paerdegat Basin. Water quality modeling showed that the greatest positive impact on the waterway would be to return the aerated flows towards the head end of the basin. Return of these flows would require the construction of a large outfall structure capable of conveying the flows mentioned.

VOC generation is another concern common to all three (3) alternative technologies. However, the side-stream alternatives lend themselves to a solution. The side-stream tanks, at a significant addition to the construction cost, could be covered and the off-gases collected in some form of emission control system. VOCs generated by the in-stream aeration alternative cannot be readily contained, and remains as a disadvantage that would require further investigation.

CONCLUSIONS

Three (3) aeration technologies were further developed as having the potential to sufficiently raise the levels of DO in Paerdegat Basin throughout the summer months. Specifically, in-stream diffused air employing blowers and an air distribution network on the basin's bottom, and two (2) side stream alternatives were evaluated. One side-stream alternative relied on pumping equipment to bring the waters of Paerdegat Basin to an on-shore aeration tank, where aeration is accomplished using air distribution piping and coarse bubble diffusers. The second on-shore alternative utilized screw pumps to move water from Paerdegat Basin into a series of cascades designed to physically aerate the flow. Both side-stream alternatives would require construction of large outfall pipes to deliver the aerated flows back to Paerdegat Basin in model segments where it was shown through water quality modeling to be the most beneficial.

The exclusive use of any of the in-stream or side-stream technologies discussed above as a CSO treatment alternative would not, by themselves, meet all water quality goals in this CSO basin. The use of aeration as a supplement to conventional CSO controls (i.e. maximized use of existing facilities, retention tanks, etc.) could be used to address DO concerns. However, the continued discharge of solids during wet weather events would result in an increased oxygen demand by the sediments within the basin and must be carefully considered. Further information is required regarding the long-range impacts of a reduction in CSO storage volume and the resulting additional loading of solids, coliforms, and BOD to the basin. The combined use of CSO volume capture and supplemental aeration could provide the needed improvements to water quality in Paerdegat Basin.

All three (3) alternatives have been presented to the NYCDEP recently, and remain under final review and evaluation. Each of the alternatives for aeration of Paerdegat Basin waters will be retained and further analyzed in conjunction with resizing of the CSO retention facility. Remaining issues to be analyzed are as follows:

1. Hydraulic analysis of reduced capacity CSO retention facility;
2. Interaction of aeration system with downsized CSO retention facility;
3. Impact of increased solids/siltation on in-stream aeration equipment;
4. Potential VOC generation and impacts;
5. Permitting and construction issues.

ACKNOWLEDGEMENT

The Evaluation of Supplemental Aeration Project was performed as part of the Paerdegat Basin Water Quality Facility Planning Project for the New York City Department of Environmental Protection's Bureau of Environmental Engineering, under the direction of Robert Gaffoglio, P.E., Deputy Commissioner, and Les Kloman, P.E., Chief Division of Water Quality Improvement.

URBAN RUNOFF FILTRATION FOR CRITICAL SOURCE AREAS

ABSTRACT

Filtration is attractive in the treatment of stormwater runoff because filters will work on intermittent flows without significant loss of filtering capability. They also do not require a large surface area, and can easily be retrofitted in urban areas at the base of a watershed or problem point source area where land is expensive. Several types of media, peat moss, activated carbon, zeolite, sand, composted leaves, and an agrofiber have been used successfully or have been proposed for use in stormwater runoff filters in the United States. Experiments have been run during the past three years to test the usefulness of each medium as a stormwater filter under 'typical' loading rates, to determine the chemical breakthrough of each medium when in solution with other competing ions, and to analyze the effect of non-normal pHs and ionic strengths on the sorption ability of each medium. Each of these media was combined with sand in a 50/50 mixture by volume in order to control the hydraulic flow rate through each column.

Results of the field testing under 'typical' conditions showed that the activated carbon, peat moss, zeolite and compost were the most efficient at removing toxicants (including organics and metals) from the runoff and retaining them during subsequent flushings with clean distilled water. Sand, the most common filtering medium, was found to effectively remove toxicants from the runoff; however, analysis of the effluent from subsequent flushings of the sand with clean water indicated that the toxicants were being displaced from the pores where they were "trapped" by the water, resulting in effluents that were more toxic than the influents. Additions of color-causing compounds occurred in both the compost and peat media. Both a high ionic strength influent (conductivity > 1000 µS/cm) and a high pH influent (pH > 9) were shown to interfere with sorption of many pollutants for all media examined. Pollutant removals were poorest when the pH and ionic strength were both high, although each could affect pollutant removal independently.

Breakthrough tests at extreme conditions of low pH show that these media are capable of removing greater than 80% of the influent copper until the cumulative copper loading on the media exceeds 0.1 – 0.4 mg Cu/g media for the zeolite, agrofiber, and activated carbon and 1-1.5 mg Cu/g media for the peat moss and compost. Tests done under more normal conditions (influent pH 6.5-7) showed that copper removals exceeded those at low pH conditions. Eighty percent removal is expected for these media at neutral pH until the cumulative copper loading exceeds 0.35 mg Cu/g media for the activated carbon and zeolite and greater than 1-2 mg Cu/g media for the peat moss, compost, agrofiber, and a cotton textile plant waste. For phosphate, greater than 80% removal of phosphate from a low pH influent was possible until the cumulative loading exceeded 0.1 – 0.4 mg PO_4/g media for the compost, peat moss, and zeolite, and exceeded 1.2 mg PO_4/g media for the activated carbon and agrofiber. When the influent pH was neutral, the cumulative loadings for 80% removal were significantly poorer than they were for the low pH conditions, approximately 10% of those found for the low pH conditions.

Data from these laboratory tests has been used to prepare design guidelines for stormwater filters. If the runoff is not being pretreated by settling, then the suspended solids loading on the media will be the controlling design factor. The filters will clog long before their chemical removal capacity is approached. However, if the runoff is pretreated by sedimentation, then the chemical capacities of each media for the pollutant(s) of interest will control the quality of the effluent and the life of the filter. Example design calculations are given in the discussion section of this paper.

INTRODUCTION

Two popular methods of disposing of urban stormwater runoff are discharging it to a surface water or infiltrating it at designated locations to replenish the groundwater. Due to urbanization, many natural infiltration areas have disappeared permanently, due to both covering the land with roads and buildings and to the regrading and compacting that accompanies construction. Along with the decrease in area available for infiltration, the volume of runoff from urban areas has increased, as has the runoff's pollutant loadings. The need for 'relatively clean' stormwater runoff for either surface water discharge or infiltration has led to the investigation of cost-effective treatment techniques, especially for areas where the pollutant loadings are expected to be greater than normal. The rationale for treating runoff at its source comes from the knowledge that stormwater runoff from many areas is not badly polluted and is suitable for discharge or infiltration. It is just the runoff from certain problem locations, "critical source areas," that cause the receiving water or groundwater problems, and it is cost-effective to treat these smaller volumes of water before they contaminate the larger volume of runoff in a municipal storm sewer system. Examples of these 'critical source areas' where higher than normal pollutant loadings can be expected include the following: airport deicing facilities, auto recyclers/junkyards, commercial nurseries, parking lots, vehicle fueling and maintenance stations, bus or truck (fleet) storage areas, industrial rooftops, marinas, outdoor transfer facilities, public works storage areas, and vehicle and equipment washing/steam cleaning facilities (Clark, 1996).

Urban runoff is comprised of many different flow phases. These may include dry-weather base flows, stormwater runoff, combined sewer overflows (CSOs) and snowmelt. The relative magnitude of these discharges varies considerably, based on a number of factors, especially season (cold versus warm weather or dry versus wet weather) and land use. Land development increases stormwater runoff volumes and pollutant concentrations. Impervious surfaces, such as rooftops, driveways, and roads, reduce infiltration of rainfall and runoff into the ground and degrade runoff quality. Generally, the 5-day biochemical oxygen demand (BOD_5) and nutrient concentrations in stormwater are lower than in raw sanitary wastewater; they are closer in quality to treated sanitary wastewaters. However, urban stormwater has relatively high concentrations of bacteria, as well as high concentrations of many metallic and some organic toxicants. A brief summary of stormwater runoff quality is given in Table 1.

Single, small point-source treatment devices have been developed and are currently being marketed. Most of these treatment devices, however, are designed to remove settleable solids, not colloidal or soluble pollutants. Only recently are these in-line treatment devices beginning to use filtration as a planned treatment step to remove the colloidal and soluble pollutants. Filtration removes pollutants from the solution by attaching them either to the media itself or to previously attached particles. Filters with an adsorption/ion exchange capability will retain pollutants that were removed during prior storms and not allow them to be flushed out of the filter. The performance of these filters is measured not only by the traditional filter parameters (surface area, depth and profile) but also by percentage of removal of the pollutants of interest from the influent. Stormwater filters currently in operation typically use sand, leaf compost, or peat. The purpose of this project is to determine the design parameters for stormwater filters based upon both the physical and chemical capacities of the different media.

Sand

Sand filtration is common throughout the United States, especially in water and wastewater treatment plants. Slow-sand filters are characterized by low filtration rates, an extremely narrow range of particle sizes (low uniformity coefficient, between 2 and 5), the lack of chemical pretreatment, relatively long filter runs between cleanings and surface scraping and sand removal instead of backwashing. Slow sand filters are extremely effective in removing suspended particles (effluent turbidities below 1.0 NTU), bacteria, viruses and Giardia cysts. Sand filters in Austin, Texas, used both for single sites and for drainage areas less than fifty acres, are designed to hold and treat the first one-half inch of runoff with very good pollutant removal ability. Sand filters in the Washington, D.C. area are designed to retain and treat three-tenths to one-half inch of runoff, depending upon the impervious surface amount in the drainage area. The Delaware sand filter should remove 75 – 85% of the influent suspended solids but with minimal to no removal of soluble compounds (Clark, 1996).

Activated Carbon

Activated carbon has been used for more than fifty years in the drinking water treatment industry to remove taste- and odor-causing compounds, along with most synthetic organic chemicals, pesticides, herbicides, color and trihalomethane precursors. Slow granular activated carbon filters achieve excellent (> 90%) organic removals, with the removal efficiency being limited by the depth of the filter due to 'slowness' of the transport kinetic and attachment mechanisms inherent in activated carbon sorption. Aged activated carbon filters, i.e., those with a growing microbial community are especially effective at treating wastewaters with toxic or inhibitory organic chemicals in it. Iodine and iodide compounds, chlorite, phenols, hexavalent chromium and mercury have been successfully removed by activated carbon (either granular, powdered, or imbedded in a synthetic fiber) (Clark 1996).

Peat

Peat filters can extract substantial amounts of either free-phase or dissolved hydrocarbons from water. Peat adsorption generally seems to increase as the degree of decomposition increases. The binding of polycyclic aromatic hydrocarbons (PAHs) appears to be controlled by both adsorption and partitioning with the filter media. Nitro and hydroxyl groups on a sorbate molecule tend to strengthen the molecule's sorption. Peat can easily adsorb polyvalent cations, including transition metals, and polar organics. Substances adsorbed by peat include calcium, copper, lead, zinc, mercury, nickel, iron, manganese and chromium. When filtering unbuffered solutions of metals with peat, the pH will drop between 0.2 and 0.6 pH units because of the release of humic and fulvic acids during adsorption or ion exchange. Another disadvantage of peat as a filter material is that it will leach color and possibly some nutrients upon wetting. Peat-sand filters have been used for stormwater treatment. They are expected to have excellent removal rates for phosphorus BOD, trace metals and pathogens, and with a good grass cover, other nutrients

(Clark, 1996). Multi-Chamber Treatment Trains in Milwaukee, WI (peat-activated carbon-sand filter) and Minoqua, WI (peat-sand filter) in which the filter has been used to 'polish' the settling chamber effluent have shown that the device to remove heavy metals, PAHs, pesticides, and COD (Pitt, *et al.* 1997).

Compost

Composts made from yard waste, primarily leaves, have been found to have a very high capacity for adsorbing heavy metals, oils, greases, nutrients, and organic toxins from the influent water due to their high humic content and large number of sorption sites. The composted leaf filter was developed by W&H Pacific for Washington County (WA), the Unified Sewer Agency and the Metropolitan Service District of Washington County, and is now marketed by Stormwater Management Systems, Inc. (Portland, OR). The filter consists of a bottom impermeable membrane with a drainage layer above it. Above the drainage layer is a geotextile fabric upon which rests the compost material. During testing of the prototype as a treatment for stormwater runoff, turbidity, suspended solids, volatile suspended solids and settleable solids removal was greater than 80%, as was removal of copper, zinc, lead, aluminum, iron, petroleum hydrocarbons and oil and grease. Removal of total solids, COD, total phosphorus, ammonia and total Kjeldahl nitrogen was between 40 – 80% (CSF Systems, 1994).

Zeolite

Zeolites have been used for many years in the chemical process industry as molecular sieves, i.e., they will adsorb a wide range of compounds up to the size limit of their pores. Unlike activated carbon, zeolite pore sizes are more uniform without having macropores, mesopores and micropores. Also, because zeolites are polar, it will have not only van der Waals forces to aid in sorption, but also induced dipole interactions and other electrostatic forces, such as polarization, dipole and quadrupole interactions. Zeolites can adsorb higher molecular weight aromatics, as well as unsaturated hydrocarbons. Modified zeolites can remove chlorinated aliphatics and benzene derivatives, as well as transition metal cations (such as lead, chromium and selenium) (Clark, 1996).

Agrofiber and Cotton Textile Waste

The Forest Products Research Lab agrofiber product was developed as both an economic oil adsorbent and an economic ion-exchange media for pollutant removal from water. Kenaf and jute fibers, along with forest wastes such as barks and pine needles, have been found to remove copper efficiently from water (Forest Products Research Lab, 1995).

The cost of disposing of large quantities of waste cotton thread has led Russell Athletic Corp. (Alexander City, AL) to look for alternative uses for this material, such as its use in stormwater treatment devices. Prior testing of a cotton waste called Enretech (RAM Services, Birmingham, AL) indicated that there was a limited capability for sorption and ion exchange on these cotton wastes with removal capabilities being approximately equal to that of the agrofiber.

METHODOLOGY

The main objective of this research was to monitor a variety of media used to treat stormwater runoff to determine their overall pollutant removal capabilities. The media included those described in the introduction (sand, activated carbon, peat moss, zeolite, compost, agrofiber and cotton textile waste). Generally, a variety of mechanisms, including straining, sorption, and ion-exchange, is responsible for removing pollutants during "filtration." No attempt was made to determine which mechanisms were responsible for removing a particular pollutant.

Filter columns containing the various media were constructed in glass, Kimax-brand, one-liter, graduated burets (ID = 48 mm), giving a cross-sectional area for filtration of 18 cm^2. Filter columns were constructed first by placing a square piece of fiberglass window screen in the bottom of the buret and filling the buret to the 1000 mL line with epoxy-coated fish tank gravel (3-4 cm depth). A 15 cm deep layer of fine sand (sandblast grade from Porter Warner Industries, Birmingham, AL) was added on top of the gravel (fill to

700 mL line) before a 30 cm layer of selected filtration media was put in the column (fill to 100 mL line). The columns were constructed using the recommended depths for the Austin sand filter and preparatory times and steps being those of compost filter system, as supplied by CSF Systems, Inc. All sorption media were mixed with an approximately equal volume of sand in order to maintain a relatively consistent hydraulic conductivity between media. Filter columns were reconstructed between each type of test.

The filter columns were placed on a specially constructed carousel. The water was delivered to a flow splitter using a Masterflex® Peristaltic Pump with Masterflex Tygon® tubing. A funnel-type flow splitter was constructed of Delrin™ plastic. Reinforced Tygon® tubing was used to deliver the water from the flow splitter to the individual columns. Prior to construction of the carousel and splitter, all proposed construction materials were leach-tested by soaking representative pieces in 18 MΩ water for approximately 65 hours. Testing of the leachate water showed that the materials were acceptable, with minimal-to-no adverse contamination expected.

The first tests performed were those which determined the solids removal capacity and solids loading at clogging for these media. The solution used was tap water in which a known quantity of a local clay soil had been suspended (approximately 4 g/L). A constant head of approximately 8 cm of clayey water was maintained on the tope of each column. The flow rate of the effluent was measured for each column at designated intervals until clogging occurred.

The second series of tests (performed on new columns) included evaluating the effects of pH and ionic strength on the pollutant removal capabilities of these media. This work was performed as a 2 x 2 factorial design for pH and ionic strength. The test water was runoff water collected at the storm drain inlet for the UAB Remote Transportation Parking Lot and Fleet Services Maintenance Yard. This location was used because it was expected that the pollutant loadings from this area would be similar to that found at similar locations. pH was adjusted using sulfuric acid (pH 4 – 5) or sodium hydroxide (influent pH 9 – 10). Ionic strength was adjusted using a salt made from evaporated sea water. Influent and effluent samples for each media were analyzed for toxicity, turbidity, conductivity, color, pH, chemical oxygen demand (COD), hardness, suspended solids, particle size distribution, and heavy metals (copper, lead and zinc).

The third series of tests were the breakthrough tests to determine chemical capacity of the media. These tests used a tap water to which specific concentrations of certain stormwater pollutants (reagent grade copper, lead, zinc, phosphate, nitrate, and ammonia) were added. Since the standard solutions were acidic (pH < 4), they used up the buffering capacity of the tap water. Sodium hydroxide was added to the test water for the neutral pH breakthrough tests to raise its pH to 6.5 – 7. Influent and effluent samples were tested for turbidity, conductivity, color, pH, chemical oxygen demand (COD), hardness, and heavy metals (copper, lead and zinc).

The final series of tests included evaluating the filtering ability of the media using pre-settled stormwater runoff. The runoff water was from the UAB Remote Transportation Parking Lot and Fleet Services Maintenance Yard. The samples were analyzed for toxicity, turbidity, conductivity, color, pH, hardness, solids (total, dissolved and suspended), particle size distribution, major cations and anions, semi-volatile organics, pesticides and heavy metals (copper, lead and zinc).

RESULTS

The ability to remove suspended solids also is dependent upon the particle size distribution of the influent, with all media having difficulty removing solids that are less than few microns in diameter. Removal efficiency is generally greater when the influent TSS is higher for two reasons: 1) captured particles help trap other particles by reducing pore sizes; and 2) runoff with a low TSS likely has more particles that are closer in size to the pore size of the media (therefore less likely to be captured). The test observations indicated that only about 2.5 cm of the filter columns (about 10% of the column depth) were actually used for solids retention during these tests. It is assumed that a full-scale filter could use about 5 times these depths for solids retention if careful, selective piping to deeper depths, while preventing short-circuiting of the entire filter, was allowed. Results of the clogging tests are shown in Table 2 for a full-scale filter installation.

TABLE 2. **Removal Efficiency for Suspended Solids for Pre-settled and Unpresettled Influents**

Media	Percent TSS Reduction (Avg. Influent TSS = 10 mg/L)	Percent TSS Reduction (Avg. Influent TSS = 30 to 60 mg/L)
Sand Carbon-Sand	>50%	>90% >90%
Zeolite-Sand Agrofiber, Cotton Waste	20-50%	>90% 80%
Peat-Sand Compost-Sand	<10%	80-90% 80%

The effects of pH and ionic strength were also investigated. It was found that a non-neutral influent pH and ionic strength generally significantly affected the removal capability of the media. In the carbon-sand material, metals removal was dramatically affected by influent pH, with the greatest removal efficiency and best effluent quality occurring when the influent pH was greater than 7. A high ionic strength enhanced the carbon-sand's ability to reduce turbidity but negatively affected its ability to remove toxicity, color and COD. For the peat-sand material, a low influent pH caused a poorer effluent quality in terms of hardness, zinc, copper and color, while a high influent pH caused higher effluent COD concentrations. The effluent turbidity and color were lower for the zeolite-sand material when the influent ionic strength was high, but the effluent hardness was greater. For the metals for the compost-sand medium, the poorest effluent quality occurred when the influent pH was low and the influent salt concentration was high. The addition of salt to the influent also increased the effluent hardness of the compost-sand material. The benefit of the compost is that it always moved the solution pH toward neutral (for both low and high influent pHs).

Chemical capacity of the media was evaluated in a series of breakthrough tests. The results are shown below for copper and phosphate for both the low pH and neutral pH tests (compost not shown for phosphate since no removal occurred). Copper removal improves when the pH is closer to neutral while phosphate removal is best when the influent pH is low. Figures 1 through 4 illustrate the chemical capacity of the media as found during the breakthrough tests.

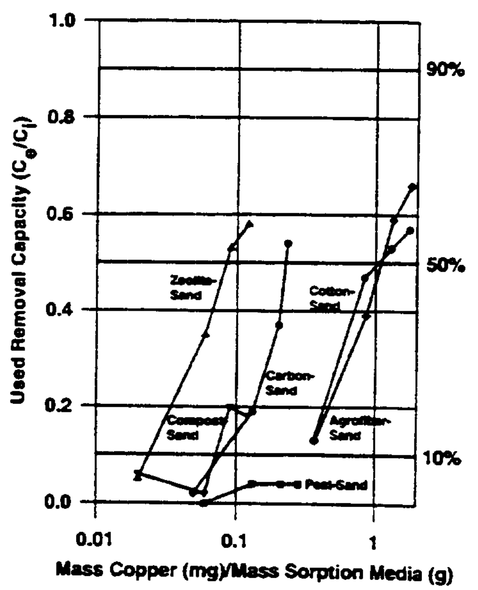

Figure 1. **Copper Breakthrough at Neutral pH (Influent 6.5 – 7)**

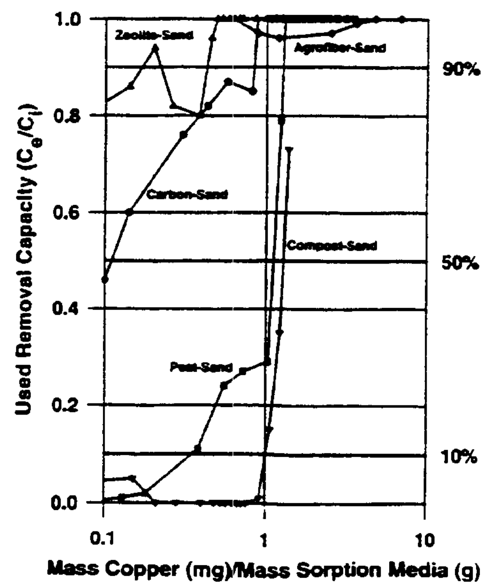

Figure 2. **Copper Breakthrough at Low pH (Influent 3.5 – 4)**

R0024946

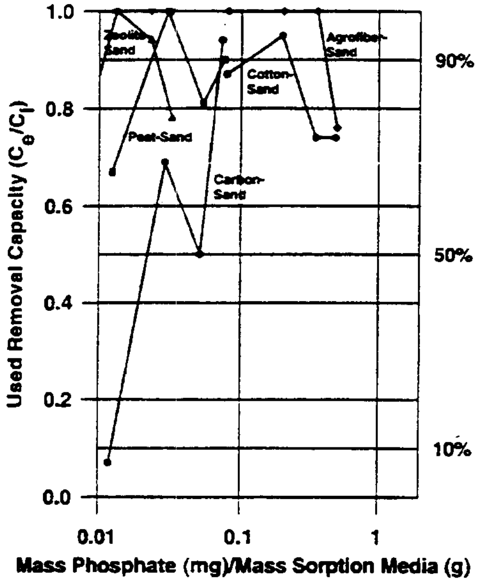

Figure 3. **Phosphate Breakthrough at Neutral pH (Influent 6.5 – 7)**

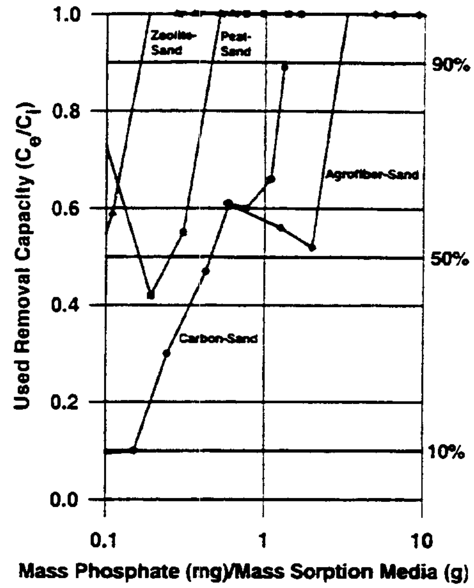

Figure 4. **Phosphate Breakthrough at Low pH (Influent 3.5 – 4)**

Testing with pre-settled stormwater was conducted to evaluate, under typical field conditions, the run times before either clogging or chemical breakthrough occurred. The settling reduced the stormwater suspended solids concentrations to about 10 mg/L, with about 90% of the particles being less than 10 µm in size. The presettling also reduced the other stormwater pollutants (for example, color and turbidity by about 50% and COD by about 90%). This presettling had a significant effect on the media's pollutant removal performance with the results shown in Table 3.

Table 3. **Removal Capability Using PreSettled Influent (Influent TSS = 10 mg/L)**

Media	Additional Comments
Carbon-Sand	Removed toxicity (80%), color (25%), alkalinity (>95%), zinc (50-75%), COD (85-95%), 2,4-dinitrophenol (40%), bis(2-ethylhexyl) phthalate (90%), with minimal effluent degradation
Peat-Sand	Removed toxicity (60%), alkalinity and hardness (50-100%), chloride (<20%), large solids (<50%), zinc (60-70%), 2,4-dinitrophenol (35%), di-n-butylphthalate (65%), bis(2-ethylhexyl) phthalate (20%), dieldrin (70%), while adding color, turbidity, and reducing pH (1-2 units)
Zeolite-Sand	Removed toxicity (>90%), chloride (<10%), potassium (40%), calcium (15%), zinc (60-75%), bis(2-ethylhexyl) phthalate (80%), pentachlorophenol (90%), with minimal effluent degradation
Agrofiber-Sand	Removed zinc (75-80%), pentachlorophenol (90%), with minimal effluent degradation
Sand	Removed volatile solids (<10%), zinc (75-80%), bis(2-ethylhexyl) phthalate (100%), with minimal effluent degradation
Compost-Sand	Removed zinc (75-80%), while adding color to effluent

R0024947

DISCUSSION

As can be seen by these results, the characteristics of the influent water should greatly influence the selection of the treatment medium. Generally, most stormwater filters are designed based upon the influent suspended solids concentration and desired suspended solids removal. For most applications, this likely will remain the primary design factor. However, the choice of media likely may be different when the influent suspended solids concentration is low, or when the pH is not near neutral and/or the ionic strength is high. Designers also must remember that most of these media are ion-exchange materials. This means that when ions are removed from solution by the treatment material, other ions are released into the effluent. In most instances, these ions are not a problem in receiving waters, but the designer should know what is added to the water. For this activated carbon, the exchangeable ion was found to be typically sulfate; while for the compost, the exchangeable ion was found to be usually potassium. The zeolite appeared to exchange sodium and some divalent cations (measured as increasing hardness).

Design of Filters for Specified Filtration Durations

The filtration durations measured during these tests can be used to develop preliminary filter designs. It is recommended that allowable suspended solids loadings be used as the primary controlling factor in this design. For these designs, clogging is defined to occur when the water flow rate through the medium becomes less than one meter per day. Filtration, obviously, will still occur when the flow rate becomes less than one meter per day; however, except for small rains in arid areas, much of the runoff would have to bypass the filter and would not be treated. Table 4 summarizes the results of these tests by giving the amount of suspended solids that can be loaded onto a full-scale filter before the capacity is reduced to the flow rates shown. A multiplier of five was used to account for the greater anticipated filter flow capacity associated with full-scale operations.

Table 4. **Filter Categories Based on Capacity as a Function of Suspended Solids Loading**

Capacity to <1 m/day (gSS/m^2)	Capacity to 10 m/day (gSS/m^2)	Filtration media in category
5,000	1,250	Cotton-sand; Agrofiber-sand
5,000	2,500	Compost-sand; Peat-sand
10,000	5,000	Zeolite-sand; Carbon-sand
15,000	7,500	Sand

The wide ranges in filter run times as a function of water loading are mostly dependent on the suspended solids content of the water, especially for the tests where the water was presettled. For this reason, the suspended solids loading capacities (Table 4) are recommended for use when selecting a filter. The most restrictive materials (the cotton textile waste and the agrofiber) are very fibrous and, even when mixed with sand, they still show some compaction. The most granular media (activated carbon and zeolite) are relatively uniform in shape and size but are very large when compared to the sand grains. Sand was used with the carbon and the zeolite to reduce the water's flow rate through the media to increase contact time for better pollutant removal.

One proposed maintenance technique to ensure longer filter run times is the mechanical removal of the clogged layer (top five centimeters). Mechanical removal of the clogged layer to recover filter flow rates was not found to be very satisfactory during this research, but it has been used successfully during full-scale operations. Great care must be taken when removing this layer since loosening the media may enable trapped pollutants (associated with the suspended solids) to be easily flushed from the media.
The above filter capacity ranges are associated with varying test conditions and may be further grouped into the approximate categories shown in Table 4. A multiplier of five was used to account for the greater anticipated filter flow capacity associated with full-scale operations.

Example Filter Designs (Pitt, 1996)

Filter designs can be performed based on the predicted annual discharge of suspended solids to the filtration device and the desired filter replacement interval. As an example, volumetric runoff coefficients (R_v) can be used to approximate the fraction of the annual rainfall that would occur as runoff for various land uses and surface conditions. Table 5 summarizes likely suspended solids concentrations associated with different urban areas and waters.

Table 5. **Suspended Solids Concentration by Land Use**

Source Area	Suspended Solids Concentration (mg/L)
Roof runoff	10
Paved parking, storage, driveway, streets, walk areas	50
Unpaved parking and storage areas	250
Landscaped areas	500
Construction site runoff	10,000
Combined sewer overflows	100
Detention pond water	20
Mixed stormwater	150
Effluent after high level of pretreatment of stormwater	5

Using the information in the above table and the local annual rain depth, it is possible to estimate the annual suspended solids loading from an area and to size a needed stormwater filter. The following three examples illustrate these simple calculations.

Example 1. A 1.0 ha paved parking lot (R_V = 0.85), in an area receiving 1.0 m of rain per year:
(50 mg SS/L) (0.85) (1 m/yr) (1 ha) (10,000 m^2/ha) (1,000 L/m^3) (g/1,000 mg) = 425,000 g SS/yr

Therefore, if a peat/sand filter is to be used having an expected suspended solids capacity of 5,000 g/m^2 before clogging, then 85 m^2 of this filter will be needed for each year of desired operation for this 1.0 ha site. This is about 0.9% of the paved area per year of operation. If this water is pretreated so the effluent has about 5 mg/L suspended solids, then only about 0.2% of the contributing paved area would be needed for the filter. A sand filter would only be about 1/3 of this size but would provide little added benefit if the water was pretreated.

Example 2. A 100 ha medium density residential area (R_V = 0.3), 1.0 m of rain per year:
(150 mg SS/L) (0.3) (1 m/yr) (100ha) (10,000 m^2/ha) (1,000 L/m^3) (g/1,000 mg) = 45,000,000 g SS/-yr

The unit area loading of suspended solids for this residential area (425 kg SS/ha-yr) is about the same as in the previous example (450 kg SS/ha-yr), requiring about the same area dedicated for the filter. The reduced amount of runoff is balanced by the increased suspended solids concentration.

Example 3. A 1.0 ha rooftop in an area (R_V = 0.85) having 1.0 m of rain per year:
(10 mg SS/L) (0.85) (1 m/yr) (1 ha) (10,000 m^2/ha) (1,000 L/m^3) (g/1,000 mg) = 85,000 g SS/yr

The unit area loading of suspended solids from this area (85 kg SS/ha-yr) is much less than for the previous examples and would only require a filter about 0.2% of the roofed drainage area per year of operation.

CONCLUSIONS

Filtration can be a very successful treatment technique for urban stormwater runoff, if the filters are designed and maintained correctly. In general, it is recommended that the filter media be about 50 cm in depth and that a surface grass cover be used (roots should not extend below the top half of the filter). This should enable a filtration life of about five times the basic life observed during these tests. In addition, it is highly recommended that significant pretreatment of the water be used to reduce the suspended solids concentrations to about 10 mg/L before filtration for pollutant removal. This pretreatment can be accomplished using grass filters, wet detention ponds, or other specialized treatment (such as the sedimentation chamber in the multi-chambered treatment train described by Pitt, 1996). The selection of the specific filtration media should be based on the desired pollutant reductions, and the selection should include amendments to plain sand if immediate and permanent pollutant reductions are desired.

ACKNOWLEDGEMENTS

This project was funded as part of a multi-year cooperative agreement with the Storm and Combined Sewer Program of the U.S. EPA. The U.S. Army Corps of Engineers Construction Engineering Research Laboratory provided additional funding in Champaign, IL. TECHNOLOGY IN THE SEWER BUSINESS

Lisa Martin, Sanitation District No. 1
Joe Castillo, Woolpert LLP
Drew Ackerman, Limno-Tech, Inc.

ABSTRACT: The increasing public awareness of the health hazards associated with wet weather pollution has prompted the Sanitation District No. 1 of northern Kentucky (the District) to develop a sophisticated implementation and response system. The District is utilizing technology to develop strategic plans to meet environmental sewer system regulations and serve its customers. The plans begin with databases and mapping in a Geographical Information System (GIS) for a three county wide area. The District has then taken GIS to the next level, it uses a translator to provide the data from GIS to external applications. The applications include hydraulic sewer and river models which simulate combined sewer overflows and the local rivers. The model results are then used in GIS to illustrate and develop plans to address sewer system issues which included combined sewer overflows and inflow/infiltration. This paper explores the applications which use GIS data to assist the District in project scheduling and management.

INTRODUCTION: In early 1995, the District comprised the trunk and interceptor sewers in northern Kentucky's Campbell and Kenton Counties. Late that year through county and city acquisitions the District grew from 100 miles to more than 1,000 miles of sanitary sewers. The District now serves more than 301,000 people and a facility plan projects that number will be around 392,000 in the year 2017. From development of a Geographic Information System (GIS) to computer modeling to billing implementation, technology investments were viewed as necessary changes to allow the organization to meet the needs of the region into the 21st century.

METHODOLOGY

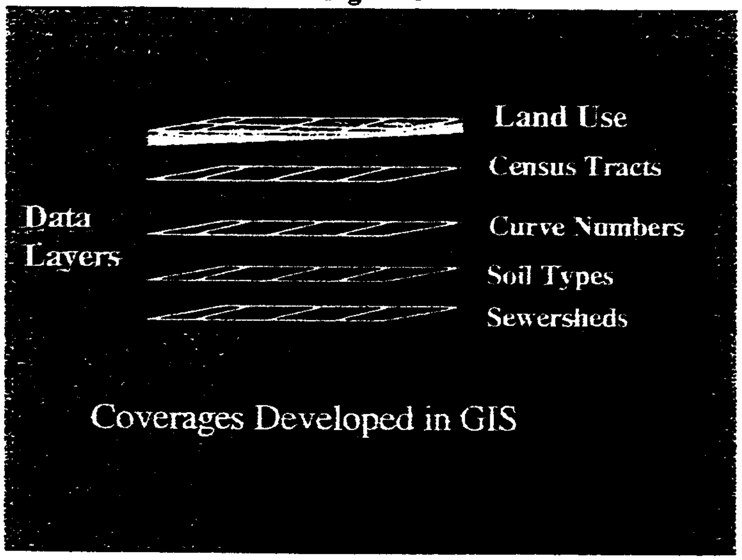
Geographic Information System: In early 1995, all plan and profile information for the sewer system in the newly consolidated district were on paper. An existing third party Arc/Info GIS was used to develop the District's sewer system. With basic attribute data in the GIS, the framework for a Computer Maintenance Management System (CMMS) was developed that included sewer component tables.

Various forms of information can be input into the GIS coverages. These can be defined in Polygons—shapes input to define data in specific areas—which were created to identify different types of statistical, soil, or land use information. The polygons for soil can be used to develop stormwater runoff coefficients. The land use polygons were used to calculate dry weather flows. The statistical landuse polygons were used to develop population projections within certain areas. Through the development of programs within ARC/INFO and FoxPro, this data was indirectly used as input for the sewer system models. The GIS coverages developed or used are shown in **Figure 1**. Satellite technology-based Global Positioning was used to update the mapping for modeling environmentally sensitive structures such as combined sewer overflows.

A coverage containing all the generalized land uses was developed for planning purposes. Polygons were created to separate different land uses throughout the District. The land use database was used to develop dry weather or sanitary flows for use in the model. Soil survey data was collected for the three counties from the National Resources Conservation Service. The soil survey data was categorized into four hydrologic soil groups necessary to perform the runoff analysis. Population census tracts can be unioned with other polygons to determine populations within certain areas. This provides the population densities within certain land uses in a sewershed. Hydrologic soil type, curve type, and curve number polygons can be used to develop wet or rain weather flow. The polygons have their areas and typical land classifications. These values were imported into a translator where they can be queried for each item in a sewershed.

For a logical development of the land uses within the northern Kentucky area, 1995, 2002, 2007, 2012 and

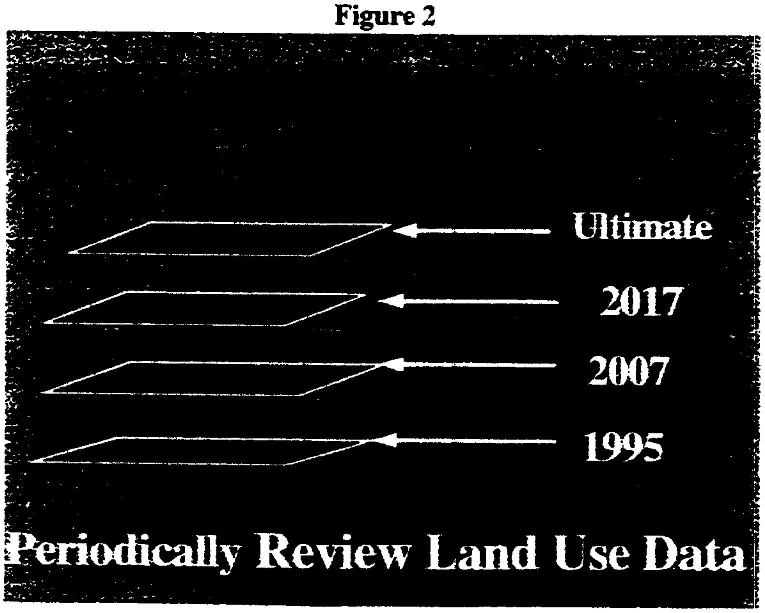
Figure 1



"ultimate" land use polygons were developed. To create the future hydrographs, the respective land use polygons were used. A schematic with the years available in GIS is shown in **Figure 2**. These polygons will permit the District to set up different alternatives on how the system will operate in any of those years.

This complete methodology allows for change in the land use data. Any changes in the land use coverages

Figure 2



in GIS can be updated by creating a new polygon file. The file can then be exported to XMS in FoxPro for a new system analysis.

The 2017 and Ultimate polygons were used to develop the Facilities Plan. **Figures 3** and **4** illustrate how the high density residential area, shown in yellow, is projected to increase by the year 2017.

Figure 3

Figure 4

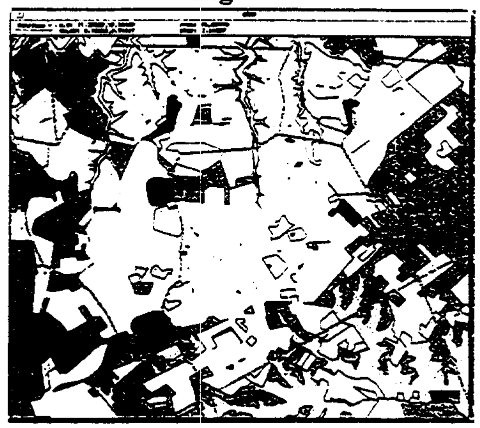


Figure 5 numerically represents the landuse and is available for each polygon in the GIS land use coverage The future land use polygons are estimates of how the area will develop. As actual developments occur, the databases should be updated to represent actual conditions. This complete methodology allows for change in the land use data. In order to generate accurate results the land use data must be periodically revised. Any

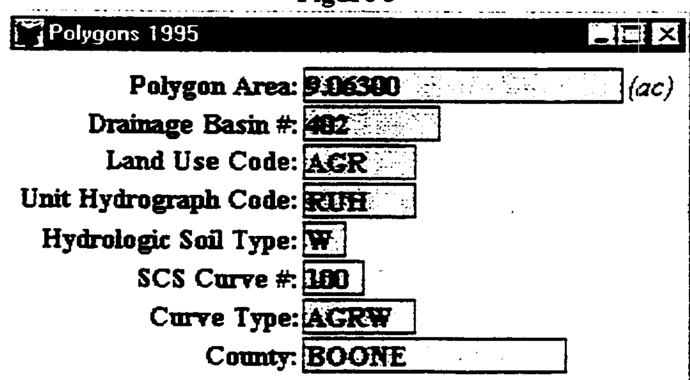
Figure 5



changes in the land use coverages in GIS can be updated by creating a new polygon file. The file can then be exported to a FoxPro XMS for a new system analysis.

FoxPro—GIS Translator

With the concurrent tasks of updating the GIS and the startup of a facility plan for the new District, a common database was developed. The purpose of the database was to provide a central location where data could be stored and used for the benefit of all tasks. An XP-SWMM Management System (XMS) was developed within FoxPro which provides the translator between software packages. It provides the user with a database that keeps track of all items entered by a naming setup in the GIS. Using this setup will allow the data in XMS to easily be transferred to the CMMS in Arc/Info, or other software packages. The prime objectives of the District models are to simulate actual field conditions and to provide a tool for modeling alternatives. Using FoxPro, the polygon data can be used to generate values needed to develop both wet and dry weather hydrographs. Through the development of programs within Arc/Info and FoxPro, this data can indirectly be used as input for sewer system models.

The development of the XP-SWMM Management System (XMS) within FoxPro provided the needed link

R0024953

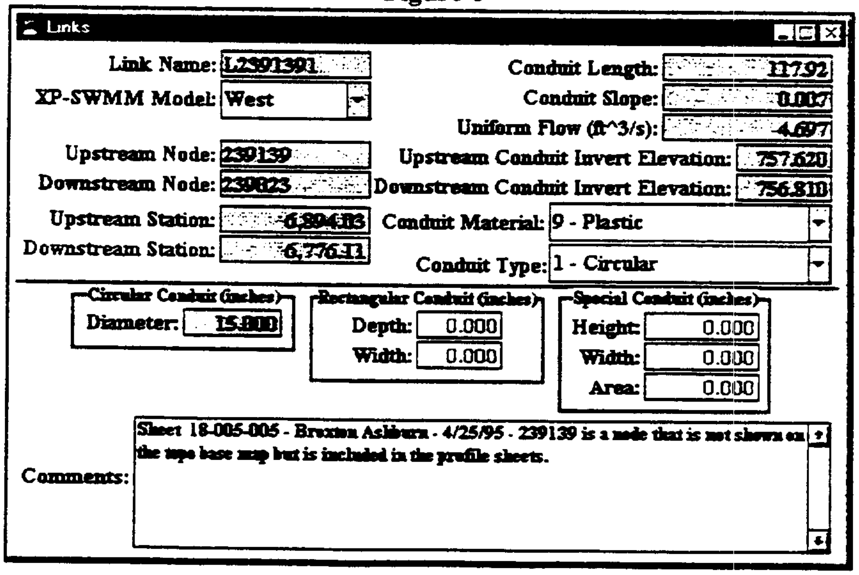
between GIS and XP-SWMM. The purpose of the database was to provide a central location where data could be stored for use in the models. FoxPro, a relational database management tool capable of performing large queries, was identified as the appropriate package for integrating the sewer system data. It is understood that the land use polygons will change over time. This translator between GIS and XP-SWMM was developed to accommodate the changes in GIS. As the coverages are updated in GIS, a database file is created for import into XMS.

RESULTS

Virtual Hydraulic Modeling: The final product is a compilation of team work encompassing databases, GIS and hydraulic models. Each team member played an important role in the creation of dynamic models accurately representing the sewer system and its effects on the environment. Creating a virtual model required the use of several complex modeling packages. The software chosen to model the District sewer system was XP-SWMM. The hydrodynamics of the Ohio and Licking Rivers are being modeled using RMA-2V. WASP5 is being used to develop predictions of bacteria levels in the Ohio and Licking Rivers from XP-SWMM loadings. The results of these three software products, GIS and an IBM Data Explorer resulted in a virtual model of sewage flow from the sewer system into and through the Ohio River. The following sections outline and illustrate how the virtual models at the District were setup and how they are being used.

DISCUSSION

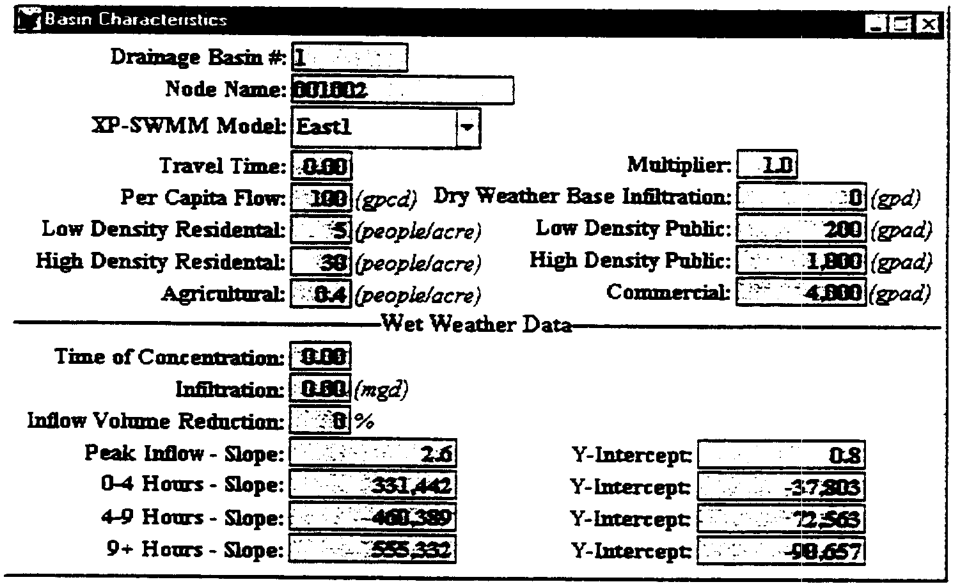
Figure 6



XP-SWMM Model Development: An important factor for choosing a sewer model included its ability to represent both hydraulic and physical field conditions. These models required extensive input requirements to account for the sewer components. Inputting of a single pipe required the opening of several time-consuming windows. Therefore, building the sewer model conventionally would have meant manually inputting physical characteristics for more than 6,280 pipes and manholes. The immense amount of manhole and pipe data to be input into the sewer model required the automation of the task. This was accomplished by developing a program within XMS. The program provided a single input window for each manhole or pipe and formatted the data into a setup that was useful by the sewer model. **Figure 6** is a typical Links input table for pipes. The Links table connects the pipes to their appropriate manholes by name association. The conduit type defines the shape of the pipe. After the shape is defined, the correct sizing menus are highlighted by XMS. Specific model requirements are entered and from that XMS calculates the slope and design flow of the pipe. For model data management the District service area was broken up into six models. Using the "XP-SWMM Model" field, XMS inserts this particular manhole in the correct import file.

Hydrology: The XP-SWMM models require hydrographs in order to simulate actual hydraulic conditions in

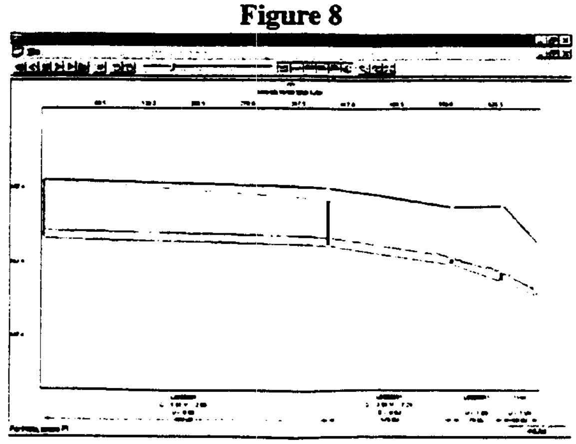
Figure 7



the sewer system. For each sewershed and point source a hydrograph was developed. The fields in **Figure 7** show the type of data entered for each sewershed. The upstream hydrographs were accounted for by inputting them into their actual receiving manholes (Node Name) in the model. Travel times to get to the interceptor sewers were assigned to upstream hydrographs. The creation and manipulation of these hydrographs were performed in XMS. The program in XMS first lags all sewersheds in reference to time zero. Then all sewersheds with the same inflow node are added to make a composite hydrograph. The hydrographs account for flow over a 24-hour period, with inflow at every 15 minutes. These calculations would have been painstaking using regular methods; XMS quickly generates new import files to be used by the sewer model. Using this information dry weather hydrographs were developed for use in the facility plan models. The wet weather hydroghraphs for the combined sewer overflow (CSO) models were developed in XP-SWMM using areas developed in GIS.

To develop dry weather flows, XMS queries for the sum of the different land uses within a sewershed. The land use classifications used include low and high-density residential, agriculture, low and high-density public, open space, and commercial development. Flows from industrial land use are accounted for as point sources. User input based on monitored data define unit hydrographs in XMS to represent land use flows. The unit hydrographs are then multiplied in XMS by areas with the same land use to obtain hydrographs. The separate land use hydrographs produced within a sewershed are then added to make a sewershed hydrograph.

Figure 8



Sewer Modeling: Once input parameters are defined in XMS, hydrographs can be developed for the sewer models. XMS can provide the peak flow and volume of a combined hydrograph for a storm within the monitored range. These hydrographs are then exported into XP-SWMM and checked from monitored data. Hydrographs can be calibrated by adjusting the input variables in XMS.

Figure 8 is a view of a sewer profile in XP-SWMM. Using this model the District can analyze the hydraulic levels in the sewer pipes based on monitored data. The CSO XP-SWMM models provide output used for modeling of the local rivers.

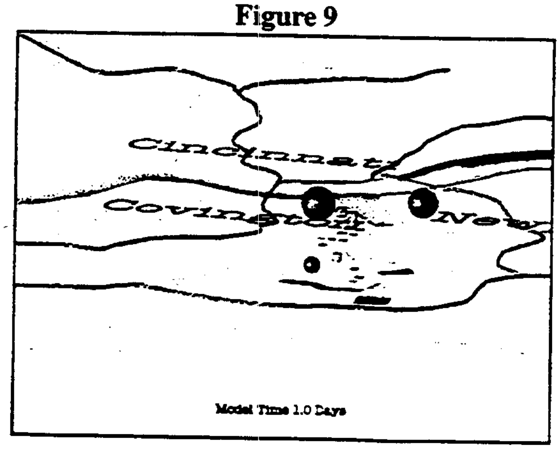
River Modeling: The Banklick Creek water quality model is a one-dimensional finite element model. The hydraulic model, HEC-RAS was used to develop a relationship among velocity and segment depth with flow. This relationship allowed the model to be run dynamically to estimate the stream's response to CSO loadings. Since the CSO flows were estimated to be equal to, or greater than the creek flow, the water mass loadings were included in the overall hydrodynamic modeling of the wet weather events.

The hydraulics and geometry of the Licking/Ohio River system were determined using RMA-2V. This finite difference model conserves momentum to determine the flow conditions based on upstream flow and downstream head. The water quality model of the rivers is two-dimensional. The linkage of the finite difference hydraulic and finite element water quality models presented a unique problem in that RMA-2V only conserves momentum while WASP5 requires conservation of mass. Thus, an algorithm was developed to smooth the flows from RMA-2V and route them through the finite element water quality model.

Water quality: The water quality model WASP5 was employed to estimate the response of Banklick Creek and the Ohio/Licking River system to CSO loads. The WASP5 model simulated fecal coliform loading and a first order die-off term to the system. The dissolved oxygen dynamics consisted of nitrogen kinetics, two types of CBOD decomposition (riverine and CSO), and algal concentrations to scale production/respiration. The model included two CBOD types because the readily available fraction for consumption is different (the "fresher" organics from the CSO discharges are more quickly broken down).

Visualization: The visualization of the system using IBM Data Explorer incorporates all aspects of the efforts. Within one series of images, we have included GIS streams and roads (as a frame of reference), rain gage information (initial frame of reference for runoff), XP-SWMM output (give a frame of reference to load sizes to the streams), Banklick Creek model output (show fecal coliform response of the creek), and Ohio/Licking River model output (includes Banklick Creek and CSO loadings and the response of the rivers).
The inclusion of these data, as shown in **Figure 9**, provide an overall picture of the system that was not available before. By including all five data sources, a more complete cause-effect relationship is presented.

Figure 9



Management Software

The incredible growth of the District required the implementation of a maintenance management system. The growth of the sewer system also meant an increase in customer complaints and maintenance crews. CK System Inc. developed a management system named MaintiMizer. It was implemented to keep track and schedule the daily operations of the District's field crews and operations. Each incident about a structure becomes a permanent record in the MaintiMizer. The history of all maintenance in the system is maintained and any item can quickly be queried in the system. It is used to inventory supplies and to keep track of material as it is installed at different locations. Continuing the planning for the eventual consolidation of all databases in Arc/Info, the naming scheme for the pipe and manholes was maintained. This will allow the data to be imported into the existing databases in Arc/Info by name association. Using this software in conjunction with Arc/Info allows incoming customer complaints to be referenced with pipes and manholes. This software has eliminated large amounts of paper work and improved customer complaint response time.
Telemetering is used to monitor pump stations. All data is sent to a central location where a single person can dispatch crews to a malfunctioning station.

CONCLUSIONS

The District has implemented technology that will take it into the next century. The continued use of databases with the same naming schemes will allow for all data to be centrally located. The eventual goal is to have all databases export their data into Arc/Info. All pipe and manhole changes will be input into the Arc/Info databases. Arc/info will be the central location from where all hydrograph polygon databases and physical model parameters can be exported into XMS. XMS will then develop the input for the sewer model. The use of MaintiMizer moves the District into a scheduled system. Through planning and immediate action these systems have streamlined the time to correct problems in the sewer system. The billing system databases could also eventually be tied into Arc/Info. This would tie customers to certain parts of the sewer system. The continued development of the Arc/Info CMMS will provide the District with a central location for data management as shown in **Figures 10** and **11**. These tables in GIS are being used to inventory the new developments within the District.

Figure 10

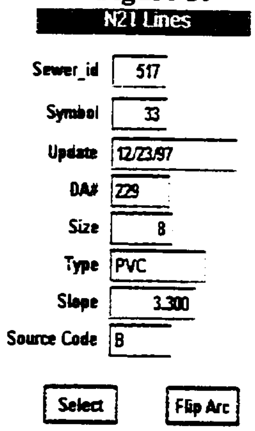


Figure 11

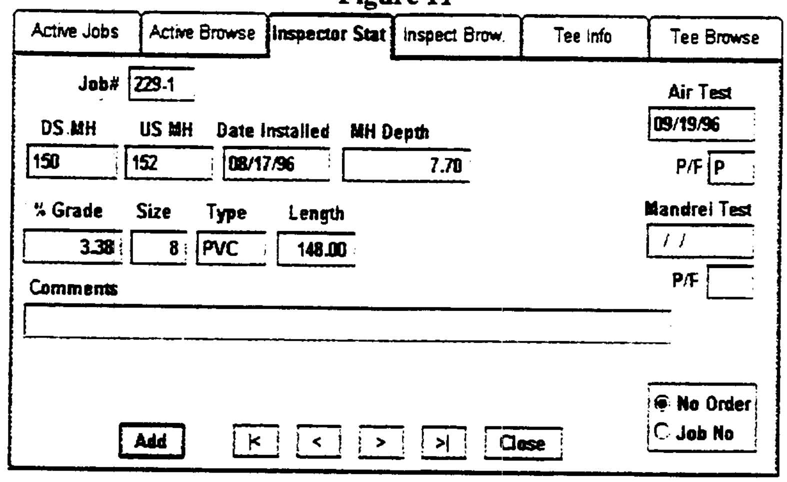

The District is using technology to face its environmental challenges and assists in prioritizing of projects. The results obtained from the modeling and inflow and infiltration studies are being graphically represented in public meetings by using GIS. Using XP-SWMM the user is able to view sewage levels in pipes including bypassing through CSO structures. This information is then fed into RMA-2V and WASP to analyze the hydrodynamics and bacteria concentrations of affected rivers. These additional results are then imported into an IBM Data Explore where the effects of the overflows are seen in a virtual model of the river. Today's technology provides the District with data in ARC/INFO to a dynamic analysis of its sewers operation and effect on the environment. The goal of providing quality services to its customers has taken the District into the 21st century.

ABSTRACT

Many cities and municipalities throughout the United States experience overflows and bypasses from sanitary sewer systems during periods of intense rainfall. With the nation's population becoming more environmentally conscious, environmental regulatory agencies have seen increased pressure to implement more stringent regulations and enforcement policies. Most regulatory agencies encourage and in some cases require cities and municipalities to implement a Sanitary Sewer Evaluation Study (SSES) as a first step to reducing sanitary sewer overflows and bypasses.

Oftentimes, management of data collected during SSES field activities becomes overwhelming and requires automated tracking methods. Data collected during field investigations may include manhole inspection, smoke testing, dyed-water testing, lamping inspections, flow monitoring, CCTV inspections, flow isolation, and building inspections. In addition to SSES field data, historical information, such as maintenance records, reported overflows, and previous rehabilitation, is also evaluated and used as a basis for determining locations of further field investigations.

Once data has been collected, the seemingly insurmountable task of evaluating all the data and developing recommendations for cost-effective inflow and infiltration (I/I) removal and structural rehabilitation must be completed. The data evaluation process can be somewhat simplified with the use of graphical methods to view the data. In an effort to avoid cumbersome paper maps, the industry has developed computerized Geographical Information Systems (GIS) for mapping and graphic data queries. As with many types of new technologies, development of a GIS can be quite time consuming and costly, preventing smaller municipalities from successfully acquiring such tools.

The purpose of this paper is to present the steps followed by Wade & Associates and the City of Fort Worth, Texas in the implementation of a low budget GIS used for successfully evaluating field data and developing recommendations for I/I and structural rehabilitation of the City's Main 390 sanitary sewer collection system. Wade & Associates linked the database developed during field investigations, past maintenance records, and reported overflow records to the City's current AutoCAD® sewer map and orthographic images, using, resulting in a valuable evaluation tool. By using existing computer aided drafting (CAD) maps and providing only information required for sanitary sewer evaluation, costs were kept well within typical non-GIS SSES costs and completed within a short time frame. In addition, due to the time schedule stipulated in the City's Administrative Order, the $20 million rehabilitation effort recommended during the study will require multiple design consultants. The GIS developed during the study will be used to track design efforts of each consultant.

KEYWORDS

Sanitary Sewer Evaluation Study, Geographical Information Systems, Rehabilitation, ArcView®, AutoCAD®, Orthographic

INTRODUCTION

History

The City of Fort Worth operates and maintains an extensive system of wastewater collection facilities. The Main 390 Drainage Area (Study Area) is comprised of approximately 130 kilometers (81 miles) of pipe and is located within the collection system tributary to the Village Creek Treatment Facility. Currently, the entire collection system contains approximately 3,860 kilometers (2,400 miles) of sanitary sewer pipe.

The Main 390 Drainage Area contains primarily residential housing, but also includes some light-industrial, and commercial development. This project is part of the City of Fort Worth's Wastewater Program in response to an Environmental Protection Agency Administrative Order (AO) requiring the City to eliminate sanitary sewer overflows.

Goals Of Study

The City retained the consulting engineering services of Wade & Associates, Inc. in August of 1995 to conduct a flow monitoring program and comprehensive I/I investigation in the Main 390 Drainage Area. Based on the City's past experiences with excessive emergency maintenance and reoccurring storm related backups and overflows, it was believed that I/I contributions from the Main 390 Drainage Area were resulting in excessive flows in the collection system. A comprehensive I/I investigation of the sanitary sewer collection system in the Main 390 Drainage Area was conducted to develop a cost-effective plan for sewer rehabilitation and to develop projections of rehabilitation costs required to alleviate I/I related overflows within the sewer system. The intent of the study was to identify sources of I/I and to present recommendations for reducing excessive I/I through proper management approaches such as sewer system rehabilitation, and selective relief or replacement sewers.

Background Of Study

Historically, the City has experienced problems with wastewater overflows and backups during periods of either short, high intensity storm events or prolonged rainfall events. In addition, dry weather overflows have been reported which were likely due to blockages in the collection system.

Problems occurring within the system included:

- Wastewater overflows and backups.
- Structural deterioration of pipes and manholes.
- Increased frequency of maintenance and associated capital expenditures.

Study Outline

The City commissioned the study to develop a pro-active rehabilitation program for minimizing the hydraulic impacts of I/I.

The first phase of the study was initiated in August 1995. Intensive manhole inspections, lamping inspections, large and small diameter pipe cleaning, smoke testing, dyed-water testing and closed circuit television (CCTV) inspections were conducted to characterize and quantify the defects within the collection system that contribute excessive I/I to the sanitary sewer collection system. In an effort to simplify tracking field investigations and quantifying I/I, the Main 390 Drainage Basin was further divided into 15 sub-basins.

During the second phase of the study, a flow-monitoring program was established to evaluate the hydraulic behavior of the collection system under various rainfall events and conditions. The main objective of this phase of the study was to quantify I/I rates for each sub-basin and establish a correlation between peak flow response and rainfall.

The third phase of the study involved development of a hydraulic model of all City owned sanitary sewer lines identified within the Main 390 Drainage Area. By creating such a model, the hydraulic impact of I/I on the existing sewer system could be evaluated for specified storm events. Where peak flows exceeded the hydraulic capacity of segments in the system, the model selected the appropriate relief/replacement sewers and determined the associated probable cost to implement the relief/replacement sewer plan for the drainage area.

The fourth phase included recommendations for a comprehensive rehabilitation program. Recommendations were based on records of excessive past maintenance problems and cost-effectiveness analysis (CEA) which identified the least-cost means of reducing excessive infiltration, transporting, containing, and treating the remaining peak flows under conditions that correlate to a specified rainfall intensity (or return period). This analysis included a combination of I/I reduction and relief/replacement sewers. The study was conducted assuming that all inflow sources, as well as all infiltration sources found to be cost-effective to eliminate, will be removed through various means of rehabilitation. Subsequent models were developed for various I/I reduction alternatives.

The fifth and final part of the study presented recommendations regarding the specifics of the cost-effective rehabilitation plan.

Basic study components included in each phase are shown in Table 1.

Table 1

General Components of the Study

Phase	Task	Purpose
I	I/I Investigation	Identifies and quantifies I/I sources in each of the selected sub-basins.
II	Temporary Flow Monitoring	Provides information regarding wet-weather flows. Temporary flow monitors in each sub-basin quantify gross I/I and help determine the relationship between rainfall and peak flow response (basin rainfall sensitivity).
III	Hydraulic Model	Allows computer simulation of hydraulic behavior of sanitary sewer system under varying storm events and I/I reduction levels. Identifies relief sewer requirements.
IV	Cost-Effectiveness Analysis	Identifies the "least-cost" option of I/I reduction through sewer rehabilitation and relief or replacement sewer plan.
V	Final Recommendations	Presents specific recommended improvements resulting from the Cost-Effective Analysis. Outlines the projected costs for system rehabilitation in the Main 390 Drainage Area.

METHODOLOGY

Typically, field data gathered during a SSES is entered into a database and tracked graphically using a CAD program. Normally, the time required for CAD mapping can become quite extensive. For our project, all field data collected during the first phase of the project was entered into a SSES database and hydraulic modeling program called Pipedream,® developed by Wade & Associates, specifically for sanitary sewers. At the beginning of the project it was decided that a GIS would be used to track information and provide graphics to be used for reporting. After extensive research, ArcView® was selected as the GIS package that would be integrated with Pipedream®.

Prior to the development of the ArcView® GIS we, as do many people, had the preconceived notion that the development of a GIS would be costly and very time consuming. Since the project was under the constraints of an AO, time was limited. We also wanted the GIS development to be reasonably close to the estimated cost of tracking our information using a common CAD system. Our intent was to develop a GIS to be used solely for the sanitary sewer system. No attempt was made to incorporate active themes for water lines, storm sewers, streets, lots/parcels, etc., resulting in reduced cost and time. We, however, knew that we would have a substantial learning curve ahead of us.

Implementation of the GIS began with the line-cleaning portion of the project. During the initial phase of the project, it was decided that 75% of the lines in the sanitary sewer system should be cleaned. In addition, 20% of the lines selected for cleaning would be televised for QA/QC purposes. Our goal was to systematically identify lines requiring cleaning rather than a random selection process. To do so, it was decided that sewer maintenance records, reported overflows, field investigation data, and isolated rehabilitation projects currently in progress would be identified.

The City's sewer maintenance records were reviewed and a list of lines requiring chronic maintenance efforts was compiled and entered into a database. Prior to the cleaning project, approximately 1030 manholes within the Study Area were internally inspected. During the internal manhole inspections each line entering and exiting the manhole was lamped in an effort to identify structural defects or other physical characteristics that may cause hydraulic deficiencies such as poor line grade or debris. Also, during field investigations, each sewer line was smoke tested. Each defect identified was logged onto standard field forms and entered into the database.

Our goal was to provide the City with a map that identified lines with; (1) excessive maintenance history, (2) smoke defects, (3) broken, collapsed or partially collapsed pipe, (4) moderate or heavy debris, (5) moderate or heavy root intrusion, (6) recently rehabilitated or replaced or currently scheduled for such activities, and (7) reported overflows. Once the map was developed, representatives from the City's engineering and maintenance departments met with the project engineer to discuss the lines recommended for cleaning. During the meeting, lines recently cleaned by the City were removed from the list and any lines known to have a troubled past history and not identified on the map were added. Following the meeting, a final list of lines to be cleaned and a map were provided to the cleaning contractor. Cleaning and CCTV activities were also tracked using the GIS.

So, what did we learn? As with any first time endeavor, we did a few things the hard way. We did, however, learn a few important lessons that have increased our productivity tremendously. Based on what we have learned so far, the following is a brief summary of how to get started:

CAD Mapping

A common perception by most novices is that GIS is a CAD system. Although some GIS packages do have tools to conduct automated drafting, the GIS package we have selected is not known for its sophistication in drafting capabilities. Therefore, we used AutoCAD® as our drafting software. The City provided us with AutoCAD® drawings which included sanitary sewer lines with identification labels, sanitary sewer manholes with identification labels, streets, street names, lots and blocks, streams, and railroads. Hydraulic modeling and defect data were stored in FoxPro® data files.

For our project only two features were selected to be truly active, sanitary sewer manholes and sanitary sewer lines. We displayed all other data as simple images. Data shown as images in ArcView® could be seen but could not be queried by selecting a feature such as a single lot or parcel. Each active element to be included in the GIS map must have an identification label. For simplicity, we used the City's current manhole numbering system for manhole identification labels. Each record in the database must have a field containing the exact identification label used to identify its corresponding feature in ArcView®. The line segment identification labels were a combination of the upstream and downstream manhole numbers. All data collected in the field was also identified with the City's manhole numbering system, providing the common link between the databases and the GIS.

R0024962

For active sanitary sewer line segments, the following characteristics should be established:

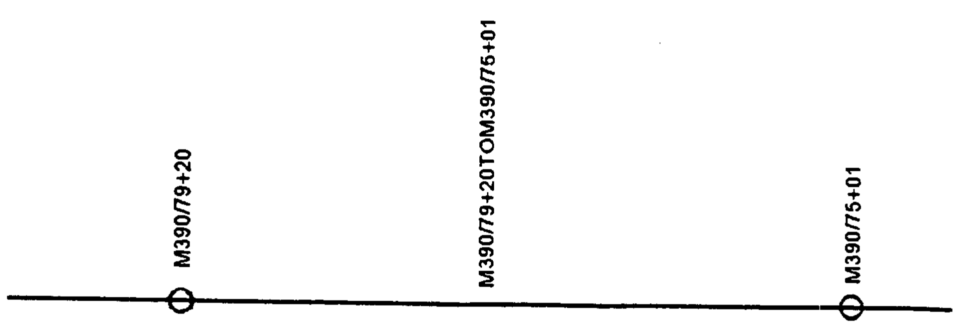
1. All sanitary sewer lines should be on a single layer with no other information.
2. Each sewer line must be drawn as a polyline and connected from end-point to end-point. It may also be helpful to draw the line from the upstream manhole to the downstream manhole. This practice is not absolutely necessary but if you want to develop a hydraulic model from tables created by ArcView®, the data will have the appropriate connectivity.
3. Each line segment must have a unique identification label. That exact identification label must be contained in the database for each record the user wishes to link to a feature. This label must be an attribute block and connected to the sewer line. To prevent overlapping of labels, we found it helpful to label the lines at the midpoint.
4. All sewer line labels must be on a single layer with no other information.

For active sanitary sewer manholes, the following characteristics should be established:

1. All sanitary sewer manholes should be on a single layer with no other information.
2. All manholes must be drawn as a point.
3. Each manhole must have a unique label. Each label must be an attribute block and connected directly to the manhole point.
4. All manhole labels must be on a single layer with no other information.

An example of the sewer line and manhole identification is shown in figure 1.

Figure 1.



We have yet to find a CAD document prepared by a municipality with the anticipation of being used for a GIS. Therefore, each sewer line and each manhole must be redrawn.

R0024963

All non-active information that you would like to display should be on a layer by itself. For example, if you would always like to show the streets and lots/blocks at the same time, they should be on the same layer. Street names may be located on a separate layer so the user can turn them on or off. It is wise to select the size of characters you want to display in ArcView® while you are in AutoCAD®. ArcView® will allow you to change the character font but will not allow you to change the character size. A list of common non-active display layers is shown in Table 2.

Table 2

Common Non-Active Display Layers

Item No.	Display Layer	Item No.	Display Layer
1	Sewer Line Identification Text	6	Railroads
2	Manhole Identification Text	7	Study Area Boundary
3	Streets/Lots/Blocks/Parcels	8	Drainage Area Boundary
4	Street Names	9	Drainage Area Sub-Basin Boundary
5	Streams	10	Orthographic Images

ArcView® can view CAD images in either of two methods, as a shape file or from a permanent shape file. Each method has advantages and disadvantages. If the CAD file is read directly by ArcView® and a shape file created each time the project is opened, any changes made to the CAD file will automatically be recognized by ArcView®. The disadvantage to this method is that more time is required when opening a project in ArcView®. If a permanent shape file is created by ArcView® from the CAD file, the project will open much quicker but changes are not automatic. The user must recreate the permanent shape file each time the CAD file is changed. As a general rule of thumb, we have found it much faster to create the shape file directly from CAD on projects where multiple changes will be required. If the shape file will be created each time the project is opened, it is possible to delete all of the tables before saving the project. The tables will be recreated each time the project is opened, saving valuable time.

GIS

Before the user determines the appropriate procedures for developing the GIS, they should consider the use of the GIS for future projects. As a consultant, it is important to implement a GIS shell that is somewhat generic and can be applied with few modifications to multiple projects.

ArcView® will allow the user to define multiple views for each project. A view is an interactive map that lets you display, explore, query, and analyze geographic data. For our project only one view was developed.

For our project, ArcView® was used only as a graphic viewer. Each piece of active information that the user would like to display, such as a manhole or sewer line, is considered a feature. Each feature must come from a feature source that may include individual layers from a CAD file, an orthographic image, photographs, or clip art. Each active feature to be displayed must be one of four types; (1) a point, (2) line, (3) annotation, or (4) polygon. Features may also be geocoded in ArcView®. Geocoding is a method of attaching active points, or features, to a map, using ArcView®.

For our project two types of active features were used, points for manholes and lines for sewer lines. All other images displayed were non-active. The point and line files were joined using ArcView® to form a shape file. After the shape file is created, it can be opened as a table. Additional data fields may be added to the tables to be used for display purposes.

Once the shape files have been created, themes must be created to display the data contained in the shape files. ArcView® features a table of contents containing a list of available themes for each view. For themes that the user will always keep in the table of contents, such as sewer lines, manholes, or study area boundary, the themes should be created and saved with the project. Each time the project is opened, the themes will be displayed in the table of contents.

Data that may be constantly changing, such as data collected in the field and entered into a database, can be displayed by writing scripts that create themes used to display data. The scripts must be written in Avenue program language for use in ArcView®. If the information in the database changes, the themes will not automatically change. By deleting the themes and recreating them using the scripts, the current data will be displayed. The Avenue scripts can be added to the ArcView® menu for ease of use. Learning to write Avenue scripts can be quite time consuming. Several example scripts, which the user may find helpful, are provided with ArcView®.

ArcView® can create two types of plots, *layout* and *view only*. The most common method for plotting from ArcView® is by using *plot layout*. *Layout* will allow the user to select the paper size, orientation of the plot, title, legend and north arrow. ArcView® allows the user to save multiple *layouts* so a new *layout* won't have to be created each time a plot is desired. Plots may be sent directly to a plotter/printer or exported to a file. When exporting to a file, ArcView® creates a raster image, sometimes requiring a tremendous amount of memory. If no legend or title is required, the user can plot a *view only* image.

Resources

Developing a GIS did consume a substantial amount of time. Our effort can be broken down into two major tasks, preparation of the CAD maps and development of the ArcView® themes. Development of the ArcView® themes can be further divided into two categories, permanent themes and themes created from scripts. Keeping in mind that we were near the bottom of the learning curve for ArcView®, a summary of hours used to develop the GIS is shown in Table 3. Since the implementation of the Main 390 project, we have developed several other projects, each requiring much less development time. An estimate of hours required to develop the Main 390 project at our current location on the learning curve is also shown in Table 3.

Table 3

Project Resource Summary

Task	Actual Project Hours	Estimated Project Hours *
CAD Map Preparation	48	24
Creation of Permanent Themes	10	4
Creation of Scripts for Non-Permanent Themes **	220	2
Total	**278**	**30**

*- Estimated Project Hours determined based on substantial knowledge of GIS development
**- Significant learning curve for Avenue program language

Learning Avenue programming language required a significant effort. Since scripts written for the Main 390 project were generic, development costs were distributed among several projects, reducing the amount of hours billed to the project. As can be seen in Table 3, the time required to utilize the existing scripts for non-permanent themes is minimal compared to the initial theme development.

Based on the size of the Main 390 project, approximately 4 hours are required to input unique information into the databases, create the theme, and review for accuracy. Graphically tracking information, such as maintenance records, with ArcView® requires only a simple data entry and no changes to the CAD map, reducing the actual time required for each map by as much as 50 percent. We estimate approximately 8 hours would have been required if CAD maps were developed and checked for accuracy for each of our plots. If 4 hours were actually saved for each plot, using GIS will become cost-effective when 70 plots are created.

For our project, we anticipate in excess of 60 plots will be generated prior to submitting the Final Report to the City. In addition to the anticipated plots, several plots were required to show rehabilitation efforts from multiple design consultants. ArcView® will be used to track progress of the design consultants through completion of construction. Based on the interim project review and reporting requirements imposed by the client, we will exceed the 70 plots required. Since we use the GIS shell developed during the project for other projects, our savings is considerably more. If the GIS/database is provided to the municipality and continually used, the savings becomes even greater.

CONCLUSIONS

By utilizing a GIS, we believe we have enhanced our performance and improved the quality of project deliverables. Although our initial project resource savings were not substantial, we have proven on projects since, significant resource savings may be achieved.

By implementing a GIS as the initial phase of a project, field activities are easily tracked, eliminating the need for cumbersome master maps, which require daily updating. Although a GIS does require daily updating, it is quicker to enter the field data into a database, which is required anyway, and simply recreate the appropriate theme(s) than to highlight maps.

Following the old-fashioned methods of presenting project findings and recommendations using limited graphics and tables is inadequate by today's standards. There is no real comparison of the archaic reports of the past to the value of an active GIS provided to a client following project completion.

Implementation of a GIS can be seemingly exhausting. If a fully active GIS is the ultimate goal, months or even years may be required for such development. By providing some forethought, the GIS application we have described can be integrated with the ultimate goal, while still being useful within a short time frame.

ABSTRACT

To better manage its sewer infrastructure, the Marine Corps Recruit Depot (MCRD) in Parris Island, South Carolina, has implemented an automated mapping and facility maintenance management program with a geographic information system (AM/FM/GIS). This program consists of a link between ArcView 3.0 (the geographic information system), which views AutoCAD (automated mapping) files, and CASS WORKS (facility maintenance management program).

The primary goals of implementing this plan were to create physical inspection and inventory databases of the sewer infrastructure; update the sewer system AutoCAD map; and to have a linkage between the facility management program, where the databases were to reside, and the sewer map. The secondary goals were to make rehabilitation recommendations based on physical inspections, establish a preventative maintenance plan, and create a work order history.

Results of Implementation

The primary goals were achieved with a combination of a sewer physical inspection and the MCRD's existing database. Above-ground manhole inspections and television inspections were conducted for one-third of the MCRD's sewer system. Physical inspection databases for manholes and line segments were created in the facility maintenance management program as a result of the field inspections. Also, sewer and line segment inventory databases were created from a combination of collected data and the MCRD's existing data.

The MCRD's sewer map was contained on twenty-five different drawings. One seamless sewer map drawing was created to be viewed in ArcView 3.0. The sewer drawing was updated for those portions of the sewer system that were inspected. Updates to the sewer map included labeling both new manholes and sewer pipes, as well as abandoned manholes and sewer pipes.

The databases in the facility management program were linked to the sewer map structures. The result was an inter-related connectivity between the facility maintenance manager and ArcView 3.0. The advantage of ArcView is the ability to perform spatial analyses of the sewer system.

The secondary goals were achieved by performing rehabilitation and cost analyses on the collected data using cost analysis program functions in the facility maintenance management program. This task also served to prioritize rehabilitation based on severity and cost. A preventative maintenance plan was established in the facility maintenance management program to inspect the remaining structures in the sewer system. Future work orders will be generated listing the structures to be inspected. A work order history enables the MCRD to keep track of costs as related to repairs for each structure or overall costs for all repairs.

The end result is an AM/FM/GIS program that allows the MCDR to perform queries, spatial analyses, and cost analyses on the databases. The databases and sewer map will become updated as the entire system becomes inspected.

INTRODUCTION

To better manage their sewer infrastructure, the Marine Corps Recruit Depot (MCRD) in Parris Island, South Carolina, has implemented an automated mapping and facility maintenance management program with a geographic information system (AM/FM/GIS). This program consists of a link between ArcView 3.0 (geographic information system), which views AutoCAD (automated mapping) files, and CASS WORKS (facility maintenance management program).

The primary goals of implementing this plan were to create databases and inventories of the sewer infrastructure; update the sewer system AutoCAD map; and to create a linkage between the facility management program, where the databases were to reside, and the sewer map. The secondary goals were to make rehabilitation recommendations based on physical inspections, establish a preventative maintenance plan, and create a work order history.

To accomplish these goals, the project was divided into two phases. The first phase involved creating one seamless AutoCAD drawing, to be viewed in ArcView 3.0, from the 25 existing sewer drawing files. After viewing the new sewer drawing for consistency, it was linked to the facilities maintenance management program through ArcView.

The second phase included the following tasks; manhole and television inspections of the sewer system, building physical inspection and inventory databases, and analyses of the collected data with rehabilitation recommendations.

METHODOLOGY

Map Linking

In order to achieve the goal of linking the sewer system entities to the sanitary facility maintenance management software (CASS WORKS) a single project sewer drawing containing only the sewer system was needed. This was accomplished by combining 25 AutoCAD source drawings of the sewer, provided by the MCRD, into one seamless AutoCAD drawing.

The first step for creating a seamless AutoCAD drawing was to remove from each source drawing all title blocks, sheet borders, legends, etc. Also, the layer colors and entity colors of each source drawing were set and standardized. These were the initial steps for developing the seamless sewer layer drawing.

Next, the 25 individual source drawings were combined into one drawing. The source drawings were geo-referenced in a common coordinate system. This is important because the placement of each individual source drawing relative to one another in the seamless drawing becomes a semi-automatic and exact process, rather than a manual placement process based on the judgment of a CAD Technician.

The new seamless drawing was then edited to conform to translation specification. Before an AutoCAD drawing can be easily and cleanly translated into ArcView, it must adhere to specific topological, entity type, and layer specifications. For example:

- Manholes, line segments, force mains, and pump stations must be on separate AutoCAD layers. In the source drawings from the MCRD, these features were on the same layer.
- A single and continuous line segment must connect two manholes or two pump stations. This condition was not always true in the source drawing. Line segments along tile edges were broken between manholes. Elsewhere in source drawings, broken line segments were observed and there were cases in which a single line segment connects three or more manholes.
- Line segments must be digitized in the direction of flow. This condition was not inherent in the source drawings.
- Manholes and pump stations should be represented by AutoCAD attribute blocks with their structure number embedded in the attribute block as the attribute value. In the source drawings, the manholes and pump stations were represented as elementary AutoCAD entities, such as filled polylines, and the structure number was a simple text entity positioned near the structure.

The AutoCAD editing involved was a manual process. The seamless source drawing was traced over and its entities replaced by standardized entities on standardized layers. The resulting drawing adhered to an AutoCAD drawing specification that translated easily and cleanly into ArcView. A series of AutoCAD menus was used to facilitate the editing of the source drawing.

Once the editing process was completed, the seamless drawing (which is now the project sewer layer) was viewed in ArcView for consistency. After proofing for consistency, maps were printed and provided to the Depot for consideration in determining the line segments to be televised. Nine maps were provided, along with an index sheet, which contained geographic areas/grids of the MCRD for each map. Also provided was a line segment listing by grid that was generated from ArcView.

In order to reference one force main intersection from another, a reference point was required where force main symbols met at an intersection or did not have a point where it intersected a pump station. To complete this task, nodes and node numbers were placed at each pump station where force mains begin or end and at the intersection where force mains joined together.

The last phase of the map linking involved linking CASS WORKS to the sewer layer in ArcView using a series of ArcView operations. Once this linkage was established, GeoCAD enabled CASS WORKS to be directly accessed from ArcView, or ArcView to be directly accessed from CASS WORKS.

FIELD INVESTIGATIONS

The field investigations consisted of above-ground manhole inspections which were performed in conjunction with the television inspection of the gravity sewer lines.

Manhole Inspections

The purpose of this task was to visually inspect sanitary sewer manholes and record the materials and condition of the manholes. In addition, this task served to update the AutoCAD sewer drawing based on a physical survey of the areas inspected. The MCRD sewer system is divided into a system of 25 grids, with 193 manhole inspections conducted in 11 of the grids.

The manhole inspections were conducted from above-ground and all observations recorded on standard Manhole Inspection Forms. The manhole inspections focused on specific areas of observations. For example, the inspection differentiated between the condition and type of defect (e.g. cracked or deteriorated), construction, and evidence of inflow among the frame, frame seal, and corbel. A rate expressed in gallons per minute (gpm) was assigned to each defect during inspection if active. If inactive a rate was expressed by a default value based on manhole location, location characteristics, and defect type.

The manhole inspection for this project was divided into seven specific areas. The following lists an overview of the specific areas with their corresponding recorded observations.

- Manhole Surrounding Area - Type of precipitation, ground condition, manhole location, and location characteristics.
- Cover Description - Type, cover to rim fit, diameter of clear opening, cover bearing surface, number of holes in cover and size, grade elevation, and evidence of inflow.
- Frame - Condition, frame adjustment construction, frame to corbel seal condition, and evidence of inflow.
- Corbel - Construction, condition, and evidence of inflow.
- Walls - Construction, condition, and evidence of infiltration.
- Bench/Trough - Trough construction, trough condition, bench deposition, evidence of infiltration, pipe seal condition, and evidence of infiltration.
- Miscellaneous - Step condition, surcharged at time of inspection, evidence of surcharging, and indication of groundwater level.

Three additional observations were also recorded, which is not part of the standard Manhole Inspection Form, during the inspection. The number of laterals within each manhole and whether a manhole contained a rainguard or was previously grouted were recorded. These additional observations helped update the new sewer source drawing and the MCRD records of maintenance previously performed.

Television Inspections

This task consisted of conducting a physical survey of selected gravity sanitary sewer lines. It also assisted in updating the sewer drawing and supported the manhole physical survey for the areas inspected.

A total of 31,603 linear feet of gravity sewer lines were televised. All observations were recorded during the television inspection process. This included recording observations such as lateral location and position, identification and quantification of defects, and line segment length. During the inspection a rate expressed in gallons per minute (gpm) was assigned to each defect if active or by severity if inactive. If a defect was inactive and was not quantified during the inspection, then a default value was assigned based on the type of defect.

Observations were recorded electronically using a television inspection software, LineView with Video Capture for Windows. Video capture allows the user to capture images of defects in a digital format so that they may be viewed on a computer. An image becomes part of the database because it is linked to its associated line segment.

RESULTS

The results, analysis, and rehabilitation recommendations were based on utilizing specific program functions within ArcView 3.0 and the facility maintenance management program. ArcView 3.0 enables the user to perform spatial analyses. The facility maintenance management program's report writer is used to create television reports, cost analysis reports based on television inspections, and perform queries such as total length of sewer pipes televised

Spatial Analysis

The number of manholes and line segment lengths per grid of the entire sewer system were acquired using ArcView 3.0 spatial analysis functions and from the revised AutoCAD drawing from the field inspection phase. New manholes found during the field investigations were added to the AutoCAD sewer drawing. Adjustments to the location of an existing manhole, which in effect adjusts the length of a line segment, were only made in those cases where moving a manhole would not affect any upstream manhole locations. The spatial analysis also indicated there was a total of 94,307 linear feet of gravity sewer lines and 565 manholes for the entire sewer system.

The spatial analysis functions for ArcView 3.0 were also used to determine the total lengths of the force main. This consisted of determining the length of each force main from pump station to pump station and pump station to force main. Results of the spatial analysis indicated 50,343 linear feet of force main exist in the system.

Manhole Inspections

Data collected from manhole inspections was input into the facility maintenance management program to create a manhole physical inspection database for the MCRD. The manhole physical inspection module in which the database was created, is modeled after the standard Manhole Inspection Form. Therefore, all of the data collected was entered into the physical inspection database, including the three additional observations recorded.

A database for the entire system of manholes was also created in the sewer inventory module. The sewer inventory manhole database includes manhole number, manhole type, street name, location, map reference, remarks, as well as other manhole specific information. The information in the manhole inventory database varies depending on whether the data was provided from the manhole inspection or from the MCRD's existing data, or both. For those manholes inspected, the rim and invert elevations from the existing MCRD database were added to the manhole information entered from the inspection. If a manhole was not inspected, then only the manhole number, rim and invert elevations, and grid location from the existing database were added to the manhole inventory database.

The invert elevation from the MCRD's database was entered into the 'user defined' field in the manhole inventory and the rim elevation into the 'rim elevation' field. The depth was automatically calculated from the rim elevation minus the invert elevation. It was assumed that the rim and invert elevations were obtained from the same datum.

Manholes that no longer existed were removed from the sewer drawing to reflect accuracy, but were included as part of the manhole physical inspection and inventory databases. Manholes that no longer existed were included in the databases for possible future reference and as a matter of record to show that a physical survey was performed for those manholes.

Television Inspections

All observations recorded in LineView with Video Capture were uploaded into the facility management program. Television inspection reports were generated from the facility management program for each line segment televised. The first page of the television reports include the direction of gravity flow from upstream manhole to downstream manhole, length and diameter of pipe, tape index, street name or building number, remarks, and general observations. The second page of the television report contains a listing, in chronological order, of the observations recorded during the inspection.

Cost reports produced from the facility management program list the unit costs and total rehabilitation cost for each repair method. The unit rehabilitation costs listed are the ratio of the repair cost to removable infiltration in $/gpd and the ratio of the repair cost to length of pipe in $/ft. The reports recommends rehabilitation by choosing the rehabilitation method with the lowest $/gpd. The cost analysis and rehabilitation recommendations are based upon various factors such as repair methods, repair cost, length between joints, and number of laterals.

Preventative Maintenance Plan

A preventative maintenance plan was established in the facility maintenance management program to inspect the remaining structures in the sewer system. Future work orders will be generated listing the structures to be inspected. A work order history will enable the MCRD to keep try track of costs as related to repairs for each structure or overall costs for all repairs.

DISCUSSION

Maps were generated from ArcView that visually displayed the manholes and line segments, based on tables created listing manhole I/I severity and line segment infiltration, for each grid of the system where field investigations were performed. To identify manhole structures symbols of varying sizes and color were used to represent ranges of I/I severity. For line segments, different colors were used to represent ranges of infiltration severity. The resulting maps produced a visual representation of the clustering of manholes and pipe by extraneous flow severity. The benefit of this type of map display is that it enabled the MCRD to see visually where the greatest concentration of extraneous flow was entering into the system. This visual scenario of cluster concentration can be used for any criteria, such as the cost to treat ($/gpd) to determine where to proceed with rehabilitation based on the cost-effectiveness of repair and reduction of infiltration migration.

After all the data was entered, an analysis was performed on the manhole database which produced a listing of all defects, associated inflow or infiltration, cost to repair, and rehabilitation recommendation based on the type, location, and characteristic of the defect for each manhole. Tables were created which listed by grid number the results of each manhole rehabilitation analysis. Included on the tables were manhole construction, I/I quantification, cost of rehabilitation, unit rehabilitation cost in $/gpd, and recommended rehabilitation.

To generate rehabilitation recommendations of all defect sources as required by the MCRD, the cost to treat wastewater was set at $100/gpd in the cost analysis report.

The following were other considerations in determining costs and rehabilitation recommendations:

- A rehabilitation recommendation for a cost report is based on the most cost-effective rehabilitation method ($/gpd) from MH to MH (e.g. Fold & Form). Individual joint grouting and spot repairs are not considered as a MH to MH rehabilitation, but as a combination they are. If no MH to MH rehabilitation is cost-effective, then spot repairs or grouting is recommended if either is cost-effective. If neither is cost-effective then no recommendation is made.
- Being a study project, exact unit prices for the MCRD area were not determined. Repair costs were based on previous unit budgetary design/construction projects.
- Majority of repairs occur in paved areas or where unpaved areas are not easily accessible.
- Five feet is a nominal length for determining repair length.
- Recommended spot repairs (point repairs) may be needed before MH to MH rehabilitation begins. The need to perform each spot repair should be evaluated before the start of rehabilitation.
- The costs for spot repairs are not reflected in rehabilitation costs, when a different rehabilitation method (such as Fold & Form) is more cost-effective.
- All joints are recommended for grouting to prevent groundwater migration to unrehabilitated joints. Joints may not be active with infiltration, but may become active when the joints with visible infiltration are rehabilitated.
- Generally, the reduction in capacity from lining is not significant unless the system is already flowing at full capacity. The reduction in cross-sectional area is compensated by the reduction in friction.

Unit prices include the following estimated construction and related costs:

- By-pass pumping and dewatering
- Trenching and backfill
- Sheeting and shoring
- Nominal select fill and seeding
- Pavement removal and replacement

The rehabilitation methods considered for the cost analysis included fold and form, cured in place, complete replacement, joint grouting, and spot repair. The cost of repair for several methods were calculated so that during the construction bidding process, when the MCRD receives bids from contractors in their area of specialty, the cost report can be a barometer for the different types of construction bids that come in.

CONCLUSION

The end result is an AM/FM/GIS program that allows the MCDR to perform queries, spatial analyses, and cost analyses on the databases. The databases and sewer map will become updated as the entire system becomes inspected.

RELATIONAL DATABASE SYSTEM FOR IN-SEWER AND CSO MONITORING

ABSTRACT

In urban hydrology, the refining of models for calculating sewerage system dynamics requires more and more numerous measurements which can be taken at time steps down to the order of a minute. Hydrologists and hydraulic engineers are now faced with the problem of managing, validating and processing these measurements or time series. We have developed a relational database application, which specifically addresses the problem of managing time series in urban hydrology.

The relational model contains three fundamental entities, which are the local station, the sensors linked to a local station, and the measurements taken by the sensors of a local station. With these three entities, the positions of time series in time and space are determined, which permits the establishment of relations among them and the identification of behavior expectations for the sewerage system. Complementary entities are also included which help grasp the more global aspects of the in-sewer flow such as its behavior during dry weather, rainy periods which are deduced from rainfall measurements, and the dynamics of the controlled devices.

A group of primitive functions makes it possible to validate and process the time series through a graphic interface. These primitives introduce various techniques such as splines, averaging and exponential filters, Manning's formula, etc. Once processed, the data can be used with a simulator, and exported or printed in various report formats. The database is an open system and its relational format renders the data accessible to any specific processing procedure.

The database was used for in-sewer and CSO on-line monitoring in the City of Paris (France). More thant 100 points were monitored simultaneously, of which 50 were permanent, the others were moved from one site to another after having recorded enough data. Measurements included water levels (at three levels) and water velocities. Flow was computed out of this data and with consideration from in-sewer sediment level data. Water quality data included suspended solids, BOD and COD, although the database accepts more water quality parameters.

This first application demonstrated the good representation of the relational data model the great performance of the query mode. Object-oriented modules were later added to enable data input in both on-line and off-line modes, and to validate and adapt to hydraulic or hydrologic simulation models. The time series can then be used for the model calibration, for system diagnosis, and for the design of new engineering structures.

Urban Hydrology, Relational Database, Combined Sewer Overflow, Monitoring, Data management, Local Station, Sensors, Measurements.

INTRODUCTION

In urban hydrology, activities such as monitoring, characterization, diagnosis, calibration, simulations and real time control require more and more measurements which become difficult to manage. The quantity of measurements, which can be taken at one minute time steps and often on a period of one year or more, easily attains a few million for each sensor. Hydrologists and hydraulic engineers are now faced with the problem of validating, storing, recuperating, and processing all this data.

A relational database becomes essential and seems to be the solution to efficient and reliable data management. A relational database enables a logical and conceptual description of elements such as sensors and all the associated data, eliminating the problem of having a multitude of files. Moreover, recent developments of database structure and Object-Oriented enables to recuperate and process data with simple query tools.

Having numerous experiences in urban hydrology activities using a great quantity of data, Asseau-BPR through CEGEO Technologies research program has developed a relational database specifically for this purpose including user-friendly interfaces with numerous functions to calculate, produce reports, link to models such as SWMM, graphically observe simulation results or measurements, etc.

The database called MED-DB was used in 1996 for in-sewer and CSO on-line monitoring in the City of Paris and Vicinity (France) (population: 8 million). More than 100 sites were monitored simultaneously, which 50 were permanent, the others were transferred from one site to another after having recorded sufficient data. Measurements included water levels (at three levels) and water velocity. Flow was calculated from this data and with consideration of in-sewer sediment level data. Water quality data included suspended solids, BOD and COD.

This first application and others since, have demonstrated the good representation of the database and the great performance of the query mode. This paper will present the database model necessary to secure and structure data as well as the interfaces developed to facilitate the query mode and the overall work in urban hydrology.

Database Model

Two qualities required for a relational database used in urban hydrology are the robustness and a great volume capacity. For these reasons, Oracle was chosen as the basis of our development, although other relational database software can be used along with the interfaces described in the next section.

The key to a good relational database is the simplicity and the quality of the logical structure of its model. This will assure stable and reliable performances for queries and will facilitate the management and maintenance. For example, when a database model contains too much relationship levels and inheritance, the performance of data processing is poor and queries are difficult to perform. On the other hand, a simple logic database structure enables the easy access to information and short time process. For the Paris project, MED-DB was used on an IBM RS 6000, the disk space used by the large quantity of data was 4.5 GIG and the response time to a query was less than 30 seconds and around 15 seconds in average.

In the MED-DB, the logical structure is very simple, it is based on the three fundamental field elements:

- Local stations
- Sensors
- Measures

R0024976

These three elements constitute the entities of the relational model. Among these three entities, relations of time and space are determined to properly represent reality.

In the database each entity is represented by a table, rows being the instance and columns being the attributes of the entity. Table 1 illustrates a simplified example of these tables.

Table 1. **Entities represented by tables in the database model**

Local station					
Identification	In service	Time of acquisition	Status (Permanent or Temporary)	Phone number or IP address	Localization (X,Y)
P1	96/04/25	11:23:44	P	4188665567	1432522,2002428
P2	96/04/25	11:23:51	T	4188665543	1432538,2002404
WWTP1	96/04/25	11:23:57	P	145.200.120.240	1432562,2002389
...					

Sensor						
Identificatio n	Local station identification	Channel	In service	Out of service	Absolute Minimum; Maximum	Acceptable Minimum; Maximum
Quality 1	P1	Q1	96/04/25	-	(0;120)	(30;100)
Flow 1	P1	F1	96/04/25	-	(0;7)	(0;5)
Quality 1	P2	Q1	96/04/25	-	(0;130)	(30:90)T
...						

Measure							
Local station identification	Channel	Date of acquisition	Duration (min)	Value	Validated value	Validation method	Validation status
P1	Q1	96/06/27	5	63,4	63,4	-	Valid
P2	Q2	96/06/27	5	-545	60	Frequency	Invalid
WWTP 1	F3	96/06/27	10	3,6	3,6	-	Valid
...							

This structure has been developed with the objective of query time saving. For example, the relations created between tables with foreign keys enables the access to data using only two tables at the same time, this reduces time of response. In fact, each measurement is independent from its sensor. Hence, measurements at one local station become a stream of measures without interruption and independently of its sensor and the local station. The relation between sensors and measurements, through the local station table, is used only for data validation.

A good relational database model is essential to ensure the security of data, to store it in a more convenient and logical manner and to reduce time of SQL queries. On the other hand, the database model with SQL is not enough to ease the engineering work behind all this data. Even if one is perfectly at ease with SQL queries, the data analysis, the data validation, etc. are not easily performed. The next section will present the user-friendly query mode of the MED-DB database that has been developed for this purpose.

Interfaces, the query mode

The query mode has been developed with one objective: facilitate the work of engineers. Once that a good relational database is developed, efficient and easy access, treatment, printing as well as storing data and results are possible with practical interfaces. The interfaces were developed in C++ Object-Oriented and Delphi. These software combine the performance of screen display and graphic quality (C++) to the rapidity of development and customization (Delphi). C++ Object-Oriented and Delphi software have the advantage of producing direct executables in compiled language to reduce management file time.

The database MED-DB is linked to 4 Work Modules : Monitoring, Modeling, Simulation-Optimization (MED-SOM), and Real-Time-Control. These Modules work in hand with a utility called MED-MEASURE. This utility is used for handling measurements, hence it is the main tool of in-sewer and CSO monitoring. MED-MEASURE is useful to observe and treat data and to prepare data for further steps such as simulations for diagnosis, design and operation. Only MED-MEASURE will be presented in this article. For more information on the Work Modules, refer to other articles in the present and in past WEF conferences.

MED-MEASURE is composed of a set of interfaces acting as a bridge between the database and the user. The query mode becomes simple because of the SQL pre-programmed queries. MED-MEASURE has the following main functionality:

- Data acquisition
- Validate data
- Data analysis
- Export data and reports

Data acquisition

With different research types(parameters, period, location), MED-MEASURE can retrieve data from the MED-DB or from any other database. Furthermore, field data can be recuperated and integrated in the entity tables in real time or in differed time. Furthermore, the user can pre-program a field data retrieval at each chosen time step. This direct data acquisition reduces risk of errors and minimizes the engineering time normally needed for these operations. A first interface enables to retrieve data and an other to visualize the data arriving graphically as time series.

When data is retrieved in differed time, data is read by a standardized format file, as it is done in most software. The files are read, measures are verified, according to predefined validation, and they are integrated, file by file by the SQL Loader tool furnished by Oracle. In real time data acquisition, a communication is established between the database and the local station, and measures are directly transferred into the database tables with automatic verification of data. In both cases, the local validation is predefined with upper and lower acceptable limits.

Data validation

Although sensors are more and more robust, communication breakdowns, calibration default, etc. often occur. Therefore, the user must be able to validate or invalidate and replace data. According to the graphic interface the user can choose a time series for which he will identify non-valid data. The invalid data or time zone is selected with scroll bars and can be invalidated and replaced with new data. Figure 1 and 2 show the interface for selecting a time series and the data validation interface. MED-MEASURE provides different validation methods to replace invalid data such as:

- Duplication
- Interpolation
- Filtering
- Thresholding
- Flow recalculating
- Fitting curves
- Orthogonal search (for signal reconstitution)

The validation results can be saved in the database as well as the original time series. A registered measure in the database contains the original value, the validated value and the validation method used. The user is able at any time to recuperate original time series for equipment verification or revalidation.

Data analysis

Figure 3 shows the interface which enables the user to display multi-curves of any type of data. The user can elaborate its one graphs along with its needs of comparison. Measures can be compared to simulation or calibration results. 6 different variable types can be displayed and 14 different time series. To facilitate different analysis, the user has the possibility of choosing his templates, whereas axis, time zones, parameters, etc. are variable. The templates developed by the user can be saved and retrieved.

Rainfall analysis can also be done, whereas highs, maximum intensity, frequency, etc. are automatically calculated. Figure 4 illustrates the interface developed to select rainfall events along with their calculated characteristics.

Export data and reports

Data treatment is often used to prepare input for future analysis. Validated measures are available for these studies through the other modules with an export program that transfers data in table format. For monitoring campaigns and preliminary analysis, treated and untreated data can also be printed as graphics or as reports through other modules or directly through MED-MEASURE.

CONCLUSION

The database MED-MEASURE has been utilized with success for different projects. For the Paris project, MED-MEASURE became essential to manage 500 sensors for 100 sites of which 50 were permanent for a campaign that took more then one year. Automatic data processing on top of usual data treatment processes was useful to validate and take advantage of the 4.5 GIG of field data. These measures and the same database is know used for a diagnostic for the Ile-de-France Region (Paris and surroundings) whereas the same measures are transferred to the Mouse and Caredas simulation models. The Ile-de-France Region project is a good example were the database enabled to evolve from a monitoring campaign towards a diagnosis. The evolving aspect of the database will enable also to facilitate a further step towards Real Time Control.

The development of a database such as MED-MEASURE is not a scientific breakthrough, useful database software development exists for that matter and facilitates database development. The interest of this database is not the development but the result it answers specific needs in urban hydrology that is to facilitate data management.

ABSTRACT

Desktop mapping systems, also known as Desktop GIS, have improved greatly in power and functionality in the last few years. Geoprocessing that would have required tens of thousands of dollars in hardware and software just five years ago can now be performed on a mid-range desktop system with about fifteen hundred dollars worth of software. Further, the software is easier to learn and use, and a wider variety of data formats is supported, making Desktop GIS a very attractive platform for some sophisticated geoprocessing in support of environmental engineering studies.

This paper explores the application of a Desktop GIS to the East Baton Rouge City/Parish Sanitary Sewer Overflow Corrective Action Plan. While the GIS was instrumental to all phases of the process, including data collection/translation, database development, hydraulic modeling, model calibration, and options development, its key functionality was in the areas of overlay analysis and network tracing. Overlay analysis was used to allocate residential population from the census data to the sewer subbasins, and to compile a breakdown of land use by sewer subbasin. Network tracing was implemented to a) characterize the area upstream of a point, such as a pump station or flow meter; and b) to select facilities downstream of a point, for example to determine which facilities must be in a model for a selected area.

Other tasks the GIS was employed to perform include:

- QA/QC of survey data through automated profiling
- Calculation of storage volumes
- Calculation of angular head losses
- Export of model input files
- Import/display of model results

The desktop system was able to handle a large amount of data. Over 35,000 manholes and pipes, about 400 pump stations, 1200 subbasins, 350 census blocks and 10,000 land use polygons were in the study. This project proves that it is possible to build an effective GIS without spending a lot of time and money, and that the investment in Desktop GIS can save an incredible amount of time in the hydraulic modeling process.

KEYWORDS

Hydraulic modeling, geographic information systems, wastewater, sanitary sewer overflow

INTRODUCTION

The East Baton Rouge Sewerage Commission (EBROSCO) is responsible for sewerage services for most of the Parish of East Baton Rouge and all of the City of Baton Rouge, Louisiana. In anticipation of Federal EPA requirements concerning Sanitary Sewer Overflows, EBROSCO initiated an SSO Corrective Action Plan, a two-year study involving water quality monitoring, flow monitoring, system data collection, and hydraulic modeling, with the goal of eliminating sanitary sewer overflows.

THE HYDRAULIC MODELING PROCESS

Because of the expanse and complexity of the EBROSCO sewer system, a sophisticated. dynamic computer model was required to analyze the system and plan corrective measures. The Hydroworks hydraulic model by Wallingford Software was chosen because it can handle a manifolded pressurized main system and real-time control options. The hydraulic modeling process is very data-intensive. Steps in the process include data collection/translation, database development, model calibration/verification, and solution options development. It was immediately obvious that some sort of Geographic Information System (GIS) would be required to manage and process all of the data.

This paper examines the application of a Desktop GIS to the hydraulic modeling of the sanitary sewer system in Baton Rouge, Louisiana. The focus will be on some sophisticated GIS functionality that was not available on the desktop until fairly recently.

GIS: THE SOLUTION FOR DATA HANDLING

Desktop GIS systems have come a long way in the past ten years. What started out as very basic GIS data viewers have evolved into fairly powerful systems capable of some sophisticated GIS functionality. ArcView GIS by ESRI was chosen for this project because of its capabilities, low cost, and ease of customization through its Avenue programming language. This paper focuses on two key GIS functions:

1. Overlay Analysis, and
2. Network Tracing,

but first, let's look at the GIS data structure.

GIS Data Structure

This GIS implementation utilizes a classic node-link "tree" structure, with polygonal area themes as the "leaves." Nodes include any point-type feature, such as manholes, pump stations, flow monitors, etc. Links include anything that conveys sewer flow from one node to another, such as pipes, force mains, pumps, weirs, orifices, and the imaginary subbasin-to-manhole linkages. Area themes include subbasins, land use, and census blocks. Subbasins are the basic unit of area in a hydraulic model.

Overlay Analysis

A critical input to the hydraulic model is residential populations by subbasin. This can be derived from the census data, by overlaying census blocks and subbasins, assuming that a population distribution can be defined. Another critical input is a breakdown of land uses by subbasin. This is a straightforward overlay of land use and subbasins.

Components of the overlay process described herein are:

1. Census Data in MapInfo Format
2. Land Use Data Digitized in Microstation
3. Sewer Subbasins Digitized in ArcView

The census data were translated to ArcView shape files. The land use data could have been used in its original Microstation format, except for a problem with "doughnut" polygons. "Doughnut" polygons are polygons that completely surround one or more other polygons. In the overlay process, the ArcView routine cuts these "doughnuts" incorrectly. Nonetheless, it was easy to translate the Microstation files to ArcView shape files so that the topology could be corrected (no "doughnuts") in ArcView. Sewer subbasins were digitized right in ArcView, with sewers, streets and land use in the background for reference.

An overview of the overlay process is as follows:

1. Census and land use are overlain to produce a population distribution map.
2. The resulting population distribution map is checked against the original census data, and
3. Subbasins and the population distribution map are overlain to derive:
   a. Residential population of each subbasin, and
   b. Land use breakdown of each subbasin.

Population from the census is moved around based on land use weighting factors. No population is moved from one census shape to another, and the sum of the populations of the resulting fragments for a given census shape is equal to the original, given population of that census shape.

The land use weights are relative to each other, and do not have to add up to any particular number. In this case the single-family residential number is set to 1.0 and all of the others are related to this. See Table 1 for an example.

Table 1. Land Use Weighting Factors

Land Use	Land Use Weighting Factor
Single Family Residential	1.0
Multi-Family Residential	2.0
High Density Residential	3.0
Rural Residential	0.25
Industrial	0.05
Park	0.0
Commercial	0.1
Agriculture	0.1

The output theme has all of the fields and information in the two input themes, plus more. The additional derived output information includes each resultant polygon's area, population, and population density. This theme must be checked to ensure that no population has been lost, and there are no unrealistic population densities caused by aberrations inherent in the overlay process.

Items to check in the output theme include:

1. Attach the same population distribution legend as on the census theme to this theme. First make the "Classification Field" the same as in the census theme. The picture should look exactly like the original census, except for more polygon outlines.
2. Attach the same land use legend that you have on the land use theme and compare to the original land use. They should match.
3. Look for unreasonable population density values.

Residential population from the population distribution theme is aggregated by intersecting the theme with the subbasin theme, and multiplying the fragment density from the population distribution theme by the resultant fragments' areas, and then summing up. Landuse breakdowns are simple additions of fragment areas for each land use.

The output table has all of the fields and information in the two input tables, plus each resultant polygon's population, area, and population density. The output theme and table are intended for checking purposes only. The population and land use data are put directly into fields in the input subbasin table.

The processing of this overlay analysis takes place in two customized Avenue scripts. The sample script named "intersect.ave," which is provided with ArcView, was modified to include the area-weighting calculations used in generating the population distribution map. The same sample script was also used as a base for the subbasin population calculation step. See Figure 1 for an example of the analysis of one census district.

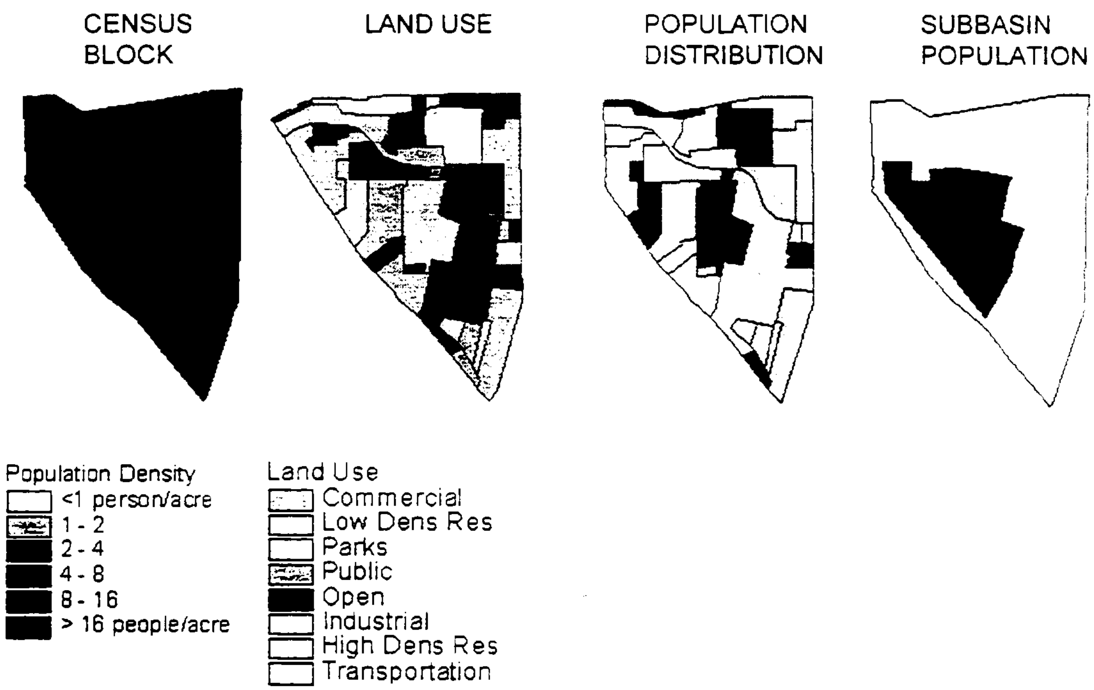

FIGURE 1. Population Distribution by GIS Overlay Analysis. For clarity and simplicity, only two subbasins are shown. Note that the residential population density is highest in the residential land use areas.

Network Tracing

Network tracing is the process of selecting elements upstream or downstream of an element based on directional connectivity of the network. There are two fundamental reasons for tracing up or downstream:

1. Tracing Upstream:
   To characterize the area upstream of an element, such as a manhole, pump station, or flow meter.
2. Tracing Downstream:
   To select facilities downstream of a point, for example to determine which facilities must be included in a hydraulic model for the selected area.

R0024988

Tracing is performed by an Avenue script that iteratively searches through the links table, which contains fields for upstream and downstream-side node identifiers (record numbers). These identifiers are unique for each node in the system. When a downstream search is at a link with downstream node number 2351, a query is issued to select all links with an upstream node number of 2351. These links then go into a list of links to process. The whole process moves hand-over-hand up or down the system until there are no more links left in the list of links to process. Then connecting manholes are selected, and, if it is an upstream trace, connecting subbasins are selected as well.

The obvious application for this process is in the selection of facilities to model for a given area. The user may select the subbasins to model, trace down, and then export a hydraulic model based on the selected subbasins, links, and nodes. Alternately, the user may select a point, for example a pump station, trace up to select the contributing subbasins, and then trace down to extract the required facilities to include in the model.

MODELING

The modeling process is made up of five steps:

1. Element Selection / Model Export
2. Model Running and Import of Results
3. Model Calibration and Verification
4. Model Simplification
5. Solution Options Development

Element selection and model export are performed as described in the network tracing section. The model export process writes a text file in a format readable by the hydraulic modeling program, which then reads this file and verifies the data. The user may then run the model. Hydroworks puts out a text file summarizing hydraulic grade lines, flow velocities, and flow rates for each facility in the modeled system, which are then read back into GIS tables.

In the calibration process, the user views model result graphs and compares them with recorded graphs at the flow monitors, and makes adjustments to such things as groundwater infiltration, dry-weather flow profiles, fast and slow-response contributing areas, in an effort to make the model results match the recorded flow. This GIS implementation facilitates this activity by allowing the user to select subbasins to edit based on the flow monitor immediately downstream. The model result graphs and recorded graphs and subbasin data can be displayed on screen all at once, allowing the modeler to quickly make edits to the subbasin data to make the results fit the recorded data. See Figure 2 for an example.

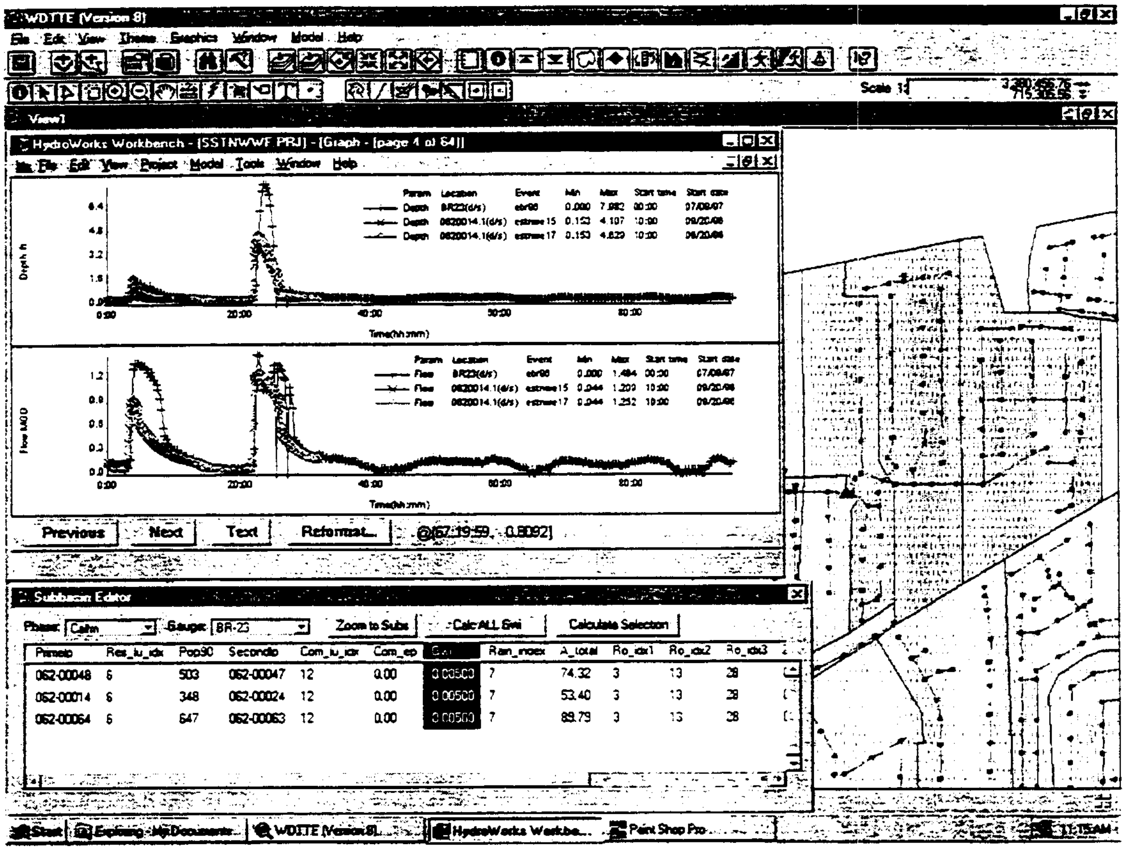

FIGURE 2. Model Calibration. The user selects a gauge in an ArcView dialog and the subbasin data for the area tributary to that gauge is immediately accessible for modification.

Once the model has been calibrated and verified (tested with data from different rainfall events), the model is simplified by generalizing the facilities, that is, taking out as many nodes as possible without affecting the hydraulic response of the model. This simplified model is then used as the base model for options development.

SUMMARY

With this desktop GIS/Hydraulic modeling system we have been able to perform some sophisticated geoprocessing, including overlay analysis and network tracing, in support of hydraulic modeling. Just six years ago, this functionality required a $30,000 unix machine running $10,000 worth of GIS software. Now the same can be done on a $3000 PC with $1200 worth of GIS software.

ACKNOWLEDGEMENTS

This project was funded by the East Baton Rouge City/Parish Sewer Commission. The authors wish to thank Andrew Baldwin of Montgomery Watson for the nuts and bolts of the model export/import routines, and Neil Moody, also of Montgomery Watson, for the loan of his modeling expertise.

UTILIZATION OF GIS IN HYDRAULIC MODEL BUILDING PROVIDES NUMEROUS BENEFITS

Gerald T. Preau, P.E., Sewerage and Water Board of New Orleans
Martin T. Dorward, P.E., Montgomery Watson
Robert Armstrong, C.Eng., Montgomery Watson

ABSTRACT

Many SSO and CSO programs require the building of a hydraulic model for the evaluation of sewer system response to dry and wet weather conditions. These models require the collection, storage and utilization of large quantities of data that will be available from numerous sources and in varied formats. In New Orleans, the collected data was integrated into a GIS system that will aid in the development of the model and provide a tool for future facility planning, design and operation.

Model data was collected from the following sources and converted to an electronic format for integration into the GIS.

- Paper sewer maps for location of sewers, lengths and connectivity
- Physical surveys for manhole elevations, pipe sizes and invert levels
- Systemwide network of flow monitors for system response to dry and wet weather conditions
- Physical inspections and paper records for details of pump stations and other structures (i.e.. siphons)
- Paper zoning maps
- Digital land use maps
- Digital census data
- Pump curves
- Aerial ortho-photography
- Digital water use database
- Digital collection system inventory and work activities database
- Digital two-line streets maps for background mapping

Utilization of a GIS to collect and store the converted data in a single location will not only ease the model building and calibration process, but will result in secondary benefits to the operator long after the modeling phase of the project is complete. The GIS benefits include: single location of collected data, direct download of data to the model, geographical display and interrogation, connectivity quality checks, and review of data before it is entered into the model. System design and operations staff are provided with a useful infrastructure management tool that may not have been developed were it not for the need to develop the hydraulic model as part of a wet weather control program.

KEY WORDS

Hydraulic Model, GIS, Wet Weather, Sewer Rehabilitation

INTRODUCTION

The Sewerage and Water Board of New Orleans (S&WB) has turned a mandate to rehabilitate their sewer system into an opportunity to develop a useful graphic information system (GIS) database that will help manage existing and future system planning and maintenance functions.

The strategies and processes utilized by the S&WB to convert numerous information sources into a single integrated Arcview based information system should provide a useful blueprint for other water and wastewater utilities to utilize a GIS database and automated applications to better manage and run their facilities.

BACKGROUND

New Orleans, the largest City in Louisiana, is located near the mouth of the Mississippi River on the Gulf coast. Most of the City lies below sea level and is protected by a system of natural and man-made levees. The City's average annual rainfall of 1476 mm (58.12 inches) is exceeded by only one other metropolitan area in the country. The unusual topography and high annual rainfall that generally comes in frequent, high intensity deluges create special challenges with respect to drainage and sewage conveyance.

The wastewater system has evolved through many additions and improvements since its inception around the turn of the century. The system, which is operated and maintained by the S&WB, services an area of approximately 220 km^2 (86 sq. miles) and a population of approximately 497,000. It consists of over 2080 km (1,300 miles) of gravity collection and trunk sewers ranging in size from 200-millimeters (8-inches) to 2100-millimeters (84-inches) in diameter and over 160 km (100 miles) of force mains ranging in size from 150-millimeters (6-inches) to 1800-millimeters (72-inches) diameter. There are 83 pump stations which help convey wastewater to the City's two wastewater treatment plants on the East and West banks of the Mississippi River with a combined capacity of 500 megaliters per day (Ml/day) (132 million gallons per day (mgd)).

During the 1970s, the S&WB concentrated their financial resources on wastewater improvements at the East Bank plant, increasing its capacity from 87 Ml/d (23 mgd) to 461 Ml/d (122 mgd). The 38 Ml/d (10 mgd) West Bank plant is in the final stages of an expansion that will double its treatment capacity.

With the treatment plant expansion program successfully nearing completion, the S&WB is now focusing on the capital improvement needs of its aging wastewater collection system.

SEWER SYSTEM EVALUATION AND REHABILITATION PROGRAM

In response to regulatory pressures and the desire to provide excellent customer service and protect the waters of Lake Pontchartrain, the S&WB has embarked on a multi-year systemwide sanitary sewer rehabilitation program aimed at restoring structural integrity and improving wet weather performance. The program, named the Sewer System Evaluation and Rehabilitation Program (SSERP), is comprehensive in nature and will likely result in over $200 million of system rehabilitation and capacity upgrade construction.

Early in the SSERP process the S&WB recognized that a successful, cost-effective capital program required careful and thorough planning to provide a complete understanding of system behavior during both dry and wet weather conditions. An essential requirement in achieving that understanding is the development of an accurate, systemwide, dynamic, hydraulic model. This hydraulic model will predict system response to dry weather conditions and, more importantly, to the frequent short duration but high intensity rainfall experienced in this Gulf coast city. The model will help identify stress points in the collection system and confirm the viability of possible solutions.

MODEL DATA REQUIREMENTS

A typical modeling process, as depicted in Figure 1, begins with the collection of data and ends in the development of a Corrective Action Plan. The reliability of the model output to accurately predict the behavior of the wastewater system during wet weather events is founded on accurate, organized and properly formatted physical system data.

The recent improvements in computing power have allowed increased sophistication in the detail included in computer hydraulic models of sewer systems. This heightened sophistication has lead to increased requirements for the collection, storage and analysis sewer system data.

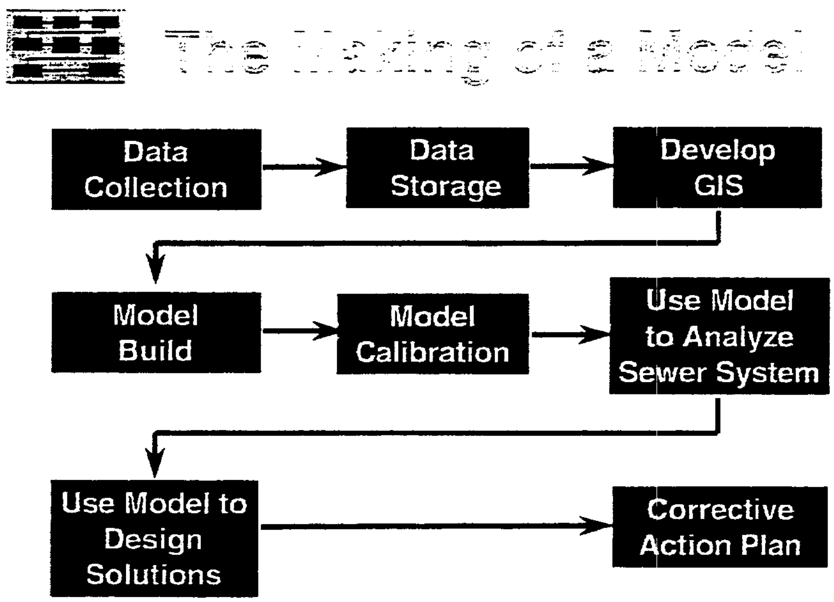

Figure 1

Following is a discussion of the data collected for use in the SSERP, its relevance to model building, and how the GIS has been utilized to store and manipulate the data.

Physical Data

The geographical configurations of both the S&WB's sanitary sewerage and water distribution systems are held on 616 paper plans on a double-line streets layout, each measuring 1-meter by 0.79-meters (42-inch by 31-inch). These plans only contain details of pipe size and location, as well as the location of manholes and water valves. Each manhole has a unique indentifier based on map sheet and manhole number. There is no information on manhole depths or rim elevations.

The S&WB uses a proprietary database system, CASS WORKS, to store details of its asset data, work activities and maintenance schedules. Within CASS WORKS there are two separate databases, one for manholes and one for pipes. The data in both of these is referenced the same as the manhole references on the paper maps. These databases contain incomplete information on street locations, ground elevations and invert levels. Also, the CASS WORKS database does not allow for the geographical display of the information.

Manhole surveying was carried out as part of the model-build task to complete missing data on pipe sizes, manhole rim elevations and pipe inverts. The X, Y and Z coordinates of each surveyed manhole was also established with the help of Global Positioning System (GPS) technology so that each manhole could be located accurately for modeling.

There are 83 pumping stations in the New Orleans sanitary sewerage system which are owned and operated by the S&WB. As part of the model build exercise, all of these pump stations were inspected and tested. Information collected included wet well sizes and pump on and off levels. Every pump was tested for a range of flow rates and delivery heads in order to obtain its current performance curve.

Data for Model Calibration

A temporary flow survey of 75 flow monitors and 20 rain gauges was carried out over an eight week period to obtain dry and wet weather flow data for model calibration. A permanent flow survey of 24 flow monitors and 10 rain gauges is ongoing.

The S&WB has recently completed the installation of a SCADA system covering all of its 83 pump stations. Data returned at regular intervals includes wet well levels at each pump station plus delivery pressure and run time for each pump.

Data for Estimating Base Sanitary Flow

Census tract boundary data was obtained in digital format. Details of the 1990 census were obtained as tables on paper and entered into the digital database of the census tracts.

Monthly water use data was obtained for each of 19,443 accounts throughout the City. For each location the water use was divided into five categories relating to the type of use (i.e., residential, industrial, etc.). The information was supplied as an electronic spreadsheet with street addresses.

Additional Data

The CASS WORKS system contained a database of 62,720 work activities which had been carried out on the sanitary sewer system since 1992. Each work activity was given a street address and the data was queried geographically. This query identified potential trouble spots in the sewerage system and was used to prioritize areas to be modeled.

GIS SYSTEM UTILIZATION

In order to store, manipulate and carry out quality assurance checks on all the collected data it was decided to use a GIS Arcview based system. The City of New Orleans was in the process of developing its own GIS system and the S&WB was working along side the City to include its data in the system. Arcview was determined to be compatible with the City's system -- an essential requirement.

The City had also completed detailed digital aerial ortho-photography of the city. These photographs were used to produce a new map of the City in GIS format which was supplied in 296 separate AutoCAD drawings. At the start of the modeling process the City's drawings contained only street lines. Some of the mapping had been enhanced to show 1-foot elevation contours and building outlines, but these features only covered part of the City's area. Both the photography and the street maps were obtained to help with displaying the sewer data geographically and to help in determining land use. To supplement the two-line street maps the paper zoning plans for the City, which contained detail down to individual housing plots, were scanned to create digital images.

A land use map produced for the City in a GIS compatible format was also obtained.

Development of the GIS system

The first step in the GIS development process was to digitize the sewer lines from the 616 paper plans. A major challenge to this task was that the plans were drawn at random orientations and did not conform to any defined grid pattern. This problem was overcome by creating scanned images of the paper plans, lining them up electronically with the 2-line GIS street map, and then tracing off the lines directly into the computer. Once this task was completed, the 616 individual units had to be combined into a single entity. Checks were carried out to confirm that all the pipes were connected and could deliver flow to the wastewater treatment plants. Finally, the digitized database of the sewer lines and manholes was cross-referenced to the CASS WORKS database and any mismatches were investigated and resolved. The pump curves for all the pumps were expressed in digital format and entered into the GIS database along with the details of wet wells and on/off levels. The location of all pump stations was highlighted geographically.

In order to geographically express the data in the water use and work activity databases, the data was geocoded. This is a GIS technique which matches a street address to a geographical location. The locations of flow monitors and rain gages, used for obtaining calibration data, was also expressed geographically in the GIS system.

The 296 separate drawings forming the 2-line street maps were combined into a few larger groupings making them more manageable. The resolution of the aerial ortho-photography was digitally reduced so that each image only was only 300Kb in size instead of the 9.8 Mb of the original. This allowed the simultaneous display of multiple photographs without over-stretching the available memory on the computers.

The scanned images of the zoning maps were scaled, rotated and positioned to line up with the 2-line street maps. Figure 2 on the following page shows the results of the digitizing efforts.

Use of the GIS in Model Building

One of the first uses of the GIS was to carry out quality assurance checks on the manhole survey data. The data was displayed geographically using the surveyed X and Y coordinates and compared to the digitized network to show any discrepancies. It was not expected that there would be a perfect match as the digitized location of the manholes was thought to be approximate, but gross differences would be investigated. Longitudinal sections were also drawn along each surveyed line using the surveyed elevation data to highlight anomalies. Figure 3 illustrates the utilization of the GIS in this quality assurance process.

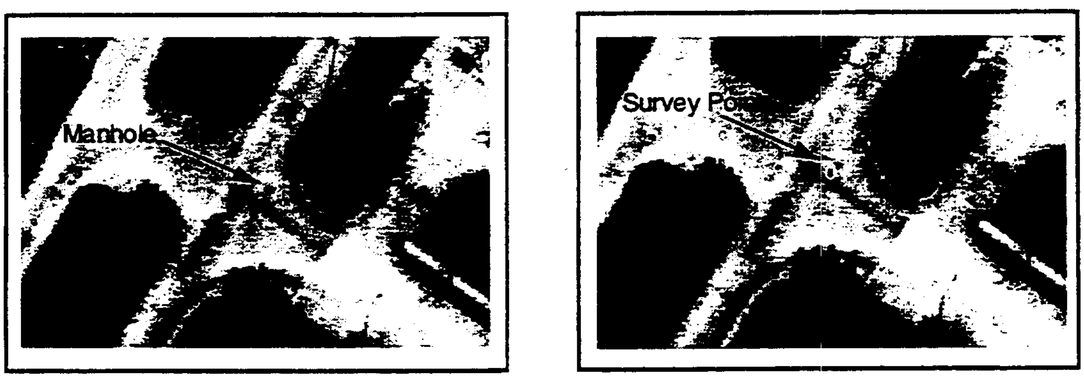

Figure 3

The aerial photo on the left indicates the location of a manhole within a street intersection. The photo on the right indicates the position of the manhole determined from the X and Y coordinates obtained in the field topographic survey. GIS enabled the model builder to check the accuracy of the survey by comparing the actual location of the manhole with that determined by survey.

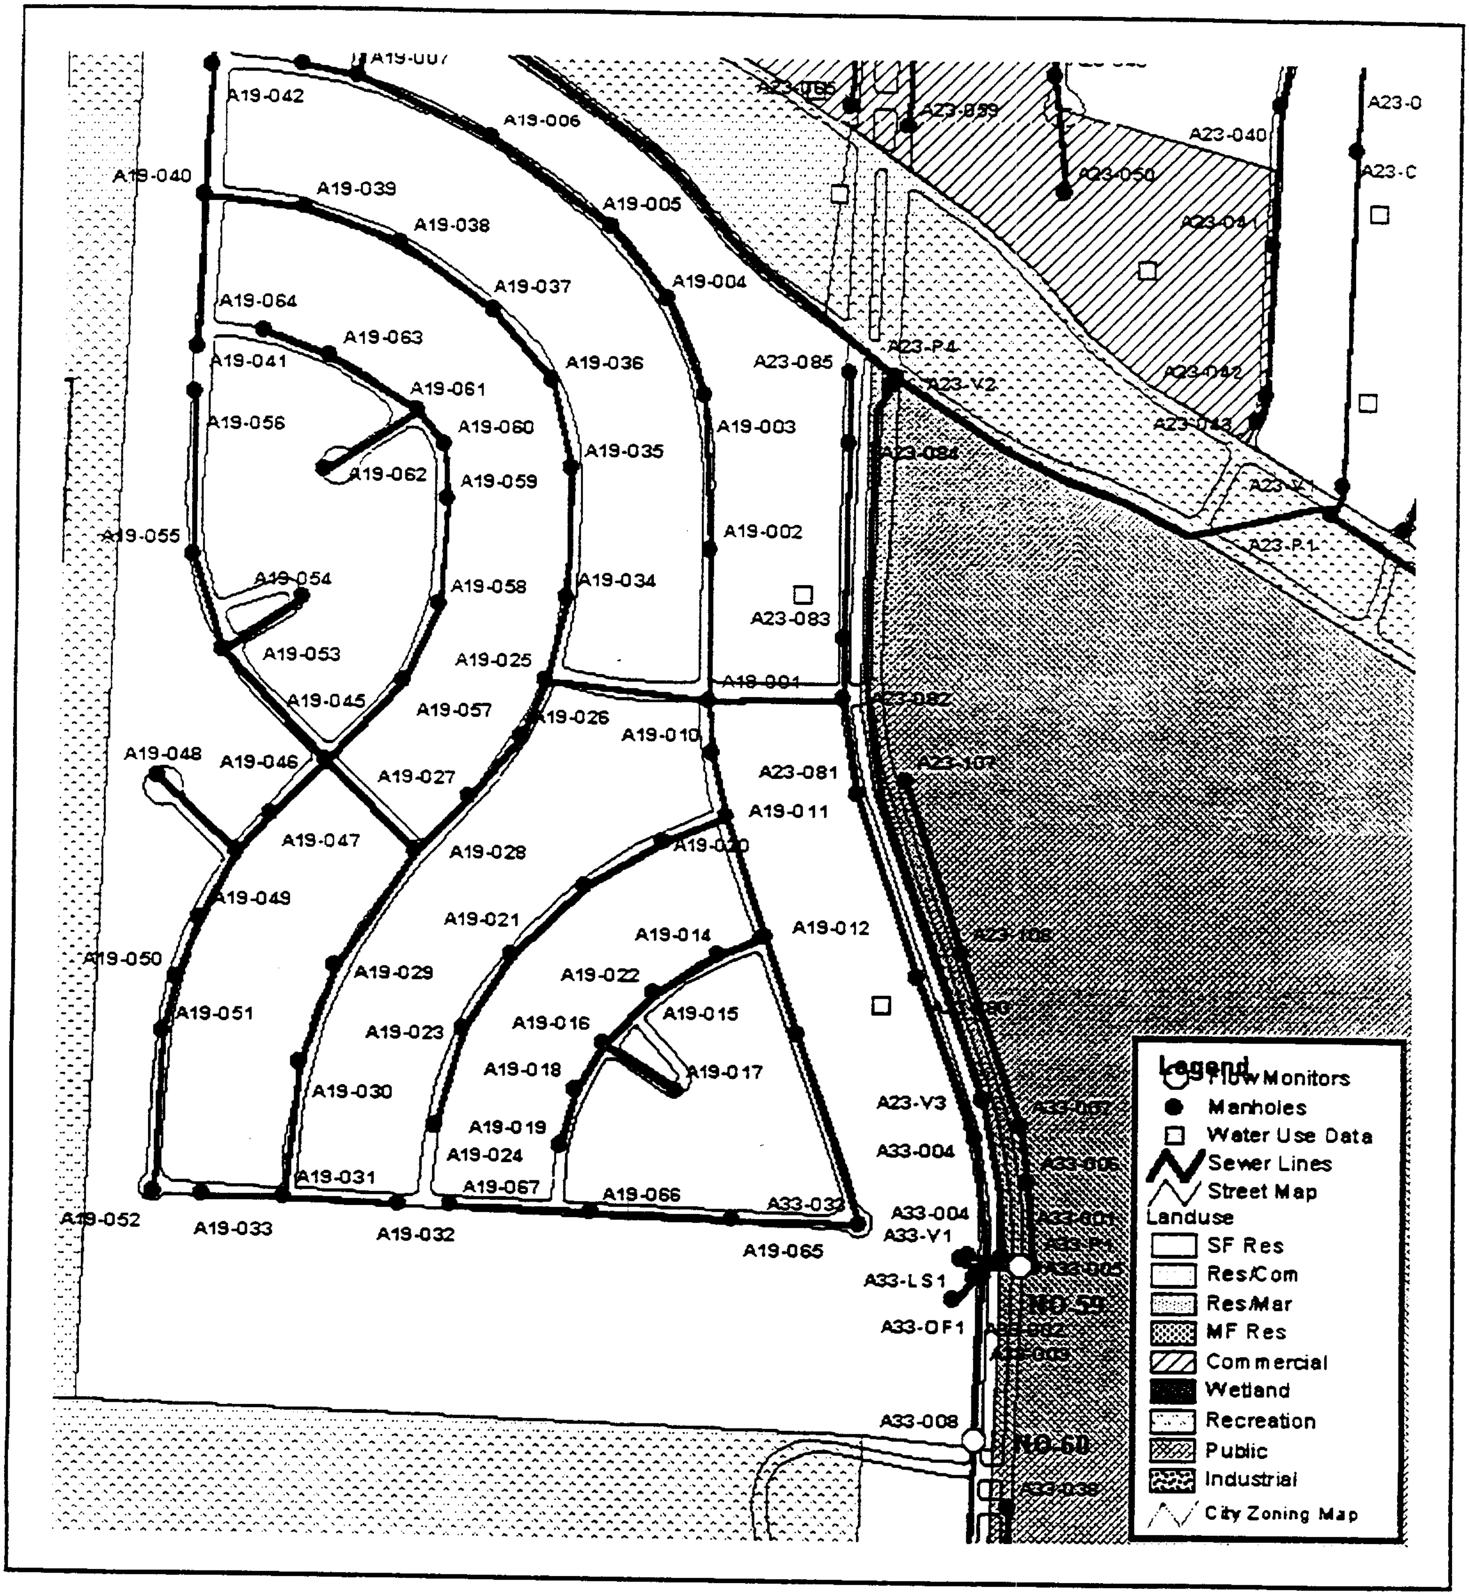

Figure 2

This is a sample of a GIS display showing the overlay of many layers of data. Displays like this allow the compilation of data for model build.

By overlaying the sewer network over the streets, land use and flow monitor data, it was possible to define model sub-basins on screen. The overlay made it possible to partition the sewer service areas logically, taking into account changes in land use and flow monitor locations. The model was to be a macro model including only pipes of 300 mm (12-inch) diameter or larger. The network feeding into each modeled manhole was defined by performing upstream traces from that point. Use of the GIS simplified the calculation of each sub-basin area. The defined areas also allowed the abstraction of population and water use data to assist with the estimation of the base sanitary flow likely to be generated. The GIS was also used to link the sub-basin to the most appropriate rain gauge for estimating run-off.

The GIS acted as a database for holding all information relative to the model. It was possible to write files compatible with the hydraulic modeling software directly from the GIS. Equally, it was possible to read model results files back into the GIS system for graphical display.

Advantages of the Use of a GIS System in Model Building

The major advantages of using a GIS system have been:

- Providing a single repository for all model data. If data requires amendment it only needs to be altered at one location, thereby maximizing efficiency and minimizing data entry errors
- The ability to display geographically and interrogate all data relevant to model building leading to a greater understanding of the system
- Geographical display allowing network connectivity to be checked easily
- Geographical display simplifying definition of sub-basins
- The GIS acts as a convenient platform for performing quality assurance checks on data
- The ability to download data directly to the model preventing data entry errors

SECONDARY BENEFIT OF GIS – REHABILITATION PRIORITIZATION PROCESS

The S&WB plans to capitalize on the GIS developed in the modeling process to help in other related planning and operational areas. One of those areas is management of the extensive library of CCTV data collected by staff and consultants conducting Collection System Evaluation Surveys (CSES) throughout the collection system service area. These surveys will collect the data necessary to identify the structural condition and sources of infiltration and inflow (I/I) in the sanitary sewer facilities in each of the ten service area basins that make up the entire S&WB managed collection system.

The CSESs involve numerous field activities such as smoke testing, dye-water testing, night flow isolation flow monitoring, manhole inspections, sub-basin flow monitoring and closed-circuit television (CCTV) inspection of sewer lines. Each study will generate approximately 72 km (45 miles) of CCTV footage, the primary tool utilized for the prioritization and method selection of sewer line rehabilitation. Because each of the ten studies will be conducted by different prime and subconsultant entities, the S&WB recognized the need to develop a centralized system that provides for consistent collection and interpretation of the CCTV data. The S&WB will utilize the GIS to help manage the storage, review and utilization of that extensive supply of system information.

The CCTV data collection system will include the following components:

- Consistent Coding of defects by field crews
- Consistent format of collected data
- Easy retrieval and review of findings due to CD-ROM indexing
- Consistent rating (grading) of defects with one S&WB standard
- Prioritization of lines for rehabilitation based on the S&WB's goal for rehabilitation (structural, I/I removal)
- Selection of cost-effective rehabilitation method for each line segment

CCTV contractors will be required to record CCTV video images in CD-ROM format. Coding will also be provided in digital format utilizing a defect coding system developed and provided by the S&WB. The coded information will be downloaded into the GIS system where defects will automatically be assigned a rating based on a predetermined grading system. The coded and rated CCTV data will then be run through a sorting process within the GIS-Arcview database that will provide for a prioritized list of sewer segments requiring rehabilitation. The sort will be based on criteria established by the S&WB to fit the goals and financial capability of the rehabilitation program.

Once the prioritized list of sewers requiring rehabilitation is generated, each sewer segment on the list will be run through a method selection decision process to determine the most cost-effective methodology to complete the rehabilitation. The method selection process will be programmed within the GIS database from decision trees. The decision process will consider all factors required to select the best methodologies including capacity needs, methodology limitations, physical pipe characteristics, surface restoration, unit costs, etc.

During the rehabilitation design process it will be necessary to review images and live video of the pipe inspections. This is where the GIS system will save time and money. With the CCTV coding residing as a layer in the GIS mapping system, and with video stored on desktop CD-ROM players, the designer can quickly access defect images with a simple 'point and click' on background system maps. The image will be displayed on screen almost instantaneously saving the time and frustration of fast-forwarding and rewinding necessary to find the sought image in the VHS format. The following Figure 4 provides a typical screen display of a CCTV image generated through the link between the line map (in background) and the video image file resident on the desktop CD-ROM.

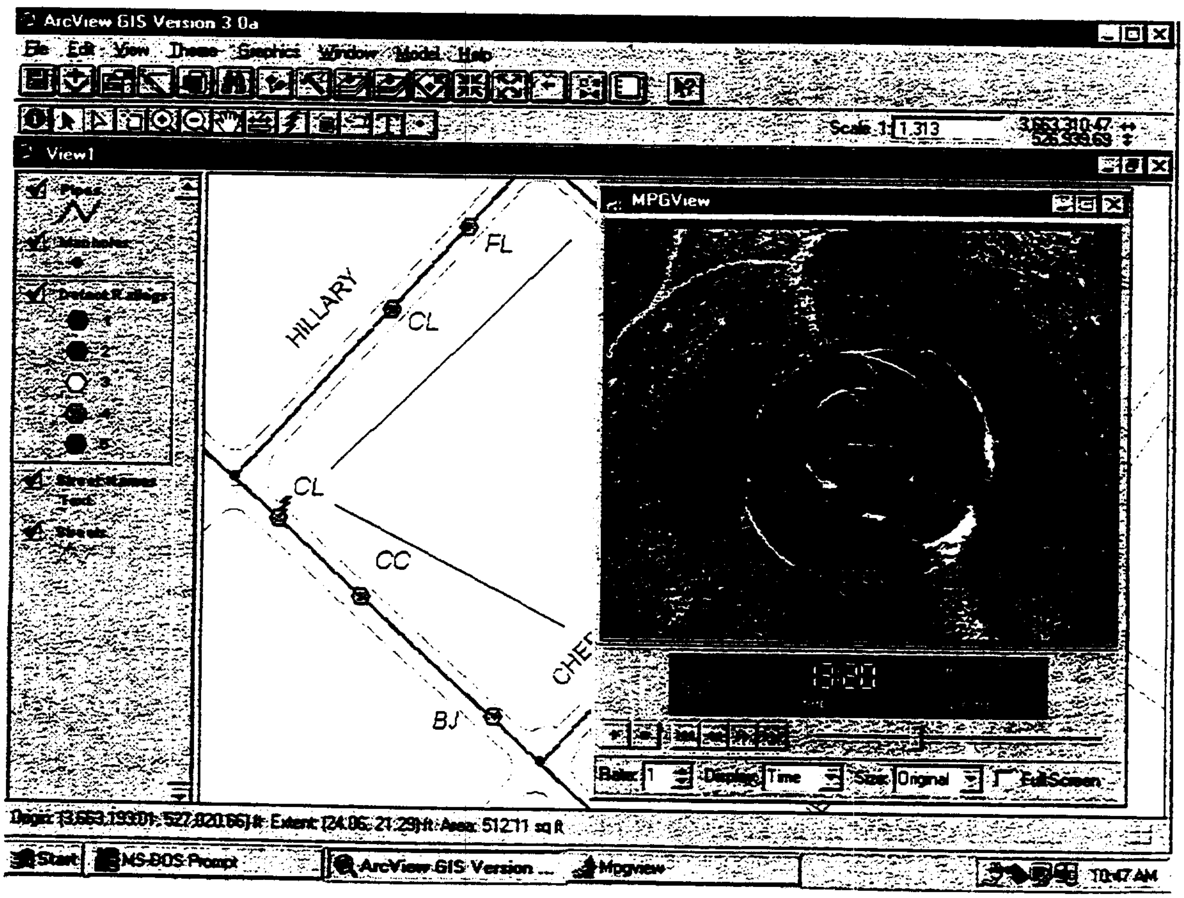

Figure 4

R0024998

Finally, the GIS system will provide the necessary mapping and graphical information required to efficiently develop maps and plans for rehabilitation construction packages.

CONCLUSION

Utilization of a GIS to collect and store the converted data in a single location not only eases the model building and calibration process, but results in secondary benefits to the operator long after the modeling phase of the project is complete. The benefits of GIS use in model building include: single location of collected data, direct download of data to populate the model, geographical display and interrogation, connectivity quality checks, and review of data before it is entered into the model.

The secondary utilization of GIS to help manage the S&WB's sewer rehabilitation is but one example of how utilities can maximize the use of GIS systems in the planning and operation of sewer and water systems. The single "one stop" geographic reference of system assets provides for quick and easy query. This can reduce emergency response times by quickly providing operations personnel with facility component locations (i.e., valves) for both the wastewater and water systems. It also provides a database to monitor operational trends, plan future work efforts and provide graphical print outs of system maps and details to assist in field reconnaissance and design activities.

In New Orleans, the S&WB system design and operations staff now have a useful infrastructure management tool that may not have been developed were it not for the need to develop the hydraulic model as part of a wet weather control program. Once in place, the full potential of GIS utilization is only limited to the imagination and a thorough understanding of its capabilities.

Wet Weather Standards and Their Role in Clean Water Act Compliance

David E. Evans, McGuire, Woods, Battle & Boothe LLP
901 East Cary Street, One James Center, Richmond, Virginia 23219

ABSTRACT

Today's "dry weather" water quality standards, which are designed to protect water quality during drought flow conditions, may not always be appropriate for judging the water quality impacts of stormwater and combined sewer overflows. EPA and many states have acknowledged the need to review the wet weather uses of receiving waters and, where appropriate, refine the designated uses and associated water quality standards. However, few states have taken advantage of the opportunity to conduct such wet weather designated-use reviews. There are a variety of reasons behind this, including scarce state resources and other priorities, compounded by limited state agency experience with, and understanding of, wet weather uses and criteria and their role in Clean Water Act compliance. Unless something is done to promote the review of wet weather uses, over the next decade communities throughout the United States face the prospect of spending billions of dollars to control wet weather discharges to meet water quality standards designed to protect dry weather uses. This presentation will explore this problem and offer suggestions for promoting wet weather use reviews and the development and the identification of associated water quality standards.

BOSTON WATER AND SEWER COMMISSION FINDS SEPARATION TO BE THE APPROPRIATE LEVEL OF CONTROL

Paul W. Keohan, P.E.,
Boston Water and Sewer Commission *

* Boston Water and Sewer Commission, 425 Summer Street, Boston, Massachusetts, 02210

ABSTRACT

The focus of this paper is the Boston Water and Sewer Commission's efforts to reduce the adverse impacts on water quality in the Lower Charles River from the combined sewer overflows carried by the Stony Brook Conduit. During the development of its CSO Plan, the Massachusetts Water Resources Authority's proposed a screening and disinfection facility to reduce the impact of combined sewer overflows in the Charles River. The Boston Water and Sewer Commission undertook a study of alternatives to the Massachusetts Water Resources Authority's proposed facility because it believed that combined sewer overflows could be significantly reduced and possibly eliminated. The Boston Water and Sewer Commission's study recommended that all of the combined sewers along the Stony Brook Conduit be separated instead of screening and disinfecting flows at the proposed facility. After reviewing the study, the Massachusetts Water Resources Authority accepted the Boston Water and Sewer Commission's recommendation and revised its CSO Plan.

KEYWORDS

CSO Plan, Boston Water and Sewer Commission, Massachusetts Water Resources Authority

INTRODUCTION

Charles River

The Charles River begins in Hopkinton, Massachusetts, and flows in a serpentine course eastward to Boston Harbor. Visitors to Boston are familiar with the Lower Charles River Basin where the river serves as a boundary between Cambridge and Boston Massachusetts.

The Lower Charles River is primarily used for rowing and sailing. The park reservation along both banks of the river is also used for walking, jogging and gatherings. Water quality samples collected from the Lower Charles River indicate that the state's bacterial water quality standards for boating are often violated in wet weather and sometimes in dry weather. In dry weather, contamination probably comes from sanitary sewers connected to storm drains or leaking pipes that carry wastewater. Efforts are underway in Boston, Cambridge and the other communities along the river to identify and correct these conditions.

This paper will address the issues related to the wet weather conditions.

The Charles River's flows into Boston Harbor are controlled by the Charles River Dam, a flood control facility built by the U.S. Army Corps of Engineers. Contaminated flows have a significant affect on water quality in the basin.

Sources of Contamination

In wet weather, there are two major sources of combined sewer overflows (CSOs) to the Lower Charles River. They are from the Massachusetts Water Resources Authority's (Authority) Cottage Farm CSO Storage Facility on the Cambridge side of the river and from the Boston Water and Sewer Commission's (Commission) Stony Brook Conduit on the Boston side of the river.

Overflows from combined sewers along the Stony Brook Conduit can enter the Lower Charles River from two outfalls; either the Authority's CSO outfall or the Commission's, both of these are shown on Figure 1. The Authority's outfall is the primary outfall for drainage from the Commission's Stony Brook System. Although essentially all of the flow out of this outfall comes from the Commission's collection system, the outlet belongs to the Authority. During very severe storms, the Commission's CSO outfall serves as another way for CSOs to enter the Lower Charles River. When flows in the Stony Brook Conduit overtop the sluice gates at the Commission's outfall, they enter the Muddy River. The Muddy River flows into the Lower Charles River near the Authority's outfall.

DISCUSSION

The Authority's CSO Plan for the Stony Brook Conduit

The Authority evaluated various methods for reducing the impact of CSOs on the Charles River. They looked at storing overflows until capacity was available at the treatment plant. Storing overflows from a large storm event such as the 1-year storm was rejected by the Authority because it would be difficult to find enough area for the storage tanks.

The Authority also considered diverting some of the overflows caused by a three-month storm into an interceptor with excess capacity (the Commission's Stony Brook Valley Sewer), and storing the overflows from the rest of the combined areas in a storage tank. Although the area needed for storage was less, this alternative was also rejected. The improvement in water quality did not justify the cost of the storage tanks and the diversion.

As another possibility, the Authority investigated separating sanitary and stormwater, but concluded that separation was too difficult and too costly since most of the combined sewers are in highly developed urban areas.

Finally, the Authority investigated and ultimately recommended that the combined flows in the Stony Brook Conduit be screened and disinfected before being discharged to the Charles River. A screening and disinfection facility was proposed, located near the end of the conduit, because overflows occur along this downstream portion of the conduit.

Along much of its length, the Stony Brook Conduit serves areas with separate storm drains. About 2,533 hectacres (6,260 acres) contribute separate stormwater flows to the upstream portions of the conduit (see Figure 1). Along the downstream sections, about 617 hectacres (1,524 acres) contain combined sewers. Overflows from combined sewers contribute a relatively small percentage of the wet weather flows carried by the conduit.

According to the Authority's computer model, the facility would be activated about 26 times in a "typical year". During these events, about 2.328 million cubic meters (615 million gallons) of stormwater plus CSOs would be treated at the proposed facility. A "typical year" is a group of rain events developed by the Authority that provides a way measuring performance on an annual basis.

When the facility screens and disinfects, most of the flow would be stormwater. Only 155,185 cubic meters (41 million gallons) or 7 percent of this volume actually comes from CSOs; the rest is stormwater and brookflow from four brooks upstream that discharge into the Stony Brook Conduit.

On average, about 80 rain events occur each year. If the rainfall is not large enough to cause overflows, the proposed facility would not be activated. During the smaller rain events, about 54 times a year, stormwater would be discharged into the Charles River without any screening or disinfection.

Commission Concerns

Based on its knowledge of the Stony Brook sewer system, the Commission believed that more alternatives should be evaluated before giving its support to a screening and disinfection facility. Alternatives closer to the source of overflows needed to be investigated so that less stormwater would be handled. If overflows could be reduced further upstream rather than near the end of the pipe, then it should cost less to reduce CSOs.

The Authority's proposed facility was to be located near the end of the pipe which would result in a significant amount of stormwater being treated whenever the facility activated. Over the life of the facility, most of its operating expenses would be due to treating stormwater, not CSOs.

The Commission recognized that stormwater also adversely affects water quality. Screening and disinfecting, however, reduces bacteria and solids, but not the other pollutants found in stormwater. The Commission questioned whether screening and disinfecting would be the appropriate level of treatment for stormwater.

In addition to the concerns about how effectively the facility would reduce the impacts of CSOs, several issues surfaced that created other reservations about the constructing a facility.

The Commission realized that there was not a consensus on the water quality goals for the Charles River among citizen groups and the Authority. The citizens clearly supported fishable and swimmable waters in the Charles River at all times. If the facility could not prevent CSOs it might only be an interim measure and not a long-term control.

Most of the vacant lands along the downstream portion of the Stony Brook Conduit are either used or designated for use by one of the institutions that are located in this section of Boston. The Authority encountered significant resistance from the local neighborhood associations, colleges and the city's housing authority about siting a screening and disinfection facility in this area.

Additionally, since chlorine was to be used for disinfecting the flows from the Stony Brook Conduit, the Authority would be required to dechlorinate the flows before they reach the Charles River. It appeared likely that the Authority would encounter problems finding an additional location to dechlorinate the flow.

The Commission's Stony Brook Sewer System Study

After reviewing the Authority's plan to reduce and treat CSOs from the Stony Brook Conduit, the Commission undertook its own study to find an alternative to the Authority's proposed facility. The Commission did not wish to duplicate efforts, but to address issues raised during the review of the Authority's plan.

The Commission believed that controls such as separation and storage, should be re-examined and studied in greater depth before building a costly and unpopular screening and disinfection facility. Even if an alternative to the proposed facility was not found, the Commission hoped that the study could identify ways to reduce the size of the screening and disinfection facility, the number of times it was activated and therefore its cost.

The Commission's study looked for controls in each sub-area where combined sewers overflow into the Stony Brook Conduit. Controls were evaluated based on their ability to reduce CSOs to four times a year or less.

Under the U.S. Environmental Protection Agency's 1994 National CSO Policy, CSO controls and compliance with water quality standards can be developed using either the presumption approach or the demonstration approach. For this study, the Commission used the presumption approach where it assumed that if no more than four overflow events per year occurred, water quality standards would be met.

Alternatives examined

To reduce overflows to less than four times a year, the Commission looked at:

- separating sanitary and stormwater flows,
- storing overflows,
- enlarging the connection at each regulator
- diverting overflows into other sewers.

In each sub-area, the study examined separating flows from a portion of the combined sewer area rather than the entire area. The area to be separated would need to be just large enough to reduce overflows to four times a year or less. Before making these calculations, it appeared that separating a portion of the combined sewer area could reduce overflows significantly and would cost less than complete separation. However, the calculations showed that almost the entire area needed to be separated to reduce overflows to four times a year or less.

The study evaluated two types of storage alternatives, one used existing sewers and the other proposed the construction of new facilities. The first alternative looked at whether overflows could be stored within existing pipes in the Stony Brook System. It was quickly determined that the existing sewers were not large enough. Then the study looked at building storage close to where the overflows occur. This alternative was dropped because siting and operating storage facilities in several sub-areas presented too many insolvable issues.

Enlarging the connection from the regulator to the interceptor was examined, because it would increase the amount of wet weather flow that stayed within the collection system, resulting in less overflows. The reduction in overflows, estimated by the Commission's computer model was not significant at most of the regulators. At two regulators, it appeared that reductions could be achieved, but more detailed investigations were needed to determine whether enlarging the connections was feasible.

Diverting overflows into a sewer that was able to direct the flows to the treatment plant was also examined. The Stony Brook System is a complex network of interceptors and outfall pipes. Using the Commission's model, overflows were routed into an interceptor with excess capacity. The model's results indicate that it would be possible to divert overflows from a three-month storm into an interceptor where the flow would be conveyed to the Authority's treatment plant.

Findings

After evaluating the alternatives, the Commission's Study found the following:

- It is possible to use a combination of methods such as separation, diverting overflows, and enlarging connections to reduce overflows to four times a year or less.

- The largest reduction in the frequency of CSOs occurs when all of the tributary areas are completely separated. According to the Authority's hydraulic model, overflows will occur about two times in a "typical year".

- Separation removes pollutants, such as total suspended solids and biochemical oxygen demand, that would not be removed by a screening and disinfection facility.

- Complete separation of the combined sewer areas tributary to the Stony Brook Conduit costs about $ 6 million less than the screening and disinfection facility

- However, separation increases the amount of stormwater discharged into the Charles River, which raises the concern about the effect on water quality from this additional flow.

Recommendation

The Commission's study recommended the complete separation of the combined areas tributary to the Stony Brook Conduit as well as the control of floatable materials, if overflows still occur in a "typical year".

To make sure the water quality of the stormwater will not further degrade the water quality in the receiving water; the Commission's study also recommended :

- best management practices, such as cleaning catch basins and public education programs on the proper disposal of motor oils and pet wastes,
- the removal of illegal connections in all the already separated areas, and
- the rehabilitation of existing sanitary sewers in common trenches

Authority Revises its CSO Plan

Shortly after the Commission's study was completed, the Authority reviewed the study, analyzing the separation recommendation with its computer model. It agreed that complete separation of the areas tributary to the Stony Brook Conduit was an attractive solution, because it provides a higher level of control than a screening and disinfection facility. Several citizens' groups concerned about water quality in the Charles River had urged the Authority to provide a higher level of control than the screening and disinfection during the review of the Draft CSO Facilities Plan.

After deciding to adopt separation for the Stony Brook System, the Authority offered to reimburse the Commission up to $ 45 million for constructing of a separate system in the combined areas tributary to the Stony Brook Conduit. The Commission readily accepted the cost ceiling and responsibility for this project.

When the Final CSO Facilities Plan/Environmental Impact Report was issued in July of 1997, the Authority changed its recommendation from a screening and disinfection facility to the complete separation of the areas tributary to the Stony Brook Conduit. The Authority appears to have made this change because of difficulty in siting the facility, the increase in the cost of the CSO facility and concerns about water quality from several citizens organizations. The selected site presented concerns about the pipes into and out of the proposed facility would be constructed. The cost estimate for the proposed facility was higher than the estimate in the Draft CSO Facilities Plan because the Authority discovered that it was necessary to dechlorinate the flows. It was also attractive that the Commission would be responsible for implementing separation and operating the separate systems whereas the Authority would have been responsible for operating the CSO facility.

RESULTS

Authority and the Commission enter into an agreement

Under the Final CSO Plan, the Authority will implement most of the other improvements such as interceptor relief, storage, a treatment facility, upgrade of existing CSO facilities and the relocation of CSOs. The Commission has already undertaken two separation projects within the city of Boston; the Stony Brook Conduit project will be its third CSO separation project.

In May of 1994, the Commission entered into an agreement with the Authority for the separation of combined sewer areas in Dorchester and in East Boston. This agreement defined the responsibilities of each agency. These separation projects were given priority because overflows in these areas discharge into Boston Harbor near waters used for bathing.

The Authority's CSO Plan was developed under a Court Order. The Court oversees the implementation of the plan. The Commission is responsible for completing the separation, according to a schedule set up by the Court. In turn, the Authority will reimburse the Commission for the design and construction costs associated with separation.

The Commission has completed the preliminary design for the Dorchester separation. According to the preliminary design about 130,000 linear feet of storm drains will be installed in Dorchester to separate its combined sewer areas. By comparison, complete separation complete separation of the areas tributary to the Stony Brook Conduit will require as a very rough estimate, about 100,000 linear feet of pipe.

Both the U.S. Environmental Protection Agency (EPA) and the Massachusetts Department of Environmental Protection support the Authority's recommendation to completely separate the areas tributary to the Stony Brook Conduit. Later this year, the EPA and the Authority will submit a schedule for the implementation of the CSO Plan to the Court for their approval. When the Court schedule is available, the agreement between the Authority and the Commission will be amended to include the separation of the areas tributary to the Stony Brook Conduit.

From the Boston side, CSOs from the two outfalls into the Charles River will be reduced to two or less a year by 2005.

CONSTRUCTED WETLANDS BALANCE URBAN WET WEATHER CHALLENGES

Thomas M. Evans, ASLA
Senior Landscape Architect
URS Greiner, 800 West St. Clair Avenue, Cleveland, Ohio 44113

ABSTRACT

Urban Planners and Engineers often face conflicting goals when dealing with urban storm water runoff: flood reduction, water quality enhancement, and habitat enhancement or preservation. This paper demonstrates the multiple advantages that constructed wetlands can offer to balance these challenges.

Creatively designed storm water wetlands can serve multiple purposes, be an attractive community asset, and provide ecological as well as economic benefits. Potential benefits of constructed wetlands include replacement of impacted wetlands, storm water management, storm water purification, reducing combined sewer overflows, parks and open space, scenic enhancement, an outdoor learning laboratory, and wildlife habitat. These additional benefits can be optimized by incorporating constructed wetlands into the design of a variety of project types and settings such as land development, parks or school projects.

Many cities and counties today face flood control, water quality, or open space issues with limited funds to address such issues. Constructed wetlands can offer cost-effective solutions to such issues. The zoning or wetland permitting process can in fact produce replacement wetland projects which fulfill community needs at no cost to the City.

Land developers can realize the economic benefits of incorporating constructed wetlands into their developments thru the added value to surrounding residential lots; through the creation of a low cost, low maintenance open space amenities; and by providing potential additional revenue from the sale of mitigation credits.

Three case studies are presented which demonstrate constructed wetlands in a range of settings:

- the Wetland Conservation Area: located in New Albany, Ohio; combining wetland mitigation, storm water management, and educational use in a 30-acre wetland park.
- the Streetsboro Wetland Park: located in Streetsboro, Ohio, combining wetland preservation, wetland mitigation, and flood control in a 58 acre open space development amenity and city park.
- the Oakland Ravine Wetland Treatment System: located in the Borough of Queens, New York City, combining CSO reduction, storm water treatment, park enhancement, and educational use.

KEYWORDS

Constructed wetlands, wetland mitigation.

INTRODUCTION

Urban planners and engineers often face quite a number of challenges when addressing urban storm water issues: flooding, erosion, wetland preservation, habitat restoration, and water quality. Urban stormwater may also be related to other urban issues such as parks and open space, park funding, property values and economic development.

Creative planning and design can produce constructed wetland projects which successfully balance ecological, economic, engineering and aesthetic values. Constructed wetlands can be successfully incorporated into a variety of suburban and urban settings such as parks, schools, commercial and industrial landscapes. Wetland preservation and wetland replacement can also be a funding tool for open space preservation or parkland acquisition. A growing body of literature is available on the engineering aspects of constructed wetlands such as stormwater management, pollutant treatment and water quality improvement; however, not much literature exists on other wetland benefits such as economic development and scenic enhancement.

METHODOLOGY

Three constructed wetland project case studies are presented to illustrate how to balance multiple challenges with creative planning and design techniques. These projects will demonstrate the multiple advantages that constructed wetlands can offer such as:

- provide replacement wetlands, fulfill regulatory requirements for wetland impacts,
- creation or enhancement of parks and open space,
- stormwater management, by reducing peak runoff rates by providing stormwater storage,
- reduction of flood damage and enhanced economic development,
- water quality improvement, water filtration pollutant reduction,
- restoration of watershed habitat, increase wildlife diversity,
- scenic enhancement,
- increase the value of surrounding real estate,
- reduction of runoff volume by providing increased soil infiltration, evaporation and transpiration,
- provide a setting for environmental education.

RESULTS

The Wetland Conservation Area (WCA) is located Northeast of Columbus, Ohio, in New Albany, Ohio, south of SR 161. The WCA is the first significant sized wetland mitigation project undertaken by the Ohio Department of Transportation (ODOT) and is a landmark project in Ohio in demonstrating that wetland mitigation can be an integral, multipurpose element in land planning and may even be planned as a centerpiece to surrounding development.

Project goals were to replace wetlands impacted by an adjacent highway project. The project represents a very successful public/private partnership between ODOT and the developer, the New Albany Company, and the Village of New Albany, in conjunction with the New Albany School District. A unique 'win-win-win' situation developed where ODOT fulfilled its regulatory needs; the Developer got a theme element, a stormwater basin, and increased land values; the Village and Schools got a new park and land lab valued at $2 million, at no cost to the Village.

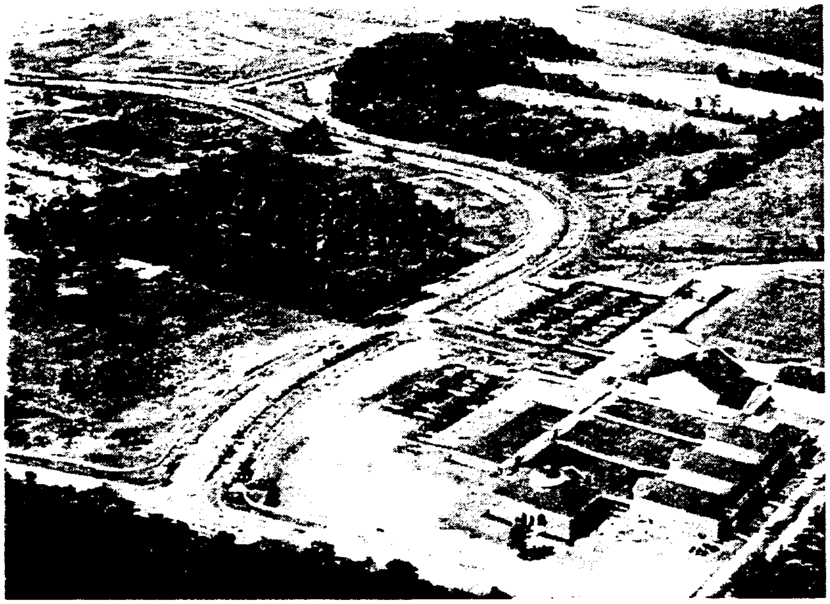

Figure 1. This aerial photo provides an overview of the WCA's surroundings: deliberately located at the primary expressway interchange entrance to a new 5,000 acre community. This location produces a high visibility open space area that establishes a strong natural theme for the New Albany community. Commercial, residential, school development, roads and trails have been designed around all sides of the WCA.

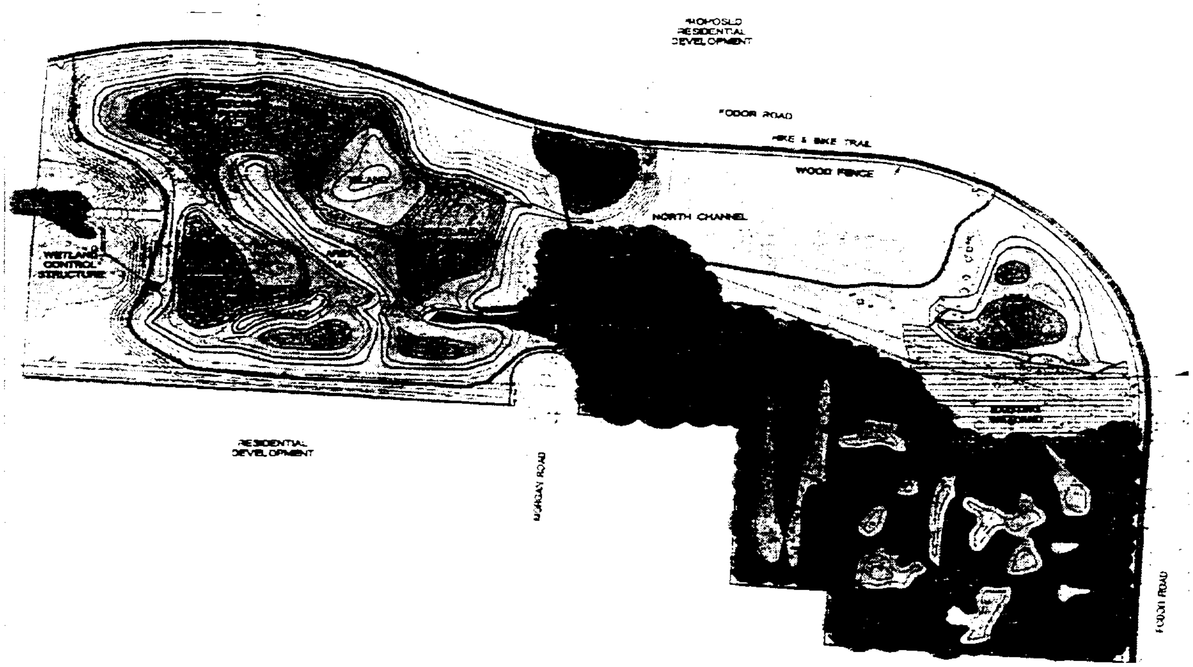

Figure 2. This plan view illustrates a number of basic design features of stormwater wetlands such as a forebay for sediment trapping, and a circuitous flow pattern to enhance pollutant reduction effects. The park provides a total stormwater storage area of more than 13 acres, dramatically reducing peak discharge rates significantly below code requirements. The control structure is the result of extensive hydrologic modeling to analyze stormwater management functions, as well as water balance modeling to document the viability of the constructed wetlands. These software analyses resulted in the design of a unique three stage control structure to enhance wetland hydrology during low flows, provide complete adjustability of discharge rates and water levels, and accommodate peak flows from the ultimate build out of the watershed.

Figure 3. Constructed wetlands can be successfully established in urbanized surroundings. The naturalized open space area is considered a desirable neighbor. It is reported that homes adjacent to the WCA are selling for $10,000-$15,000 more than homes across the street. Shallow water depths, gentle slopes, and moderate water level fluctuations are compatible with public access and in fact pose far less public safety issues than ponds or retention basins.

Figure 4. Wetland vegetation is most diverse, successful and beautiful in water depths of 0-6 inches. This diversity of form, texture, color, and height creates a visually rich landscape. From an ecological design perspective, one of the project's most unique aspects is the design of three distinct ecological zones, open emergent, emergent and forested vernal pools, a unique combination in a constructed wetland project.

Figure 5. The vernal pool area is perhaps the most unique ecological zone in the project. A number of small, organically shaped and randomly placed pools were designed in an existing wet woods area to mimic natural vernal pools. The wooded wetland areas not only add to the site's flood storage capacity but also provide a fascinating laboratory for the study of how each pool is being colonized by different species of frogs and salamanders. A number of adjacent schools and colleges have visited this area for biological study. Forested vernal pools are considerd one of the highest quality wetlands in the Ohio EPA classification system.

The WCA project earned an Honor Award in 1997 from the Ohio Chapter of the American Society of Landscape Architects.

The Wilcox Wetland Park is located in Streetsboro Ohio, on the eastern fringe of the Cleveland metropolitan area, between SR 303 and SR 14. Project goals were to develop a plan which integrated wetland preservation, wetland mitigation and stormwater management for a 200 acre mixed use development including residential, industrial, and commercial uses. The plan incorporated the preservation of approximately 20 acres of existing wetlands and a stream corridor, enlarged existing wetlands by an additional 12 acres, solved chronic flooding of SR 303, provided stormwater management for the project, all within a 56-acre central open space amenity. Presentation of this plan to City Council was instrumental to gaining rezoning for a critical piece of the property. The rezoning issue was headed for denial; presentation of the open space plan resulted in unanimous passage and praise as a prototype for an environmentally sensitive project.

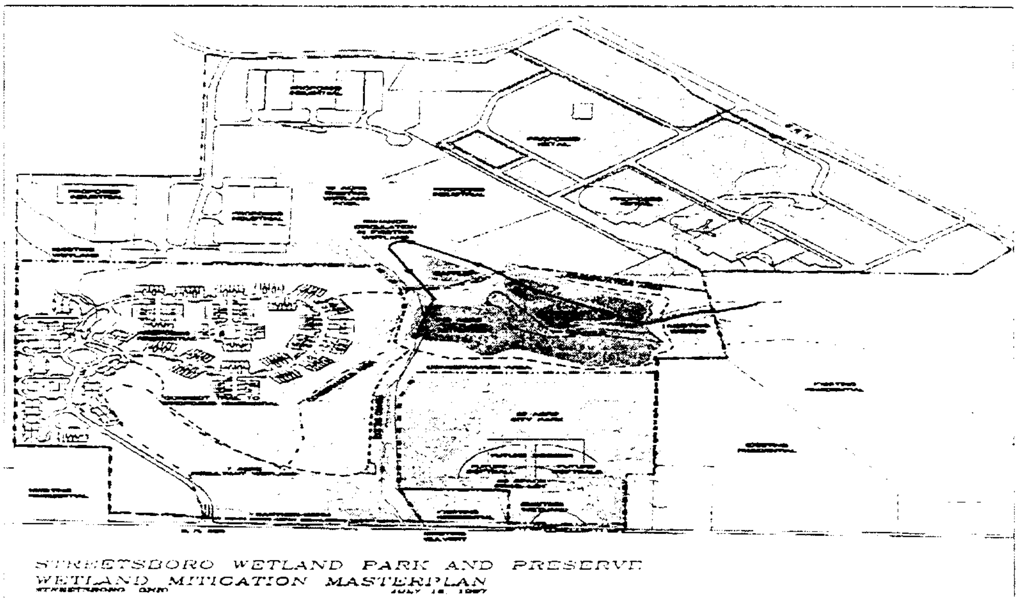

Figure 6. A plan was developed to integrate the preservation of existing wetlands, construction of new wetlands, a proposed 22 acre park to be donated to the city. The plan will eliminate chronic flooding of a state highway, and provide a huge stormwater storage facility of more than 35 acres of storage area to significantly reduce flows and volume. The result represents a successful 'win-win' between private development and public benefits.

Figure 7. The combination of existing wetlands and replacement wetlands will create an extraordinarily large central open space amenity to this mixed use project. This open space reduces the overall density of the proposed residential development and builds upon the scenic character of the surrounding landscape.

Figure 8. Native herbaceous wetland vegetation can add a unique visual character to urbanized settings; adding textures, unusual forms, lushness, and subtle shades of green, not seen in typical landscapes. These naturalized landscapes require little or no maintenance.

The Oakland Ravine Stormwater Wetland Treatment System is located in the Borough of Queens, New York City, adjacent to Alley Creek Park. This project illustrates that constructed wetlands can be designed into even highly urbanized settings. Oakland Ravine is a landmark project in New York City, designed to reduce combined sewer overflows (CSOs) and provide stormwater treatment. This project will be presented in greater detail in a subsequent paper.

Figure 9. Oakland Lake, the receiving body for treatment wetland flows, is a heavily used recreational lake in the New York City Park system. Project design goals were to reduce CSOs by disconnecting a storm sewer from the combined system and route the discharge through a 2.5 acre treatment wetland for filtration prior to entering a recreational lake. Multiple other design goals include stabilization of severely eroded ravine slopes, stormwater management of the adjacent area, ecological restoration, park access, public education.

R0025016

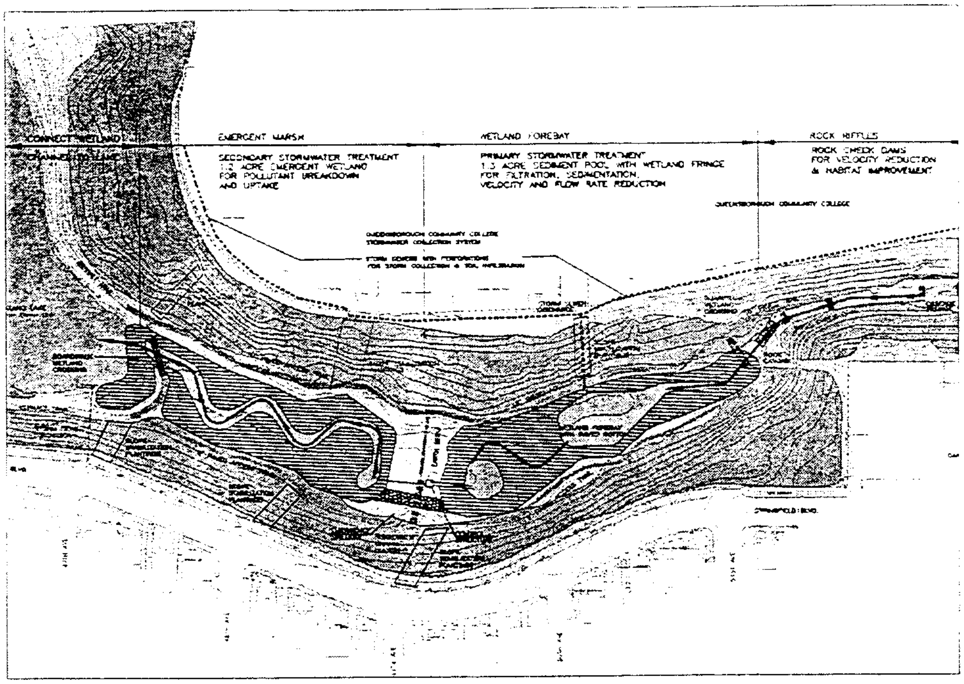

Figure 10. The site is surrounded on all sides by a community college, a grade school, and dense residential neighborhoods. This location will provide an educational resource to the three adjacent schools. A number of design elements, such as a paved sediment forebay were included to minimize maintenance operations. The stormwater treatment wetland is projected to reduce most pollutants by 50-75%. The Preliminary Plan has achieved an interagency consensus between two city departments, the Department of Environmental Protection (DEP) and the Department of Parks and Recreation (DPR).

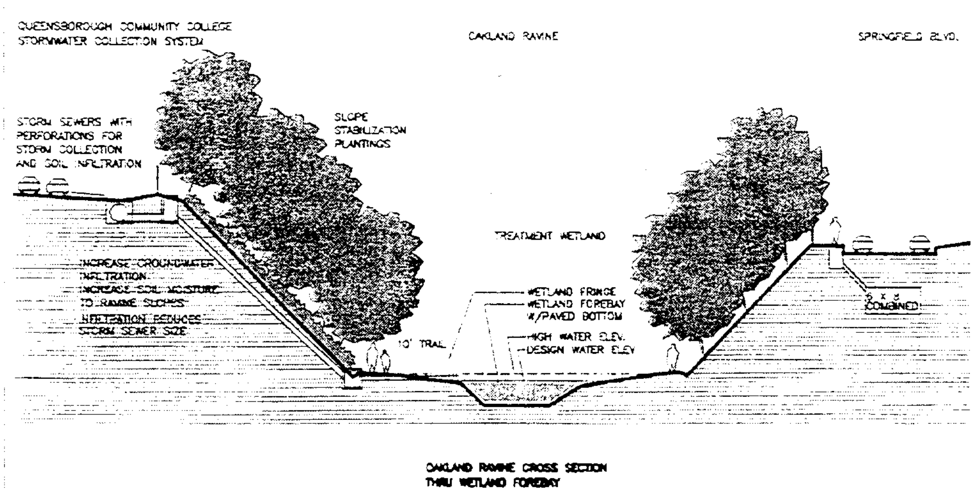

Figure 11. Oakland Ravine slopes are 60-80 feet in height, heavily wooded, and severely eroded at a number of locations. A primary design goal was to develop a naturalized design character for all hydraulic structures such as headwalls, energy dissipaters, channel protection, and control structures. This naturalized design character will provide scenic enhancement of the park and take the form of rock cascades, plunge pools, restored stream channel, and planted gabions.

DISCUSSION

The evolution of wetland protection regulations is an expression of society's growing recognition of the services wetlands provide. Current regulations require each project to demonstrate avoidance and minimization of impacts to existing wetlands. Small impacts may be permitted and mitigated with relative simplicity. Larger impacts may require a thorough documentation of project alternatives to convincingly demonstrate the unavoidable need for wetland impact. Unavoidable impacts may be replaced or mitigated either onsite or offsite according to a replacement ratio tailored to each project. Both Federal and State wetland regulations are growing more protective. In May, the Ohio EPA implemented water quality regulations implementing a wetland classification system which effectively increases the wetland replacement ratios required for wetland impacts. Impacts to wetlands classified as high quality require higher ratios of wetland replacement. These regulations make wetlands a major factor in the land planning equation. In many parts of the country, it is virtually impossible for any major infrastructure or land development project to avoid wetland impacts.

Watershed planners should be prepared to take advantage of mitigation opportunities for watershed restoration purposes. An integrated mitigation strategy which incorporates wetland preservation, wetland mitigation and stormwater management can provide higher levels of wetland functions and values than the wetlands impacted. Offsite wetland mitigation can provide a funding vehicle to address urban watershed restoration by creating opportunities for public/private partnerships. Larger wetland mitigation areas can be permitted to form "Wetland Banks" to cost effectively provide for present and future wetland impacts. Many park districts have created wetland mitigation banks to advantage of these opportunities and capture additional revenues for wetland projects.

The integration of wetland preservation, mitigation wetlands and stormwater management functions requires both careful design and close coordination with regulatory agencies. Erosive flow velocities, sediment deposition and large water level fluctuations can threaten the establishment of a healthy and diverse wetland community. Constructed wetlands can be engineered to provide stormwater retention using many of the same modeling techniques used for retention basins, such as TR-55 and HEC-RAS. However few, if any regulatory agencies will approve mitigation credit for retention basins. Successful integration may require a number of design techniques such as enhancement of existing wetlands, storm sewers discharging to pretreatment pools, and hydrologic modeling to document non damaging flow velocities and water levels. Projects which successfully integrate on site wetland preservation, wetland mitigation and stormwater management usually result in storage areas significantly larger than a traditional retention basin; a key factor for moderating water level fluctuations.

One shortcoming of most stormwater management codes is increased runoff volume. Retention basins can effectively reduce peak rate discharges from proposed developments, nonetheless, more impervious surfaces mean flood peaks for longer durations. The large storage area of wetlands can reduce runoff volumes through several methods: soil infiltration, evaporation, and plant transpiration. The degree of volume reduction can be modeled with water balance equations or software to determine the volume reduction effects of each project.

Wetlands have been described as nature's kidneys. Stormwater treatment wetlands provide both physical and biological processes for pollutant removal. Sedimentation is usually the predominant pollutant removal mechanism, using gravity to remove suspended solids. The abundance of water in wetlands makes them the most biologically productive ecosystems in North America. This high rate of biological activity provides wetlands with the ability to transform many common pollutants into harmless by-products or essential nutrients.

A sizeable body of scientific and governmental publications have documented treatment wetlands as a proven technology for the improvement of surface water quality. Stormwater wetland treatment systems use both physical and biological processes for pollutant removal. Sedimentation and filtration of floatables are usually the predominant physical pollutant removal mechanism. Adsorption of pollutants onto the surface of sediments, vegetation and organic matter is a principal mechanism for removal of dissolved or floating pollutants. Biological processes consist of pollutant digestion by bacterial action, decomposition of organic matter, and nutrient uptake by wetland plants. Published results on wetlands' ability to remove pollutants from stormwater indicate that total suspended solids and selected nutrients and metals may generally be reduced by 50-75%. Removal efficiencies may be affected by a variety of factors such as wetland sizing, seasonality, hydraulic conditions, climate, and reporting procedures (Strecker 1996). Numerous wetland treatment systems are already in place across the country, efficiently improving water quality in agricultural, mining, industrial and wastewater treatment applications.

Careful design of constructed wetlands can serve both hydraulic functions and produce a rich and diverse wildlife habitat. Irregular shoreline configurations, small islands, and small pools provide a variety of habitat niches for waterfowl, shorebirds, songbirds, amphibians, aquatic insects. Wetland complexity helps to avoid undesirable wildlife scenarios such as the 'goose pond syndrome' common to parks and golf courses containing ponds adjacent to grass areas. Such settings can develop a year round population of ducks and geese which will consume large volumes of wetland plants and leave vast quantities of droppings which raise nutrient levels in ponds. Perhaps the greatest fear about stormwater wetlands is that they will become infested with swarms of mosquitoes. In reality, mosquito problems have been seldom encountered with stormwater wetlands (Schueler 1992). A design which avoids stagnant water areas with adequate hydrologic flushing is one design strategy. Mosquitoes are part of a food chain which includes mosquito predators such as frogs, toads, salamanders, dragonflies, purple martins, and bats. Bats are the single most effective mosquito predator, consuming up to one half their body weight in a 24-hour period.

Constructed wetlands can produce significant scenic enhancement benefits. A diverse wetland plant community can create a rich visual variety of shapes, textures, patterns, colors; in sharp contrast to the typical lawn and pond landscapes found in many parks and commercial landscapes. Many wetland plants produce colorful flowers and can be designed into the aquatic landscape like an impressionist painting. The winter wetland scene can contain a variety of plant heights and textures and resemble a large dried floral arrangement. Creative design of hydrologic features such as open water, small islands, small pools and naturalized stream channels add further visual drama.

Incorporation of constructed wetlands and stormwater functions into urban parks is not a new idea. In the late 19th century Frederick Law Olmsted, the father of the Landscape Architecture profession, designed several large urban parks which successfully combined stormwater features, water reservoirs and the creation of natural scenery in well known urban parks such as Central Park and Prospect Park in New York and Fenway Park in Boston. The restorative powers of natural scenery to delight the eye and refresh the spirit was one of Olmsted's fundamental design goals (Beveridge 1995). The psychological value of natural scenery in urban areas is under appreciated, overlooked, or trivialized in contemporary park design.

Constructed wetlands may also be planned to produce a number of powerful economic effects. Land use in planned developments may be optimized by integrating wetland preservation, constructed wetlands, and stormwater management, into an open space amenity. Studies of open space have found property value increases of 7-23%, where property faced open space (Weich and Zeibst 1973). Increased property values are beneficial to both the public and private sectors, in increased tax rolls and higher revenues from land sales. Stormwater management becomes an economic development issue when chronic flooding creates community disinvestment. Identification of strategic stormwater projects to solve these chronic flooding conditions can encourage reinvestment in formerly blighted areas.

Constructed wetlands adjacent to schools can be an exciting addition to the curriculum of all ages. As an outdoor land they can provide hands on experiences to students and make curriculums more relevant in variety of subjects such as math, biology, chemistry, ecology, art, and English.

CONCLUSIONS

These case studies illustrate that skillfully designed constructed wetland projects can balance multiple challenges; fulfill ecological and engineering criteria, be aesthetic and enhance economic development. Such projects can be a vehicle for the restoration of degraded urban watersheds and represent a tool for communities to show compliance with the upcoming Phase II NPDES regulations to be implemented in March 1999.

Stormwater wetlands can be constructed for the relatively low cost of earthwork, simple hydraulic structures, and plantings. Operation and maintenance costs are also relatively low due to the utilization of natural energies of the sun, plants, soil, and animals. No fossil fuels or chemicals are necessary for the operation of stormwater wetland treatment systems. Stormwater wetlands may be constructed at costs ranging from $10,000-$40,000 per acre depending on earthwork requirements and site amenities.

A multi discipline design team is fundamental to fully realize the multiple benefits of such projects. The projects presented are the result of a multi discipline collaboration of Landscape Architects, Hydraulic Engineers, Wetland Scientists, Permit specialists, and Geotechnical Engineers. Each discipline brings to the table unique skills necessary for a successful project: watershed hydrology, hydrologic modeling, soils engineering, plant communities' identification, ecological restoration, regulatory compliance, as well as skills in land planning, park design, grading, and landscape design.

Throughout the Great Lakes Basin, 43 Remedial Action Plans (RAPs) are in operation, formulating strategies to improve water quality and enhance habitat. The Washington, D.C. metropolitan area has implemented numerous stormwater wetland projects as a means of improving water quality in Chesapeake Bay. One may envision metropolitan areas throughout the Great Lakes region planning an array stormwater wetland parks throughout their urban watersheds to solve wet weather challenges and address other community issues. Such projects could provide significant public benefits and be partially funded by private sector wetland mitigation requirements. Many urban areas contain numerous candidate sites waiting for such projects, such as parks with damaged water features, degraded flood plains, abandoned quarries, leftover commercial or industrial sites, or damaged municipal detention basins, that may be creatively reconfigured to provide an attractive asset to the watershed and the community.

ABSTRACT

The City of Winnipeg initiated a major Combined Sewer Overflow (CSO) Management study in 1994 to "establish a cost-effective prioritized implementation plan for remedial works based on assessment of costs and benefits of practicable alternatives". Results from phase 3 of the 4-phase study strongly indicate that use of available in-line storage in the 43 individual combined sewer districts (total area about 10,000 ha) is the most effective and logical first step in the emerging wet weather pollution control plan. A "demonstration approach" was used to assess whether or not a proposed control plan could effectively achieve specific water quality objectives. As well, it was deemed important to asses options that were consistent with the EPA "presumptive approach" goals of 4 overflows and 85% capture.

A detailed review of Winnipeg's combined sewer systems confirmed that the volume of available in-line storage was substantial but unevenly distributed. Planning level models were developed to assess the use of existing in-line storage, identify strategic locations for additional storage/district transfers, optimize dewatering and conveyance rates, evaluate wastewater treatment plant limitation/upgrade requirements, and assess receiving stream water quality improvements. Real-time control and non-RTC strategies were evaluated to identify practicable control options which could maximize the use of available in-line storage without increasing the risk of basement flooding. It was found that strategies involving local RTC were less costly and could fully utilize available storage but contained a small element of risk. A non-RTC option involving "finger" weirs was found to be effective, contained no risk, but could not fully utilize storage.

This paper will present the analyses and the description of trade-offs between cost, risk, and performance measures of the range of storage options.

KEYWORDS

combined sewer overflows, in-line storage, real time control

INTRODUCTION

Winnipeg is the capital city of the Province of Manitoba, Canada, and is situated on the confluence of two major rivers, the Red and the Assiniboine rivers. Winnipeg's current population is about 650,000 and comprises a developed area of about 28,000 ha. The older central portion of the City is about 10,000 ha in size, and is serviced by a combined sewer system. The combined sewer serviced area is divided into 43 combined sewer districts, each of which overflow from 7 to 37 times during the recreation season (May to September, inclusive). During dry weather, the flow is diverted into interceptors and brought to three water pollution control centers (WPCCs) for complete secondary treatment. Plans are underway to disinfect the dry weather effluent from one of the treatment plants and the other two plants are under study.

The City is currently working on a combined sewer overflow (CSO) management strategy to develop various plans to control CSOs in the future. The CSO control strategy plan development involved an extensive technology review. This included:

- Best Management Practices (BMP);
- Separation (either full or partial) of the combined system;
- Storage (with and without district transfers)
  - off-line
  - tunnel/transport
  - in-line
- High rate treatment
  - Retention Treatment Basins (RTB)
  - Vortex Solid Separators (VSS)
- Floatables capture.

An integrated modeling approach was used to determine how each of the various candidate options for CSO control would perform. The integrated modeling approach involved three types of models which were sequentially linked:

- an urban hydrology model to estimate the runoff from a wide-variety of rainstorms over the year;

- a sewer system/control alternative model to simulate behaviour of the hydraulic system and thus determine when and where overflows would occur, the volume of interception, the volume of overflow, and the benefits of various control measures; and

- a receiving stream model was used to assess the hydrodynamics and biokinetics of the river water quality, i.e., transport, mixing, fecal coliform die-off, etc., in response to dry and wet weather loadings from the full range of urban discharges.

The various alternatives were assessed in terms of their performance with respect to various performance measures such as number of overflows, volume of overflows and compliance with surface water quality objectives for the receiving streams.

SEWER SYSTEM CHARACTERISTICS

Winnipeg is a very flat prairie city located in the Red River Valley. Generally, the elevation difference throughout the City is about 3 to 4 m (10 to 13 ft.). The Red and Assiniboine rivers water level is only 3 to 4 m below street level along the riverbanks. In addition, the hydrology of the prairie region, which may be relatively dry compared to the East Coast cities, creates large and intensive thunderstorms at least once a year. These geographical factors resulted in the design of existing sewer systems for protection of basement flooding with very flat grades and large diameters.

During dry weather flow, all wastewater is diverted into an interceptor and subsequently conveyed by a gravity to one of three wastewater pollution control centers (WPCC) for full secondary treatment processing before it is discharged to the rivers. However, during wet weather conditions, flow into the system is significantly greater than dry weather flow (DWF) and results in combined sewage overtopping the diversion weir and spilling into the river.

A typical sewer in one of the 43 districts has a 3 m diameter pipe extending 2 to 3 km perpendicular to one of the rivers. During typical operation, the dry weather flow in the combined sewer occupies only a small depth in the bottom of the sewer. A low weir, 0.3 to 0.6 m in height, typically diverts dry weather flow (DWF) either directly into an interceptor or to a pump station where it is delivered to the interceptor. During severe rainstorms, these same sewers are often surcharged, however, significant sewer storage volume is available for more routine rainstorms and could be potentially accessed for use as in-line storage.

The original sewer designs in the city allowed for flood protection of up to a storm of a 1-in-2 year occurrence. Over the past three decades, the City has been upgrading the combined sewer system to allow protection from basement flooding for a storm of up to a 5-year occurrence. These sewer relief programs have often resulted in the addition of a second major sewer pipe in each combined sewer district of comparable size to the main combined sewer trunk (e.g., 3 metres). These relief pipes offers the potential for increasing the volume available for in-line storage in each district.

DEVELOPMENT OF IN-LINE STORAGE ESTIMATES

In-line storage is the latent volume contained within the existing sewer pipe network that can be safely accessed through the use of a control device. Specifically, the control device is intended to cause excessive flows in a the sewer system to be stored in the pipes up to a safe level that does not decrease the existing level of the basement of flood protection. Figure 1 illustrates a typical profile of a combined sewer trunk found in Winnipeg.

Preliminary analysis of Winnipeg's combined sewer system found that large volumes of in-line storage may be available and could significantly reduce the number and volume of CSOs in a cost-effective manner. Accordingly, it was necessary to conduct a detailed review of the combined sewer systems to assemble the data needed on pipe geometry and critical elevations (invert and ground) to improve the accuracy of in-line storage volume calculations for all 43 combined sewer districts in Winnipeg. Once this information was assembled, it was possible to calculate the volume of storage available in each pipe for a specified weir or control elevation.

During the course of the CSO study, the need to investigate the different in-line storage concepts and control technologies evolved. The following three control concepts are the most relevant to the Winnipeg situation.

- Automated gate control
- Fixed finger weirs
- Accessing existing passive / latent storage.

The following discussion elaborates on these three control concepts as they relate to Winnipeg's CSO study and relevant local circumstances.

Real Time Control Gate Option

A review of rainfall history (recent 35 years) was conducted to understand the number and size of rainfall/runoff events that Winnipeg typically experiences during the open water recreation season (May 1 to Sept. 30 inclusive). It was found that most rainfall events are well below the hydraulic capacity of the combined sewer and could be stored within the system. The use of an automated gate system to access available in-line storage by temporarily holding wet weather flows (WWF) within the system during and after small rainfall events is one option under consideration. Runoff from these small rainfall events could be completely stored within the combined sewer system and then dewatered during and after the storm event (see Figure 2b).

The gate control option was assessed to estimate receiving stream impacts. The gate, initially open and in the "home position", would shut during the start of a wet weather event and remain shut until the event was completely over and the sewer was dewatered unless the water level in the sewer rose to a specified critical condition. If the water level or the rate of rise met a predefined trigger condition at selected strategic locations within the sewer system, the gate could be operated in the following two different modes.

- continuous modulation of the automated gate to fully utilized in-system storage while maintaining the existing level of basement flood protection; or

- opening the gate fully and leaving it open to assure that levels in the sewer would not threaten basement flooding.

In the first method, the maintenance of the level in the sewer at an elevation that would not threaten basement flooding would maximize the volume of in-line storage. It requires accurate hydraulic representation of the sewer system under the range of gate operating procedures to achieve this available storage without a threat to basement flooding.

Other operating concerns related to repeated surcharging of the systems presented serious design considerations. There was concern that the modulating method may lead to waterhammer, air surges, weakening of structural integrity, and increased the formation of sinkholes in or along the sewer system due to repeated surcharging.

An alternative gate protocol was developed involving the release of all of the stored combined sewage whenever the water level reached the specified critical elevation. This operation would cause more volume of combined sewage to be released to the river. Since even a small overflow would likely cause a violation of the microbiological water quality objective (i.e., fecal coliforms) designated to protect recreation (either 200 fc/100 mL or 1,000 fc/100 mL), the number of overflow events throughout the recreation season would be the same regardless of the operating protocol used. It should be noted that the automatic gate operation can be accomplished by local, i.e., district-specific RTC, since each district acts as a relatively discrete watershed to the interceptor. The dewatering of the various in-line storage elements in the different districts may require a system-wide or global RTC.

A second consideration used in the development of the gate operation strategy was the selection of the specified target elevation below which the combined sewage could be safely stored without affecting the existing level of basement flood protection. The water level and/or its rate of rise would be closely monitored and used to initiate gate opening to maintain the existing level of service with respect to basement flood protection. A key factor in gate automation is the speed at which it could be opened to permit system hydraulics to react quickly enough to keep pace with changes in a storm intensity and associated runoff and inflows. The gate operation is considered to have a fully automated real-time control system. Selection of these "trigger" conditions would have to be developed using sophisticated computer modeling.

A Workshop involving North American and European experts was held on the operations of in-line storage systems to review and assess its practicability to local conditions. The session identified that, due to the very flat sewer grades found in Winnipeg, there was the potential that air could be trapped in pockets at the top of the sewer and result in a air surges during wet weather operation of the gates. These air pockets could cause air surges to develop in response to the rapid filling of the combined sewer system under close gate conditions and could translate into pressure surges in service connections of homes and businesses at various locations along the sewer system. To prevent this conditioned from forming, it was determined that in-system storage levels should not exceed the obvert elevation of the sewer pipe at the selected location for automated gate control. Due to the relatively flat grades of the sewers, limiting levels to this control elevation would still allow for substantial realization of available in-line storage in each combined sewer district.

A second constraint was placed on the water surface profile to maintaining existing basement flood protection levels. A minimum depth of 3.0 m (approximately 10 ft) below minimum ground level was used as the maximum elevation the water surface profile would be allowed to reach in order to protect against basement flooding under in-line storage conditions, i.e., depths greater than 3.0 m below minimum ground elevation were considered adequate to protect against basement flooding for the current level of service. Accordingly, the minimum elevation of either the obvert or minimum ground elevation less 3.0 m was used as the control elevation to estimate available in-line storage.

One of the primary concerns associated with the use of real-time control for an automated gate to access available in-line storage is the potential increase in basement flood threatening risk . In order to minimize basement-flooding risk associated with gate control to a "virtually fail-safe" condition, additional design factors were considered:

- inlet restriction on catchbasins should be utilized to reduce the rate of inflow into the combined sewer system and result in system flow hydraulics no worse than that generated by a one in five year synthetic design storm;
- the logic of gate control systems (with redundancy) have to be developed to open the gate if there is a malfunction or failure in any of the water level sensing monitors;
- gates would have to be designed to open automatically in case of power failures or interruptions (e.g., an air-accumulator connected to a hydraulic operator or an air-driven motor); and
- utilization of the existing flood pumping stations to initiate emergency dewatering of the combined sewer system if the gate fails to open, (e.g., shaft breakage or mechanical malfunction).

Fixed Weir Option

The control concept described above was considered to be "virtually fail-safe". Given a history of basement flooding, there was still concern about added risk of basement flooding to the citizens of Winnipeg under extreme contingencies. Accordingly, other alternatives, which were inherently fail-safe, were considered. A fixed weir utilizing long weir lengths to minimize flow depth over the weir was considered both fail-safe and practicable (see Figure 2c). This option requires the construction of a large weir chamber utilizing finger weirs in the sewer system to achieve the lengths of weir needed (60 m in some cases) to access available in-line storage. The weir chamber would be 13 metres wide, and fit within the roadway right-of-way. A design condition of 150 mm (6 inches) depth of flow over the weir to safely pass a 1-in-5 year design storm was selected. The existing hydraulic gradeline (HGL) for each sewer system under the design event was reviewed to establish the top elevation of the weir (i.e. each HGL-0.15 m).

To maintaining existing basement flood protection levels under this option, a minimum depth of 3.2 m (approximately 10.5 ft) below minimum ground level was used to protect against basement flooding. Accordingly, the minimum elevation of either (HGL less 0.15 m or minimum ground less 3.2 m) was used as the control elevation to calculate available in-line storage.

A fixed finger-weir system to utilize available in-line storage has the advantage of little need for operational attention relative to an automated gate control system and is inherently more fail-safe. However, it is more costly to construct and will only utilize about 80% of the in-line storage that could be achieved through the use of an automated gate control system.

Passive and Latent Storage

Many of the underground combined sewer districts have relief sewers to reduce basement flooding. The primary purpose of the relief systems in Winnipeg is to improve the hydraulic conveyance of wet weather flows (WWF)so as to protect basements from flooding for a given design level of service (e.g. 1-in-5 year return frequency storm). The relief systems are designed to be active (i.e., overflow to the rivers) only during rainfall conditions. As described earlier, a low-level weir was historically installed in the combined sewer trunk and used to redirect DWF through an off-take system to the interceptor system. The diversion structures were originally designed to divert about 2.75 times DWF. To avoid dry weather overflows from occurring in the relief systems, careful attention was placed on the hydraulic modeling and design of relief overflow activation levels. Specifically, hydraulics in both systems (combined sewers and relief piping) were synchronized such that overflow from the relief system did not occur prior to overflows from the combined sewer system. The storage of combined sewage contained in the combined sewer system up to this activation level represents existing passive in-line storage volume.

Currently, many of the relief sewer pipes that are part of the combined sewer systems are below normal river water level (see Figure 2d). Each relief system outfall has a flap-gate installed to prevent river water from entering the sewer system. The majority of these relief pipes do not have a dewatering system and remain partially full under normal river water level conditions. As such, the combined sewage will remain in the relief pipe between storms until it is displaced by flows resulting from the next rainfall event. If this combined sewage could be dewatered to the interceptor, a significant amount of storage would be available to store small storms, and accordingly is considered latent storage.

COMPARISON OF IN-LINE STORAGE AVAILABLE

In-line storage calculations were performed for each of the 43 combined sewer districts to quantify the potential volume of storage available for each of the 3 control concepts previously discussed (i.e., gate, weir, and latent storage). The results are summarized on Figure 3. The automated gate option allows for the greatest volume of storage to be utilized, about 360,000 m^3. The fixed-weir option achieves about 300,000 m^3 of storage. Accessing existing passive and latent storage would provide in the order of 130,000 m^3 of storage. The cost of the automated-gate option is about $ 50 Million compared to the higher cost for the fixed weir of $ 100 Million. The risk of failure associated with the automated-gate option must be considered and the economic penalty of failure accounted for in the decision-making process. In order to safely access in-line storage, (i.e., reassure the public that there is no increase in the risk to basement flooding), the fixed weir option may be the only option the public will support. Existing latent storage could be accessed now but would require dewatering facilities to be installed and ensuring flap gates are operating correctly. This cost associated with accessing latent storage would be significantly lower than either of the other two options.

INTEGRATION WITH FUTURE BASEMENT RELIEF PROJECTS

The City of Winnipeg has an ongoing program to improve basement flood protection on a prioritized basis. The most flood-prone combined sewer districts are ranked and given highest priority for installation of relief sewers. Figure 4 shows the combined sewer districts that have been relieved and the remaining districts that require some degree of relief to improve basement flood protection. An estimate of potential increase in the in-line storage that could result from new relief pipes, for each of the in-line storage control concepts considered is shown on Figure 3. The analysis indicates that latent storage could be significant if it were possible to install all new relief pipes at a depth that the normal river level would control (i.e., below river level and held back by flap-gates). Specifically, future relief projects could potentially achieve as much in-line storage as the existing system with an automated gate control scheme, although the distribution of the storage in the system may not be optimal. New relief projects represents a very important opportunity with respect to supplemental in-line storage volumes that could significantly reduce the need for more expensive and complicated control technologies. Clearly, the addition of new relief pipes can provide improved basement flood protection while reducing the number and volume of CSO. The need for CSO control provides the opportunity to expand the design criteria of proposed relief projects to include consideration of cost-effectively maximizing in-line storage and minimize wet weather impacts.

CONCLUSION

In-line storage can be a cost-effective method of reducing combined sewer overflows. The use of automated gate controls is one method of maximizing the use of the available in-line storage at a reasonable cost. Concerns from the public that this automated system may increase the risk of basement flooding under worst-case contingency events, even if the risk is very low, may preempt its use. Alternative methods such as use of fixed weirs and using latent storage may access significant in-line storage for CSO control

Designing future basement relief projects with due consideration for increasing latent storage may prove to be a very effective integrated long term CSO control solution.

CATCH BASINS - EFFECTIVE FLOATABLES CONTROL DEVICES

Gary Grey, HydroQual, Inc.*

*HydroQual, Inc., 1 Lethbridge Plaza, Mahwah, NJ 07430

ABSTRACT

One of the major issues of urban wet weather pollution is the control of floatable pollution. Studies conducted in New York City have shown street litter to be a major contributor of floatables to New York Harbor. Several methods for controlling floatables are being considered including increased street sweeping, end of pipe treatment technologies, booming and skimming at CSO outfalls and catch basin controls. Catch basins, which exist in most urban areas, offer a means of controlling floatable material at the source. They are simple devices which if properly maintained can be very effective in removing floatable material from stormwater. This paper presents New York City's efforts in evaluating the effectiveness of catch basins as well as a City-wide program to inspect, map and hood all catch basins.

Catch basin designs for most urban areas throughout the US are similar. The most important aspect of this design, with respect to floatables removal, is the presence of a hood or trap which is generally hung over the basin's outlet. The hood, which extends into the water surface, provides a seal which prevents the release of sewer odors into the surrounding neighborhood. The hood also acts as a baffle at the water surface which prevents the release of floatable material to the sewer system. Studies conducted in New York City have shown hoods to be capable of retaining 70 to 90% of floatables entering the catch basin.

New York City is implementing a City-wide catch basin hooding program as part of its CSO control program. This effort includes inspection, inventory and mapping of all catch basins. There are approximately 130,000 basins throughout the City. Following the inspections, basins are cleaned and hoods are installed where needed. The program, which is expected to be completed over a four year period, was started in February 1996.

A database is being constructed from the information being collected during the inspections, which includes approximately 150 data items per basin. GIS mapping of the basins is being integrated with the database to produce a comprehensive management tool which will be used to direct future catch basin maintenance and repair activities. This program, with periodic basin inspections, will provide a means of maintaining hoods on catch basins and thereby ensure the effective use of catch basins as a floatables control.

KEYWORDS

catch basins, floatables, combined sewer overflows

INTRODUCTION

The City of New York operates a wastewater collection and treatment system for approximately 1.4 billion gallons per day of sewage flow. The collection system covers approximately 190,000 acres of which approximately 120,000 acres are serviced by combined sewers. The City is in the process of developing a comprehensive plan for managing combined sewer overflows. The control of floatable pollution is a major component of this plan.

The City has conducted several studies since 1988 investigating sources and controls of floatable pollution. The primary source of floatables has been identified as street litter. Controls that have been or are currently being investigated include:

- booming and skimming
- catch basin hoods
- increasing wet weather flow capture at wastewater treatment plants
- enhanced street cleaning
- centrifugal separators
- in-line storage
- public outreach programs

Many of these controls have been adopted in the USEPA's Nine Minimum Controls for combined sewer overflows. The City has adopted booming and skimming as an interim control while a long term strategy is developed. Part of that long term strategy is the hooding of catch basins throughout the City.

The primary function of catch basins is to intercept and transport storm water from streets to a collection system. New York City has approximately 130,000 catch basins, most of which discharge to either combined or storm sewers. During wet weather events the catch basins receive storm water as well as litter scoured from the street by the storm water. The litter captured by the catch basins can be released to New York Harbor through storm water outfalls or combined sewer overflows. This pathway is believed to be a major source of floatable material found in the open waters and in beach wash-ups around the City.

Catch basin designs for most urban areas like New York City are similar (see Figure 1). They generally include a curb inlet or grate (or both), a sump and an outlet. Another common feature is a hood which restricts the venting of sewer gases through the catch basin (see Figure 2). It does this by covering the outlet pipe to a point 4 to 6 inches below the invert of the pipe. Typical catch basins hold water up to the outlet invert. The submergence of the hood creates a water seal which prevents the venting of sewer gases. The hood also acts as a baffle which prevents floating material, such as most street litter, from passing through the outlet. While many catch basin designs include hoods, these devices are often missing due to their own deterioration, deterioration of mounting hardware or accidental removal during basin cleaning or maintenance operations.

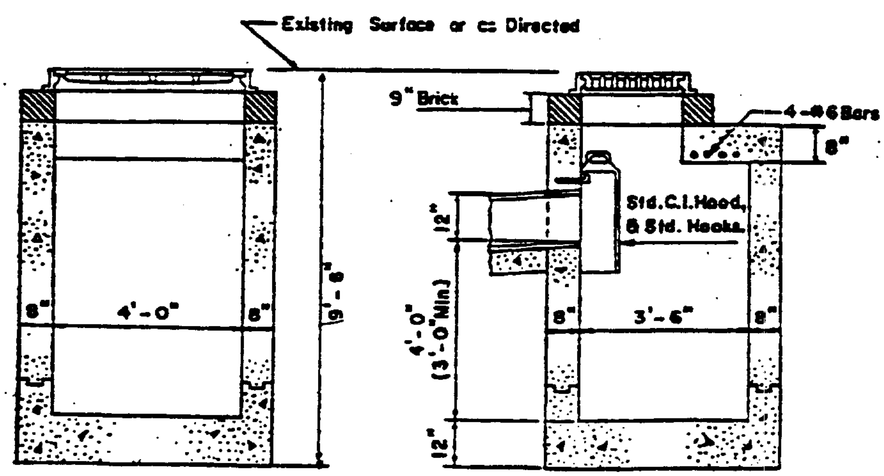

Figure 1 - Typical New York City Catch Basin

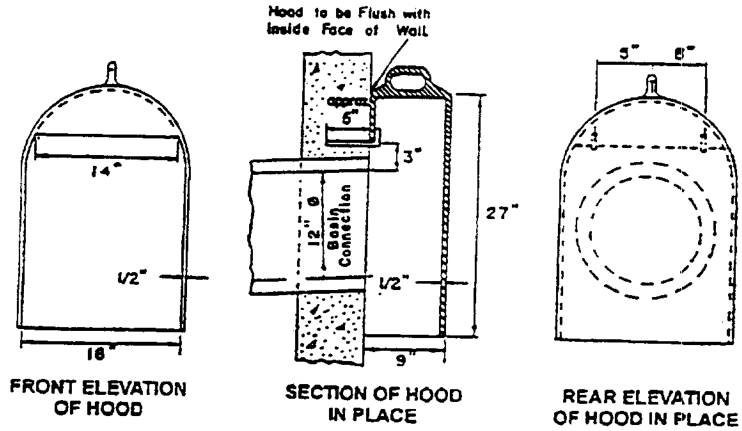

Figure 2 - Typical Catch Basin Hood

The effectiveness of hoods in their ability to retain floatables in the catch basin was investigated. This paper will present the methods and results of those studies as well as the catch basin hooding program which is currently being conducted in New York City.

METHODOLOGY

Two basic protocols were used to evaluate the effectiveness of catch basin hoods. The first protocol was developed for sampling the material discharged from catch basins to the sewer. The objective of the procedure was to develop estimates of the floatables loads discharged from catch basins as well as characterizing the material discharged. This test relied on rainfall events to transport street litter to the catch basins. The second procedure was a series of batch efficiency tests which used a synthesized litter matrix and a fire hydrant to simulate street runoff flows.

Both methods included the same sampling equipment and installation (see Figure 3). This included a 13"x13"x36" high galvanized mesh basket. The lower half of the basket was screened with ¼" mesh, the upper half with ½" mesh. The basket was positioned on a wooden platform in a manhole just beneath the catch basin outlet pipe. It was tethered to the wall of the manhole to permit placement and removal without having to enter the manhole.

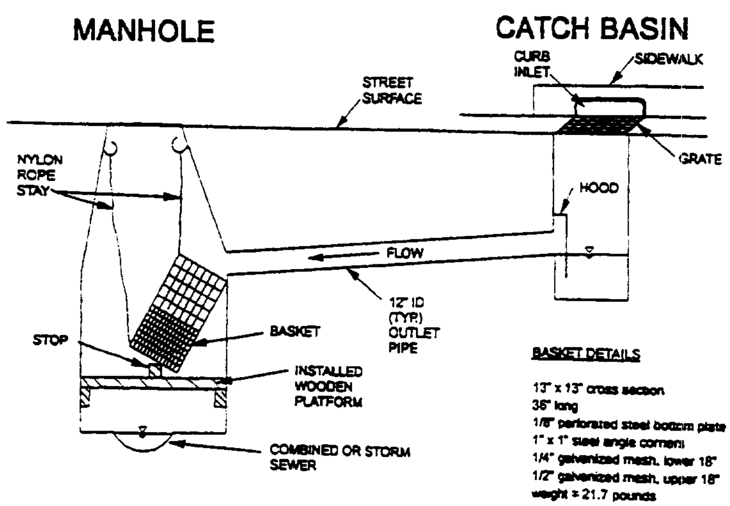

Figure 3 - Catch Basin Sampling Equipment

Catch Basin Sampling Protocol

In the first protocol sampling equipment was installed at 38 locations (six to ten in each of the five boroughs). The initial intent of this sampling program was to characterize material and loads released from catch basins. While selecting sampling sites it became apparent that approximately 60% of the City's catch basins did not have hoods. As a result half of the sampling sites selected had hoods, half did not. In addition to characterizing the loads and the material released from the basins, this also offered an opportunity to characterize the effectiveness of the hoods.

All 38 sites were continuously monitored for 3 to 4 months between the spring and fall of 1993. Eight sites were sampled weekly for approximately 4 months, the remaining 30 sites were sampled bi-weekly for approximately 3 months. The samples were collected by deploying the baskets for the one or two week sampling period after which the contents were transferred to a sample bag. The baskets were then replaced for the next sampling period and the samples were analyzed at a field laboratory. Sample analysis consisted of sorting the material into 13 material categories (see Table 1), measuring and recording the number of items, surface area and weight for each category.

Table 1 - Material Type Categories for Catch Basin Sample Analysis

	Category	Examples
1.	Sensitives	syringes, crack vials, baby diapers
2.	Paper-Coated/Waxed	milk cartons, drink cups, candy wrappers
3.	Paper-Cigarette	cigarette butts, cigarettes
4.	Paper-Other Products	newspaper, cardboard, napkins
5.	Plastic	spoons, straws, sandwich bags
6.	Polystryene	cups, packing material, some soda bottle labels
7.	Metal/Foil	soft drink cans, gum wrappers
8.	Rubber	pieces from autos, pieces from toys
9.	Glass	bottles, light bulbs
10.	Wood	popsicle sticks, coffee stirrers
11.	Cloth/Fabric	clothing, seat covers, flags
12.	Misc. Floatables	citrus peels, pieces of foam
13.	Non-Floatables	opened food cans, broken bottles, bolts

Efficiency Test Protocol

The second procedure involved seeding a street gutter or catch basin pit with ten pieces each of 12 different floatable items (120 items total). This matrix included the following common street litter items: plastic bags, candy wrappers, straws, bottle caps, juice bottles, hard plastic pieces, glass vials, aluminum cans, polystyrene cups and pieces, cigarette butts and medical syringes. Each unit of matrix also corresponded to a total volume of approximately 1 ft^3. A fire hydrant was used to provide a water flow of 75 gallons per minute which is equivalent to 0.28 inches per hour of rainfall over a 40,000 square foot drainage area. This rainfall intensity corresponds to the Maximum Likelihood Estimate (MLE) of the maximum hourly storm intensities at John F. Kennedy Airport for the 1988 to 1994 period of record. Additional tests were also conducted at 25 and 150 gallons per minute.

A sampling basket was placed beneath the catch basin outlet and flow was applied until no more floatable items passed to the basket (five to ten minutes). The items remaining in the basin and captured in the basket were separately retrieved and counted. This process was repeated 5 times for each test. Tests were conducted in this manner with and without hoods at seven sites. Ten tests were conducted in all.

RESULTS

The effectiveness of catch basin hoods in retaining floatables became apparent during the course of performing the catch basin sampling studies. Field observations also indicated that hooded basins exhibited an accumulation of floatables and litter while basins without hoods did not. The effectiveness of hoods was further supported by the results of the efficiency tests.

Catch Basin Sampling Studies

As stated previously, the objective of the catch basin sampling program was to estimate the floatables loads from catch basins to the sewer. The loads were developed on the basis of number of items, surface area and weight per linear foot of street or curb length tributary to the basin. The effectiveness of hoods became apparent when this data was reduced to hooded and unhooded basins (See Table 2).

Table 2 - Average Litter Loads and Impact of Hoods for Catch Basins Sampled During the Monitoring Program

Condition	Number of Items (No/100ft/d)	Surface Area (sq in/100ft/d)	Weight (gm/100ft/d)
Hooded	2.5	7.6	3.3
Unhooded	8.4	16	11
Load Reduction*	70%	53%	70%

*Load reduction is based on load without hood, ie = [(unhooded - hooded)/unhooded] x 100.

As shown in the table hoods reduced floatables by 53% to 70%. This should be viewed as a qualitative estimate of their effectiveness because the comparison is being made between two different groups of catch basins. Each basin in the study was unique with respect to the following variables all of which could also have affected performance:

- Tributary area which affects litter loads and runoff flow
- Street litter loads
- Basin type, dimensions and outlet alignment which affect turbulence within the basin under wet weather conditions
- Grit levels which may also affect turbulence

The efficiency test procedure eliminated these variables by permitting studies to be performed on the same basin with and without a hood.

Efficiency Tests

The efficiency test procedure was developed to be a direct way to evaluate the effectiveness of catch basin hoods. Eleven efficiency tests were performed and, in all cases, hooded basins exhibited a substantial reduction in the floatables load to the sewer (see Table 3). This reduction averaged 72% for the number of items discharged and 85% for the surface area of the items discharged. This is believed to be a more quantitative assessment of their effectiveness because the other variables which may affect performance were held constant.

Table 3 - Summary of the Floatables Capture Efficiency of Catch Basin Hoods Using the Efficiency Test Procedure

Test No.	Flow	Percent of Floatable Items: Discharge to Sewer: Hood	Percent of Floatable Items: Discharge to Sewer: No Hood	Percent of Floatable Items: % Improvement*	Percent of Surface Area: Discharge to Sewer: Hood	Percent of Surface Area: Discharge to Sewer: No Hood	Percent of Surface Area: % Improvement*
1/2	78	7.1	40.1	82	9.1	38.3	76
3/4	156	16.1	45.2	64	9.4	48.4	81
5.6	78	2.8	6.8	59	0.6	11.0	94
11/12	75	7.7	21.8	65	0.7	10.2	93
22/25	25	0.2	12.6	98	0.0	7.2	100
23/24	150	8.0	23.8	66	2.3	6.2	63
13/14	75	22.5	39.0	42	11.9	24.6	57
15/16	78	21.9	62.2	65	6.7	66.5	90
17/18	78	6.9	45.3	85	0.2	41.0	99
37/38	78	3.0	35.3	92	0.5	28.0	98
Overall Average Improvement				72%			85%

*Improvement with respect to performance without hood = [(no hood - hood) / no hood] x 100.

An obvious effect of the use of hoods in catch basins will be the accumulation of floatables and other litter in the basins. This raises a question. Will the efficiency of hoods decrease as floatables and litter accumulate in the basin? If so the use of hoods could require more frequent cleaning to keep their effectiveness at a maximum. This was investigated using a modification of the efficiency test protocol. The basic difference was that larger units of matrix were used (two cubic-feet) and the material retained in the basin was not removed, rather, it was allowed to accumulate. Only the items discharged from the basin were collected and analyzed.

Floatables capture efficiency for the particular basin studied was initially 93% (see Figure 4). This gradually declined to 86% as the basin became approximately 56% full of accumulated matrix. This test demonstrated that the accumulation of floatables and litter in a hooded catch basin does not adversely impact a hood's

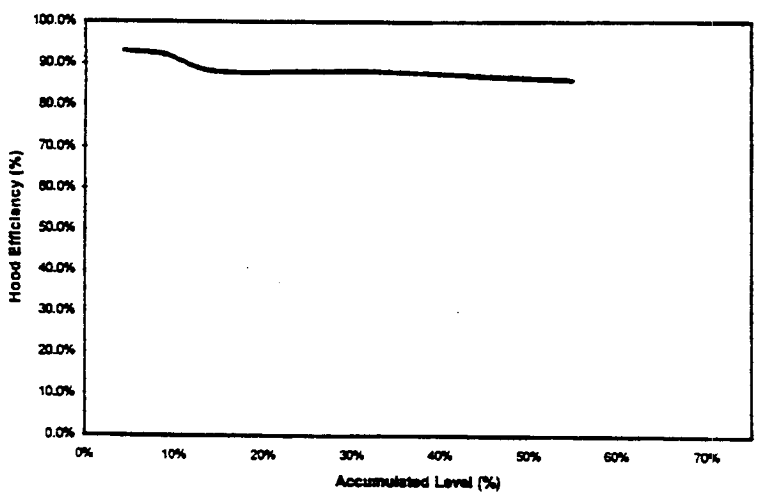

Figure 4 - Effect of Litter Accumulation on Hood Efficiency

performance. It may impact the hydraulic performance of the basin and cause premature flooding. This aspect of catch basin hoods as well as additional floatables and litter accumulation tests are scheduled to be performed in the future.

DISCUSSION

The studies presented in this paper demonstrate that catch basin hoods can reduce the release of floatables to any collection system (combined or separate) by approximately 70 to 90%. Based on these results a City-wide catch basin hooding program was started in February 1996. This program encompasses the entire 190,000 acres serviced by the City's collection system, including combined and separately sewered areas. This program is being conducted in three phases:

Phase I	44,000 structures	Areas with high street litter loads and existing controls in less than 50% of the drainage area.
Phase II	58,000 structures	Areas with moderate street litter loads or no existing controls.
Phase III	28,000 structures	All remaining areas of the City.

In implementing catch basins as a floatables control technology, the City is going beyond ensuring that hoods are simply placed on the catch basins. All catch basins are being fully inspected and located on an accurate computer based curb-line base map of the City developed from recent aerial photography. ArcView (ESRI) is being used to develop the GIS application which will employ the base map. The inspection data is being incorporated into a database which is also linked to the catch basin map. This provides a comprehensive GIS management tool which will be used to manage and maintain the City's catch basins.

The basins are being inspected by field crews who record information on approximately 150 different data items such as the basin's location, type, dimensions, and condition. Each basin is permanently stamped with a unique six digit tag number which is entered into the database and the ArcView map.

Reports indicating basin cleaning and hooding needs are prepared for each of the City's fifty-nine Community Districts. These reports are used to direct the work of catch basin maintenance contractors who clean the basins and replace the hoods. The contractors maintenance activities, as well as the City's, are documented and also incorporated into the database to develop a maintenance history for each catch basin.

The approximate costs for this program are as follows:

Inspection, database and mapping	$45 per basin
Catch basin cleaning	$170 per basin
Catch basin hooding	$45 per basin
Contractor oversight	$23 per basin

To date, all Phase I inspections, cleaning and hooding have been completed. Phase II inspections will be completed by June 1998 and cleaning and hooding of these areas is expected to be completed by November 1998. Phase III work is expected to be completed in 1999. The City has also instituted a catch basin reinspection program which will be performed every two years. This inspection will determine if a basin requires a hood or if it needs to be cleaned. This is being done to ensure that hoods are maintained on the basins.

Between 1993 and 1995 the City instituted an interim floatables containment program (IFCP) consisting of the installation of 23 containment booms and four skimmer vessels. The installation of these facilities was based on pilot studies which demonstrated that containment booms reduced open water floatables by approximately

71%. The IFCP currently encompasses approximately 52% (62,000 acres) of the total CSO drainage area of the City.

As the hooding program proceeds through Phase II, the hooding coverage will encompass most of the IFCP drainage areas. As catch basin hooding is completed in each drainage area an attempt will be made to access the hooding programs effectiveness by reviewing IFCP loads before and after hoods were installed. Other information to be considered in the analysis will be rainfall records and street litter loads for both periods.

ACKNOWLEDGMENTS

Funding for the projects referenced in this paper was provided by the New York City Department of Environmental Protection. The authors would also like to express their appreciation to the members of the New York City Bureau of Environmental Engineering, New York City Bureau of Water and Sewer Operations, New York City Bureau of Wastewater Pollution Control, National Water Main Company, LiRo Consulting Engineers, Staunton and Chow Engineers and HydroQual's catch basin inspection field staff for their cooperation and contributions during the City-Wide catch basin hooding program.

ABSTRACT

Underflow baffles have gained in popularity over the last few years as a viable mean to intercept floatables in Combined Sewer Overflows (CSOs). This has happened in consideration of the extremely low application cost of the solution although the efficiency of underflow baffles has never been clearly proven. Furthermore, there are no guidelines helping planners in the correct and efficient design of underflow baffles. For this reason, review of the behavior of floatables in a rapid flow is paramount. Subsequently, comprehensive design criteria for the underflow baffle itself and the overflow chamber can be deduced. Pilot scale tests, performed in a 17 meters long basin at various flowrates, show that a critical horizontal velocity for floatables may develop in the overflow chamber (V_{cr}). Whenever this critical velocity is exceeded, floatables that would normally rise to the surface are kept within the flow and can consequently not be intercepted by surface restrictions. In other words, the underflow baffle cannot, under specific flowrate conditions, be effective in intercepting floatables. The equation relating the critical horizontal velocity to the vertical velocity in still water of any given floatable type is found to be : $V_{cr} = 16\, w\, R_H^{\ 1/6}$, where w is the vertical velocity in still water and R_H is the hydraulic radius of the pipe. This deduced criteria can also be used to evaluate the efficiency of existing overflow chambers. Preliminary analysis of existing chambers show that interception efficiency of floatables using underflow baffles can be, at best, very low.

INTRODUCTION

The presence of floatables in Combined Sewer Overflows (or CSOs) represents a pollution that is both aesthetically unpleasant, affecting harbors, beaches, coves and river beds, and a source of physical and chemical pollution. Floatables have also been known to impede propellors and cause navigational hazards in harbors (St-John *et al.*, 1994). The USEPA recenses approximately 11000 CSOs in 1100 American cities and towns (EPA, 1994). Removal of floatables from these remaining CSOs is one of the Nine Minimum Controls required under the April, 1994 EPA CSO Control Policy (EPA, 1994a).

Utilisation of underflow baffles in front of overflow weirs for control of floatables in CSOs is one of the several technologies considered by EPA. The Agency recommended it as a short-term BMP and, also, as part of long-term solutions. This technology has attracted much interest from consultants and utilities, due to its apparent simplicity, low cost and, especially, advantages in the operation and maintenance (O&M). All this took place although the actual efficiency of the underflow baffles has never been clearly demonstrated.

R0025039

In this context, we have been actively pursuing the study of interception of floatables in CSOs using baffles. ***The objective of this article is to present the results of experimental data leading us to believe that a critical velocity exist rendering the underflow baffle ineffective unless some very severe design conditions are respected.***

DEFINITIONS

Floatables are solids that are lighter than water ($\rho_{SOLID} < 1000\ kg/m^3$). In favourable circumstances, they tend to rise to the surface of the flow. These floatables are divided in two categories according to their state in the flow:

1. If they are suspended within the flow, by the action of turbulence, they are called swimming solids. ($\rho_{SOLID} \cong 1000\ kg/m^3$)
2. If they are floating on the flow surface, they are called floating solids.

It should be noted that some suspended solids that initially behave as floatables, would turn to settleable solids after becoming saturated with water. Furthermore, a given floatable at a given time may be either swimming or floating, depending upon hydraulic conditions of the flow, i.e. according to the velocity of the flow. The comprehension of this concept is crucial for the deisgn of efficient underflow baffles.

The critical velocity concept

The transport of floatable solids in a suspended state (swimming) is due to the condition of the flow. It is generally accepted that the turbulence lifts upward the settled solids from the bottom and drags downward floating solids from the surface. In laminar flow, all "heavy" solids would gather at the bottom of the channel and all light solids would float at the surface of the flow, as it is the case in a gentle stream or a stagnant body of water.

Previous work done on oil-water separators by the petroleum industry have shown that a critical velocity (V_{cr}) of oil globules exists in the flow. Conclusions from these research project have shown that an horizontal velocity of 15 times the vertical velocity of the oil globules will refrain the oil globules from reaching the surface, keeping them in suspension in the flow (API, 1990).

$$V_{cr} \cong 15w \qquad \text{(Eqn 1)}$$

where :

V_{cr} = Critical velocity of the oil globule in the separator, in (m/s);
w = Vertical velocity of the design oil globule in still water, in (m/s);

Floatables found in an overflow chamber during a CSO event can be assimilated to oil globules in an oil-water separator. Does the same phenomenon apply to floatables in overflow chambers as encountered in CSOs? It is evident that the wide composition of floatables in CSO's will generate a wide range of vertical velocities. A good knowledge of the floatables vertical velocity distribution is then paramount. If this were the case, the evidence of a critical velocity (V_{cr}) would mean a large difference in the optimal design of a baffle.

If the average horizontal velocity of the flow in an overflow basin is lower than the critical horizontal velocity, the swimming floatable should rise towards the surface without dropping back by the action of the turbulence. On the other hand, if the average horizontal velocity of the flow is greater than the critical horizontal velocity the suspended floatables should remain imprisoned in the flow and could not be intercepted by the baffle.

METHODOLOGY

Floatables used for the essays.

The floatables used in these tests correspond to those sampled in the Greater Montreal area as described in Paradis *et al.* (1996). A total of 51 experimental classifications representing all 2021 intercepted items were formed. The principal representative of CSOs are: cigarette butts (1045), Q-Tips (169), plastic debris (118), candy wrappings (101), polystyrene debris (72), preservatives (47), etc...

Description of the essays.

Hydraulic essays were conducted in a channel 1 m wide and 17 m long at the Hydraulics Laboratory of the École Polytechnique of Montreal. These studies had the objective of verifying the existence of a critical flow velocity (V_{cr}) for floatables, for a given efficiency and a given chamber length, and to relate it with the vertical velocities of the floatables as in the API studies. The critical velocity will therefore be expressed as $V_{CR\ \%,D}$, the critical velocity not to exceed to reach a given percentage (%) of removal of floatables for a given length of chamber D.

Figure 1 shows the trajectory of a floatable and the different dimensions used in the definition of terms K_1 and K_2.

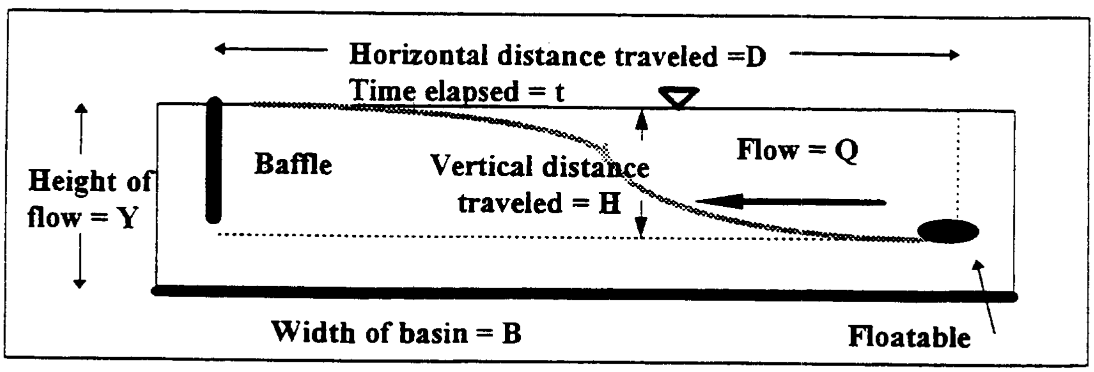

Figure 1. Schematic view of a channel used for the vertical velocity essays

The K_1 Ratio.

The parameter K_1 measures the ratio of horizontal velocities of the floatable in the flow. K_1 is defined as :

$$K_1 = \frac{V'}{V} \text{ (Eqn 2)}$$

where

R0025041

$$V = \text{Average horizontal velocity of flow in basin} = \frac{Q}{YB} \text{ ,in (m / s)}$$
$$V' = \text{Horizontal velocity of floatable in flow} = \frac{D}{t}\text{, in (m / s)}$$

The K_2 Ratio

On the other hand, the rise of floatables is studied through the relation K_2 defined as:

$$K_2 = \frac{w'}{w} \text{ (Eqn 3)}$$

w' = Vertical velocity of a floatable in a flow $= \frac{H}{t}$, in (m / s)

w = Vertical velocity of a floatable in still water, in (m / s)

The Rouse number

The influence of turbulence is given in relation to the Rouse number (Z) as described by Simons *et al.* (1977) and Van Rijn (1984). This number is mainly used in transport of sediments.

$$Z = \frac{w}{\kappa U*} \text{ (Eqn 4)}$$

where

κ = Van Karman constant = 0.4

w = Vertical velocity of a floatable in still water (m / s)

$$U* = \text{Root–Mean Square turbulent velocity component} = Vn\sqrt{\frac{g}{R_h^{1/3}}} \quad \text{(Eqn 5)}$$

and

n = Manning coefficient = 0.017 for our concrete basin

g = Gravity accelaration = 9.8 m / s^2

R_h = Hydraulic radius of the cross section of the basin, in (m)

Experimental protocol

An essay consists of the release of the floatable, in the flow, at a given proportion of the depth of the channel, ranging from 20% to 50% of the total water depth. Two informations are retrieved for each essay: the horizontal distance travelled (D) and the elapsed time (t) for the floatable to reach the surface. Whenever a floatable does not reach the surface, its elapsed time to reach the surface is infinite and therefore its vertical velocity is considered nil. Ten repetitions of the release for each of the floatable were done to obtain a significative average and median. The horizontal water velocity in these experiments ranged from 0.2 to 1.4 m/s. Twelve categories of CSOs were used in 8 sampling campaigns for this study for a total of 75 experimental points. Vertical rising velocities for a particular floatable are ranked in descending order for a serie of 10 essays. The vertical velocity of the 8^{th} element of the ten essays represents the minimal velocity ($w'_{8/10}$) to obtain an efficiency of 80%. In a number of tests, some solids released in the flow at different depths were not able to rise to the surface for the entire length of the test channel. These pilot-scale essays seem to confirm the existence of a critical velocity ($V_{cr, \%, D}$) for floatables in CSOs.

R0025042

RESULTS

The K_1 ratio

Results show that the horizontal velocity of the floatables is roughly stable throughout the flow. We also noted that K_1 is not greatly affected by the turbulent flow and corresponds to the average horizontal velocity of the flow. The numerical value of K_1, for all practical purposes, is therefore of 1. This means that we can correctly hypothesise that the horizontal velocity of the floatable is the same as the velocity of the flow.

The K_2 ratio

A graph of K_2 in function of U* is presented in Figure 2. In this case, results show that vertical velocities can be enhanced or hindered according to the value of the root-mean square velocity of the turbulent flow (U*). A turbulent velocity ranging between 0.015 et 0.035 m/s will, on average, ameliorate vertical velocities by a factor of up to 20% when compared to the vertical velocity measured in still water. Higher turbulent velocities will, on average, create adverse situations where the vertical velocity will be greatly reduced. A very high intra-essay variability was measured for each of the replicates, ranging from 25 to 50% of the mean values. These large variations are to be expected when dealing with such random events. The error bars plotted on the experimental data show that for the turbulent velocity range previously discussed, 0.015 to 0.035 m/s, the vertical velocity of the floatable can range between an increase of 50% or a decrease of 30% from the average vertical velocities values. Outside this range, the vertical velocity diminishes as soon as the turbulent velocity increases, reaching as low as 20% of the vertical velocity in still water.

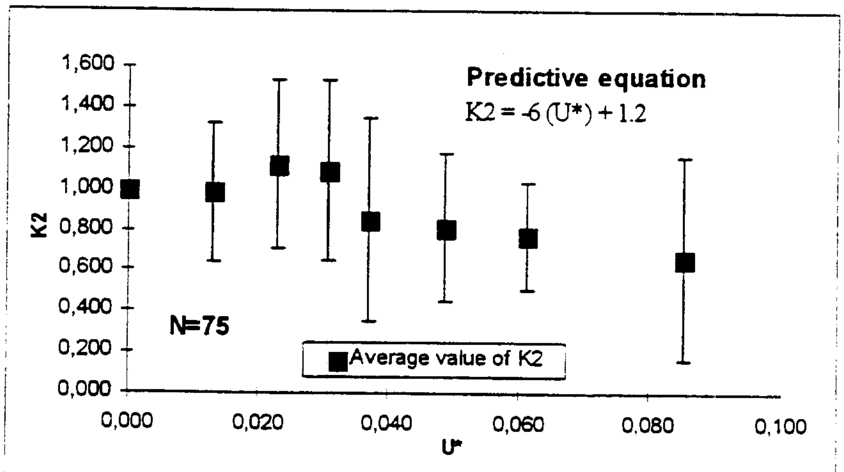

Figure 2. Graph of K_2 in function of U*

The critical velocity, V_{CR}, %, D

Finally, Figure 3 shows a graph of the Rouse number (Z) calculated for each of the essays in function of the minimal vertical velocity necessary to obtain an 80 % efficiency ($w'_{8/10}$) for a chamber length D. This curve shows that an exponential relationship exists between the Rouse number and the vertical velocity necessary to obtain an 80% efficiency in floatable removal. Although there is a lot of dispersion in the experimental points and a low coefficient of correlation derived from the data, the general trend of the curve is well established. Fifty of the 75 experimental data points falls between the minimal and maximal lines of influence. The critical horizontal velocity in the flow is obtained when the vertical velocity of the 8th element tested is equal to zero, i.e. when $w'_{8/10}$ is equal to zero. This means that the 8th floatable never reached the surface and was not intercepted by the underflow baffle. The critical Rouse number found in our data is $Z_{CR,\ 80\%}$= 2.89 when $w'_{8/10}$= 0 m/s. The basic tenet of this analysis is that a floatable that doesn't reach the surface in 17 m will probably never reach the surface. In this sense, the notation $Z_{CR,\ 80\%,\ D}$ becomes $Z_{CR,\ 80\%,\ D=\infty}$.

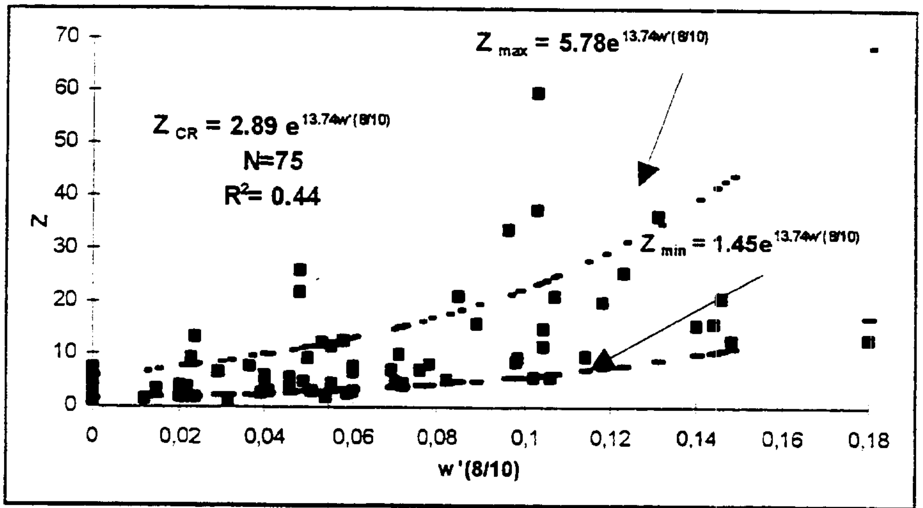

Figure 3. Graph of Rouse number (Z) in function of w'(8/10)

Determination of the critical velocity

It is possible to relate the critical Rouse number exhibited in a flow to the horizontal critical velocity ($V_{CR\ \%,\ D}$). By simultaneously solving for U* in equations 2 and 3, it becomes possible to isolate $V_{CR\ \%,D}$.

$$U^* = \frac{w}{\kappa Z} \quad \text{(Eqn 6 derived from Eqn 2)}$$

$$U^* = \mathrm{Vn}\sqrt{\frac{g}{R_h^{1/3}}} \quad \text{(Eqn 3)}$$

Combining equations 6 and 3, it becomes possible to solve for the horizontal velocity, V.

$$\frac{w}{\kappa\ Z} = \frac{nV\sqrt{g}}{R_h^{1/6}}$$

$$V = \frac{wR_h^{1/6}}{\kappa\ Z n\sqrt{g}} = wR_h^{1/6} \cdot \left(\frac{1}{n\kappa\ Z\sqrt{g}}\right) \quad \text{(Eqn 7)}$$

If we introduce the critical Rouse number (Z_{CR}) found earlier and the numerical values in the right hand terms, we can derive an expression for the critical horizontal velocity of the flow.

$$V_{CR} = \frac{wR_h^{1/6}}{\kappa\ Z_{CR}\ n\sqrt{g}} = 16\,w\,R_h^{1/6} \quad \text{(Eqn 8)}$$

The results of our hydraulic study indicate that a experimental coefficient of 16 in Equation 8 is valid for a removal efficiency of 80% of the floatables in our experiments and a chamber length of 17m.

CONCLUSIONS

A critical horizontal velocity (V_{CR}, %, D) can develop in overflow chambers under certain hydraulic conditions. Floatables found in the flow when this critical velocity occurs will refrain it from reaching the surface. Therefore, this critical velocity greatly influences the configuration and design of the overflow chamber. Presently, this critical velocity is not taken into account in the design of underflow baffles. Although an inexpensive solution, this renders inefficient existing overflow chambers outfitted with underflow baffles. Two different approaches can be explored to correctly control floatables : stricter design rules should be provided in order to insure a better interception efficiency of floatables or investment in more sturdy and reliable equipment installed in the overflow chamber, like bar screens, for example.

WESTERLY DISTRICT INTERCEPTORS - INSPECTION AND EVALUATION PROJECT BENEFITS AND LESSONS LEARNED

Jeffrey E. Duke, P.E., NEORSD *
Graham Knott, C. Eng., Brown and Caldwell

***Northeast Ohio Regional Sewer District, 3826 Euclid Avenue, Cleveland, Ohio 44115-2504**

ABSTRACT

The Northeast Ohio Regional Sewer District (known hereafter as the District) owns, operates and maintains a large network of interceptor sewers and combined sewer overflow (CSO) sewers in the Cleveland metropolitan area. The District undertook the Westerly District Interceptors - Inspection and Evaluation Project to assess the condition of the interceptors and CSOs, the first in a series of large infrastructure assessment projects planned.

Several inspection and evaluation techniques were utilized. Many benefits and lessons were learned and rehabilitation recommendations were developed as a result of the project. During the period of October 1996 to September 1997, extensive inspection and evaluation was performed on over 200,000 lineal feet of sewers and appurtenances (manholes, regulators, hydrobrakes, etc.). Depending on the pipeline and flow characteristics, several inspection technologies including closed-circuit television (CCTV), manual walk-through, sonar and subsurface geophysical (Seismic Tomographic Imaging (STI)) were used. with varying degrees of success.

The Westerly project established several guidelines for future District condition assessment projects. Guidelines were established for manhole and pipeline defect classification and procedures for condition assessment were also developed.

INTRODUCTION

Project Description

The District owns, operates and maintains the large-diameter interceptor sewers and combined sewer outfall sewers serving the greater Cleveland metropolitan area. Some of these large conveyance sewers are more than 100 years old. The Westerly District Interceptors Inspection and Evaluation Project was undertaken to locate and assess the current condition of interceptors, combined sewer overflow (CSO) pipelines, and dry weather outlet (DWO) pipelines throughout the Westerly project area (shown in Figure 1). The project was a first step towards developing a comprehensive facilities plan for the Westerly District, which includes a detailed CSO facilities plan.

Inspection information was to be used to recommend and prioritize sewer rehabilitation projects that serve as a basis for a capital improvement program for the coming years. The scope of the project included:

- Documenting the structural and operational condition of the manholes and pipelines;
- Identifying and verifying interceptor and CSO flow routes;
- Locating and mapping all interceptor and CSO conduit manholes; and
- Identifying rehabilitation needs and estimated rehabilitation costs.

Work on the project consisted of five tasks:

- Assembly and review of background information;
- Inspection of manholes, interceptors and CSOs;
- Perform condition assessment based on inspection tapes, photographs, and field records;

- Development and implementation of a data management system; and
- Project administration - including project workshops and meetings.

Several different inspection techniques were utilized based on the pipe and flow characteristics. For pipes small than 66 inches, closed-circuit television inspection was performed. If flow levels permitted, walk-through inspections were performed on pipes greater than 66-inches high. Sonar inspection was performed on pipes with large amounts of known debris, or flow depths greater than half-full (50% of depth) and fully submerged pipes. Subsurface geophysical investigations (Seismic Tomographic Imaging (STI)) was utilized on the Westerly Interceptor near the site of a previous sewer collapse, and on a branch of the Walworth Interceptor under Interstate 90.

Description of Project Area

The Westerly Wastewater Treatment Center (WWTC) is located at 5800 West Memorial Shoreway in the City of Cleveland. It currently serves approximately 110,000 residents, primarily from the west side of Cleveland. An estimated sewered area of approximately 10,000 acres (15.6 Sq. Miles) is currently tributary to the WWTC and its general boundaries are the Cuyahoga River to the east, the Rocky River to the west, Lake Erie to the north and Big Creek generally forms the southern boundary of the tributary area. There are four main interceptor systems in the Westerly District – Low Level interceptor, Northwest Interceptor, Westerly Interceptor, and the Walworth Run Interceptor. Additionally, there are 26 CSO pipelines that carry wet weather flows to the local receiving streams and Lake Erie. Construction of the interceptors in the Westerly District was begun in the early part of the century with the construction of the main branch of the Walworth Interceptor and the Westerly Interceptor. The Low Level interceptor was constructed in the 1930's and the Northwest Interceptor added in the late 1970's.

Known problems in the interceptor system include:

- Considerable grit and sediment in the Low Level interceptor.
- Inspection concerns at the seven hydrobrakes (storage structures) in the Northwest Interceptor, and debris that is known to accumulate immediately upstream of the hydrobrakes.
- Collapse of the Westerly Interceptor from Desmond Avenue to West 65th Street in the vicinity of the Consolidated Railroad (Conrail) tracks in 1994. Soil subsidence is still noted along the repaired route of the Conrail collapse, between Lake Avenue/Desmond Avenue to West 65th Street
- Flows in the Westerly Interceptor are controlled to minimize CSOs, even if this normally results in surcharging the brick line.
- There were no known major structural and operational problems in the Walworth Interceptor.

Sewer Characteristics - Sizes and Lengths

The size of the sewers contained within the Westerly Interceptors ranges from 6-inches (dry weather outlets from combined sewer overflow regulators), to 108-inch by 240-inch box culverts at the downstream end of the Northwest Interceptor, at the entrance of the Westerly Wastewater Treatment Center. This very large range presented challenges to the inspection crews. Several different inspection contractors and inspection techniques were employed to ensure that complete information was gathered from all types of sewers. The distribution of sewer sizes in the Westerly District Interceptors is summarized in Table 1. A breakdown of sewer lengths in summarized in Table 2.

METHODOLOGY

Defect Identification Guidelines

Prior to commencement of the field inspections, the project team established inspection criteria and defect identification codes to ensure that the inspections would be conducted in a consistent manner and produce reliable data. Specific criteria were developed to identify structural and operational condition defects that might be found in manholes and sewer pipes. An important product of this project was the Manual of Sewer Defect Classification. This manual is now being utilized in a current District project and will be utilized in all future inspection and evaluation projects. It help ensure that subsequent District inspections are performed in a similar manner to the inspections performed on this project and that inspection defects are encoded correctly and consistently.

Internal Condition Assessment

A key part of a rehabilitation program is to translate the defect data into repair and rehabilitation needs. This process considers the severity of a defect or defects and assigns the sewer reach an "*internal condition grade.*" Internal condition grades were developed by assigning a score for a specific defect and summing those defect scores. The Westerly project utilized a condition assessment grading system with 5 grade levels. The five internal condition grades for the project are defined as shown in the Table 3.

Rehabilitation

Upon assignment of the structural and operational condition grade of the sewer, a rehabilitation level was developed for each segment of sewer. During the Westerly project, several possible levels of rehabilitation assignments were utilized. The levels of rehabilitation are:

- **Level 1** Continue monitoring periodically (required for all sewers - typically recommended every 5-10 years).

- **Level 2** Perform maintenance of the existing system. Examples include cleaning, local repairs, replacement of manhole covers, etc.
- **Level 3** Stabilize the existing system. Examples include repointing of the brickwork to prevent further deterioration or external grouting.
- **Level 4** Structural relining of the existing sewer. This option may be accompanied by the construction of other relief facilities if capacity problems are an issue.
- **Level 5** Replace or abandon the sewer. The structure is completely deteriorated or hydraulic capacity is an issue due to the condition of the sewer.
- **Level 6** Perform further investigations to gather the additional information needed to help define the rehabilitation needs (e.g. geotechnical/geophysical investigations to identify the presence of voids).
- **Level 7** Provide immediate attention (typically local repairs if the sewer has collapsed or failed).

All sewers were assigned a level of rehabilitation of at least Level 1. It is imperative to note that the main rehabilitation levels assigned to the sewers were typically 1 through 5. The rehabilitation levels of 6 and 7 were used as supplemental to the main ratings of 1-5 to either provide more information or to recommend immediate action. For example, a sewer could receive a rehabilitation level of 2-6, meaning maintenance should be performed and that further investigation is warranted to determined the extent of maintenance that needs to be performed.

Table 3 Condition Grades

Condition Grade	Structural Condition	Operational Condition
1	No defects, structural condition of the sewer is like new.	No defects, operational condition of the sewer is like new.
2	Minimal near-term risk of collapse but potential for further deterioration.	Minimal risk of failure - potential for further deterioration; minor impact on operation.
3	Collapse unlikely in the foreseeable future, further deterioration likely.	Failure unlikely in the near future, but moderate impact on operation of system.
4	Collapse of sewer likely in the foreseeable future	Failure likely in foreseeable future; major impact on operation.
5	Sewer is collapsed or collapse imminent in very near future	Operational failure (e.g. blockage) or failure imminent.

RESULTS

Benefits Realized

The Westerly project provided the first thorough inspection and evaluation of the District interceptors and CSOs in the project area. In many cases, this was the first time since construction that the sewers were inspected. Substantial amounts of location, inspection and condition data was gathered and produced throughout the project. Subsequently a thorough understanding of the condition of the system was gained and many benefits were realized during the project. These benefits can be divided into 3 main categories - operational benefits, structural benefits and system knowledge/data benefits.

Operational Benefits

- Identification of Buried Manholes - Throughout the project, inspection crews identified over 100 manholes (out of approximately 800 in the system) that could not be located. These manholes are either buried by debris, are paved over in the roadway, or have been removed at some time prior to District ownership. In several locations, a manhole is close by that allows for access for maintenance, ventilation, etc. However, there are locations where a significant number of sequential manholes are missing and are needed for cleaning, ventilation, access, etc. purposes. For the manholes that are needed, the District will issue a manhole rehabilitation contract to locate, inspect, raise manholes, and if needed perform rehabilitation. The sewer inspections identified the location of these missing manholes, making the subsequent location easier.

- Identification of Sewers Requiring Cleaning - Over 59,000 lineal feet of sewer throughout the project area was identified as requiring cleaning (for more details see Table 4). Over 20,000 lineal feet of sewer could not be inspected because of debris and sedimentation(causing impassable conditions for CCTV equipment and/or dangerous and impassable conditions for the manual walkthrough inspection crews). These sewers require "heavy" cleaning (heavy being defined as more than 1 or 2 passes with a Jet/Vac). As some of this cleaning is beyond the District's equipment and personnel capabilities, the District is preparing to issue a cleaning contract to remove the debris to allow subsequent inspection and evaluation.

- Hydrobrakes - The District operates and maintains several hydrobrakes (structures that store flow in the Northwest Interceptor). The hydrobrakes have accumulated large amounts of sediment behind them, in some cases up to 2 feet of debris - extending back 500 to 1500 feet. This translates amount to a significant volume of debris. A cleaning project will be performed in-house prior to issuance of a cleaning contract. The benefit of cleaning will be to increase the volume of storage during rain events.

- Miscellaneous Benefits - Many minor benefits resulted from the field inspections. In one location a weir was discovered where a 40' sewer segment has been repaired at some time in the past. The weir causes wastewater to pond behind wall and reduces conveyance capacity of the interceptor. Other benefits included the location of isolated blockages, videotapes and photographs of problem areas and others too numerous to mention.

Structural Benefits

- Early Action Projects - Two areas were identified throughout the project as in need of immediate attention. These areas are the Westerly Interceptor near the site of the previous collapse and the Walworth Interceptor underneath Interstate 90. Severe cracks and fractures were noticed in the sewers. In some cases inspectors were able to put a flat metal probe through the sewer wall into the soil behind. As a result, Seismic Tomographic Imaging and soil borings were performed at each of these locations to verify the presence of voids in the surrounding soil. As a result, the District initiated an emergency rehabilitation project (currently underway) that is providing structural relining and grouting in the sewers. The major benefit realized is the avoidance of any catastrophic collapse of these interceptors - the Westerly Interceptor parallels a high-speed railroad track and the Walworth Interceptor is a 10' diameter sewer that runs perpendicularly under an eight-lane highway (Interstate 90) with a depth of 6-10 feet to the crown.

- Recommended Rehabilitation Projects - As a result of the inspections, many locations are recommended for rehabilitation. The benefits realized will be longer life of the sewers, and decreased capital improvement/construction costs (as a result of paying for rehabilitation vs. paying for emergency repairs on collapsed sewers). For more information see the Rehabilitation Recommendation Section later in this report.

System Knowledge/Data Benefits

- Compatible Data Management System Initiated - With any project of this nature and size, enormous volumes of data will be collected. It is important to properly store that data in a manner that is readily and easily available for use. Also, with the nature of technology today, it is necessary for data to be compatible to multiple software uses. For the data collected on this project, multiple detailed Microsoft ACCESS databases were developed to store the manhole and sewer inspection data. This format was chosen because of its compatibility with any GIS platform (such as ARCInfo), infrastructure data management system (such as HANSEN) or data warehouse system (such as ORACLE) that may be used in the future by the District.

- Consistency in Defect Classification - The development of the Manual of Sewer Defect Classification ensures that current and subsequent District sewer inspection projects are performed in a similar manner and sewer defects are identified and encoded correctly and consistently. The consistency in classifying sewer defects would exist regardless or whether the inspections were performed in-house by District crews or by multiple sewer inspection contractors.

- System understanding/Connectivity/Inventory - Throughout the project area, there are many locations where flow direction and connectivity was very confusing. Past top-side reconnaissance and dye testing provided a better understanding of the system, but not a complete and thorough understanding. By performing detailed manhole and sewer inspections throughout the project area, a thorough complete understanding of system connectivity and inventory was gained. This information proves useful for the Westerly CSO Phase II Facilities Plan hydraulic modeling task and future maintenance and rehabilitation work.

- Data Availability - The data collected during the Westerly project has provided, and will continue to provide, useful information for other projects, both District and non-District. The Westerly CSO Phase II Facilities Plan Project is using location and inspection data to assist in the development of the hydraulic model of the system - which will be used to help analyze CSO control alternatives. The data collected will also prove useful when rehabilitation contracts are issued. The contractors will be able to use the inspection date to pinpoint spot repairs, identification of cleaning locations, assistance in manhole location and rehabilitation and so on.

DISCUSSION

Lessons Learned

This project was the largest infrastructure inspection and evaluation project to date for the District . While there were many benefits, many lessons were learned by the consultant team and the District. The lack of consistent basemap/historical information, data management system and institutional restrictions all led to various problems throughout the project. As a result, many steps have taken place to ensure that these problems do not reoccur. Some of the major lessons learned are as follows:

Importance of Data Management System - QA/QC of Data

With any project of this size where enormous volumes of data will be gathered/produced, it is vital to establish a detailed data management system or at least a detailed data management plan. This data management system should be developed prior to the commencement of the inspections. The major lesson learned on Westerly was that the lack of a data management system at the beginning of the project, coupled with a desire to commence field work as soon as possible, resulted in lots of data collected with "no place to go". Throughout the inspection process the data was stored in many ways: field logs, spreadsheet files, miscellaneous reports, etc., and the attempt was made to archive the data into a project database too late in the project schedule. This result was delays in project schedule, QA/QC problems and missing data.

- *The implementation of a good data management system was the most important lesson learned throughout the Westerly District Interceptors - Inspection and Evaluation project. This lesson is probably the most valuable lesson learned that was directly applied to the District's current interceptor inspection and evaluation project.*

Background Information

Lack of consistent maps led to problems early on the project. There were many sources of information regarding the facilities to be inspected. City of Cleveland general sewer maps, orthophoto maps with District interceptor sewers overlaid on top (without CSOs, regulators or any local sewers), and sets of construction plans (although incomplete) were used to assist in understanding the sewer system. However, the different sources of information were inconsistent (i.e. the construction plans did not match the sewer maps) and this led to many problems in determining the actual characteristics of the sewer system.

- *The lesson learned is that the development and assessment of all data available at the beginning of this type of project is vital to the success of the project.*

Manhole Identification System

Prior to the Westerly project, no consistent manhole numbering system has been established across the District service area. The District has had at least two different numbering systems used on past projects and several of the surrounding communities tributary to the District have implemented identification systems for their local sewer systems.

A new manhole numbering system was developed for this project for use throughout the District. The manhole numbering system is length - 15 characters long - and has identifiers for Interceptor Basin, Branch, Manhole Number, Community, Manhole Type and Sewer Type. However, the numbering system was not fully implemented at the beginning of the manhole and sewer inspections. A temporary numbering system was used to allow the contractors to begin their inspections. Problems arose with the use of the temporary numbering system in trying to rectify the temporary manhole numbers and inspection information with their permanent identification numbers in the data management system.

The new manhole numbering system provided a unique identification for each manhole. However, due to the length and complexity of the system, widespread implementation was difficult. The Westerly CSO Phase II hydraulic modelers did not use the numbering system because of the length (the numbering system was greater than 8 characters long). Other problems including the plotting of the numbers on digital sewer maps - the numbers can clutter a map to the point that the sewer cannot be properly identified.

- *The lesson learned from this is that it is important to have a usable manhole numbering system implemented prior to inspections.*

Manhole Inspections

The original intent of the project was to perform top-side inspections of manholes, supplemented by information provided by the pipeline inspection contractors when they entered the sewers to perform the sewer inspections. Complex manhole configuration, numerous manholes with significant depth (greater than 30') and lack of proper illumination led to gaps and incorrect information in the manhole database.

- *The lesson learned from performing the manhole inspections is that a thorough detailed structural inspection can not be achieved from top-side inspection only. There needs to be manual entry on some manholes in order to gain a full understanding of structural problems.*

Defect Identification Guidelines vs. Inspection Contractors Interpretations

Several contractors (2 CCTV, 2 walkthrough and 1 sonar) all worked on the pipe inspections during the Westerly project. The defect identification guidelines did ensure consistency of classification of inspection data. However, different presentation forms were submitted by the contractors, resulting in inconsistency of data submittal formats. While all submittals met the scope of work criteria, some contractors general standards of submittal (photos, inspection logs, even video tape labels) were preferred over the others. The reason for this is that clear requirements were not established at the beginning of the inspections.

- *The lesson learned is that one should establish "exact" or "precise" standards for data submittal, and not leave the format open for contractor's interpretation.*

Recommendations for Rehabilitation

The major deliverable of the Westerly District Interceptors - Inspection and Evaluation Project was the numerous rehabilitation recommendations that were developed. The recommendations were basically broken down into the following categories: sewer cleaning, repair of side sewer connections and stubouts, manhole rehabilitation and the repair of major sewer defects. The rehabilitation recommendations for each category were further broken down by interceptor/CSO basin.

Summaries of preliminary cost estimates for each rehabilitation recommendation category or included in the following tables.

Table 4 Recommended Sewer Cleaning and Sewers Not Inspected

Interceptor Basin	*Sewer Cleaning Length*	*Length Not Inspected*	*Reason(s)***
Low Level Interceptor	5823	716	Poor Access
Northwest Interceptor	27601	0	
Walworth Interceptor	7414	563	Blocked - Submerged
Westerly Interceptor	5857	2362	Poor Access
CSO's & DWO's	12524	17027	Multiple Reasons
Totals	*59219 Ft.*	*20637 Ft.*	

** *Costs not included due to differences/difficulty in estimate of debris volume.*

Table 5 Recommendations for Repair of Side Sewer Connections and Stubouts

Interceptor Basin	*No. of Connections*	*Cost of Rehab ($)*	*Urgency of Rehabilitation*
Low Level Interceptor	0	0	Rehabilitation should be completed prior to the allowance of regular surcharge (storage) in the sewer
Northwest Interceptor	0	0	
Walworth Interceptor	198	$157,000

Totals	*$3,848,955*	*$3,915,225*	*$1,651,652*	*$91,633*

CONCLUSIONS

The Westerly District Interceptors Inspection and Evaluation project provided used condition assessment data for the manholes, interceptor sewers and CSOs and DWOs in the project area. Over $9,000,000 of rehabilitation projects were recommended which, upon completion, will result in a more operationally efficient and structurally sound wastewater collection system. Many operational, structural and system knowledge benefits were gained as well as an education in large scale inspection and evaluation projects and their components, such as data management systems, condition assessment procedures and a thorough understanding of the collection system. *The most important product of the Westerly project may be the lessons learned and application of these lessons learned on subsequent projects.*

As previously stated, there were several tasks that were not performed according to plan on the Westerly project. However, many tasks did go well and these, along with the lessons learned, were applied to the District's current project - Easterly District Interceptors - Inspection and Evaluation Project. The Easterly project is 2 times the size of the Westerly project (Over 550,000 lineal feet of sewers to be inspected versus 225,000 lineal feet in Westerly).

Lessons learned on the Westerly Inspection and Evaluation project that were applied to the current inspection and evaluation project include:

- Full-scale Data Management System established prior to the initiation of the inspections.
- Utilization of one sewer map to provide baseline information (City of Cleveland General Sewer Map) supplement and verify this information with construction plans, community sewer maps and field inspections.
- Detailed standards established on all deliverables from inspection contractors and consultants.
- Establishing a sewer cleaning allowance in the inspection contract to perform some "light" cleaning on the sewers when necessary.
- Increased communication and coordination between the contractors, consultants and other projects working simultaneously in the project area.
- Manhole numbering and preliminary location (on maps) performed prior to field inspections beginning.

ABSTRACT

Due to increased awareness of the extent of pollution in stormwater runoff, we now recognize the need to manage adverse water quality impacts of stormwater runoff from developing and developed urban areas. Growing numbers of cities and counties are preparing and implementing comprehensive stormwater management programs to prevent and control adverse water quality impacts from stormwater discharges. Establishing a separate department or a separate utility with its own enterprise fund is a viable approach to financing and managing stormwater issues in a sustainable and equitable manner that provides a dedicated, stable, and predictable source of revenues for stormwater controls and best management practices. Stormwater utility revenues fund stormwater management services such as capital improvements, operation and maintenance, and program administration. This paper provides an overview of key components and issues—legal, financial, institutional, and political—in setting up a stormwater utility.

KEY WORDS

Stormwater Utility, Stormwater Management, Finance

INTRODUCTION

Stormwater management in the United States is largely the responsibility of local governments. In the past, communities traditionally financed stormwater improvements from the general fund through property tax revenues and developed their stormwater programs primarily for drainage management or flood control. Increased awareness of the extent of pollution in stormwater runoff is leading local governments to develop more comprehensive stormwater programs—designed to manage both water quantity and water quality impacts of stormwater runoff. Managing the water quality impacts of runoff is an important concern in part because of EPA's stormwater regulations, which require prevention and control of adverse water quality impacts from stormwater discharges. Local governments subject to the stormwater regulations and other communities seeking ways to address local stormwater problems need effective and feasible financing options.

Addressing local stormwater management problems will be costly for many communities, particularly where retrofitting of existing stormwater infrastructure is necessary to manage the water quality impacts of runoff. This paper provides a broad assessment of the need for funding and an overview of stormwater utilities as an effective and feasible option for raising the necessary funds.

FUNDING NEEDS

Estimation of funding needs for stormwater management programs to control the quality of stormwater runoff depends on many different factors. These factors include the characteristics of runoff quantity and quality, the size of the watersheds where projects are being planned, the extent of existing development, the severity of water quality problems, the water quality objectives, and the types of structural controls or best management practices (BMPs) that are being proposed. Recognizing the variability among places, most experts agree that stormwater management programs will be expensive, ranging from tens of thousands of dollars in relatively small places to achieve modest objectives to tens or hundreds of millions of dollars in larger cities with moderate to severe problems.

Several brief examples of the potential magnitude of the costs of stormwater management programs are provided below. These examples are by no means exhaustive and they are not necessarily representative. Nevertheless, they are published estimates of national costs or local examples (for an urban watershed and large city) to demonstrate that experts believe costs will be significant and controversial. Additionally, these examples should demonstrate that a critical task in implementation of effective stormwater management programs is identifying adequate funding sources.

In a recent study for the American Public Works Association (APWA, 1992), James M. Montgomery estimated the capital and operation and maintenance (O&M) costs for large and medium cities to comply with EPA's Phase I stormwater regulations. Capital estimates ranged from $147 million to more than $400 billion, depending on the assumptions about the level of treatment for runoff. Estimates of O&M costs ranged from $1.2 billion to more than half a trillion dollars, again depending on assumptions about level of treatment. Reasonable questions can be raised about the APWA estimates. Some experts suggest that they are too high because advanced treatment has not been contemplated for stormwater runoff. Other critics contend that these estimates were made primarily for political purposes to support opponents of EPA's stormwater regulations who argued that the costs were prohibitive. Regardless, they demonstrate clearly the potential magnitude of funding needs and show that the costs of stormwater management programs will be controversial.

More recently, as part of the 1996 Clean Water Needs Survey (EPA, 1996), EPA modeled the Phase I stormwater needs to inform Congress of the costs of local Phase I stormwater management programs to control pollutants in urban runoff. Approximately 266 Phase I stormwater program permits will be issued covering about 850 municipalities or counties. The modeled Phase I stormwater needs were prepared to estimate the public stormwater management costs that might be eligible under state revolving fund (SRF) loan programs. The SRF-eligible costs include costs for developing and implementing municipal stormwater management programs, including capital costs for structural controls and BMPs. The total modeled Phase I stormwater needs are $7.4 billion. These costs do not include O&M costs, land acquisition costs, permitting costs, costs of developer-financed BMPs, and several other categories of costs that are not SRF-eligible. These CWNS modeled estimates of Phase I stormwater needs, which were subject to peer review prior to their release, are also significant.

In general, better cost estimates can be made for smaller geographic areas because it is possible to take site-specific factors into consideration and make fewer general assumptions. The Wisconsin Department of Natural Resources (WDNR, 1992) has estimated the costs to achieve pollutant reduction objectives for the Menomonee River watershed in Milwaukee, Wisconsin. The Menomonee River watershed is 136 square miles, is 60 percent urban, and contains 18 municipalities and parts of four counties. To meet ambient water quality standards, programs are needed to reduce sediment by 50 percent, phosphorus by 50 to 70 percent, and lead by 35 to 70 percent. The corresponding cost estimates for "segment" controls for existing areas of development range from $94 million to $184 million.

Finally, in Indianapolis, Indiana, a Mayor's blue ribbon panel estimated the costs to rehabilitate stormwater infrastructure at $283 million. The infrastructure includes 1,750 miles of storm sewers, more than 1,000 outfalls, more than 50 miles of levees, and a number of regional detention ponds. The panel's estimate represents a significant cost simply to meet generally accepted engineering standards for stormwater conveyance and flood control. The panel did not estimate costs for programs to manage pollutants in runoff, such as implementation of BMPs to meet water quality objectives..

THE STORMWATER UTILITY APPROACH

Financing stormwater management through a public utility approach is an innovative alternative to the traditional financing of local stormwater programs by property tax revenues. Public resistance to property tax increases has limited the ability of local governments to raise additional funds for stormwater management or other environmental programs through the property tax. After several communities successfully implemented a utility approach to finance stormwater management in the 1970s—most notably, Bellevue, Washington, and Boulder, Colorado—stormwater utilities became a viable financing mechanism for other communities. Currently, several hundred communities across the country have instituted stormwater utilities.

A stormwater utility is a public utility established to provide stormwater management services. Stormwater utilities, like other utilities, rely on dedicated user charges related to the level of service provided. These user charges are usually based on the amount of impervious area (paved surfaces and structures) on a property (i.e., a proxy for the estimated amount of runoff discharged from a property) and are typically paid by property owners. Impervious area is generally defined as surfaces that either prevent or retard infiltration of stormwater into the ground. Dedicated means that the revenues are placed and managed in a separate enterprise fund, which can only be used to finance stormwater management.

Most stormwater utilities are administered under public works departments or local departments of utilities that also provide wastewater or water services. Stormwater utilities have been established for both large and small service areas, with populations ranging from several thousand to over 500,000 persons and ranging in size from several to over 500 square miles. While most utilities serve a single jurisdiction, several serve multiple jurisdictions and a few serve the unincorporated areas of a county.

Experience with stormwater utilities has shown that they are capable of generating substantial revenues and providing financial self-sufficiency for local stormwater management programs at relatively nominal charges. Typical monthly charges for residential users range from $2 to around $6 per month. Nonresidential property owners typically pay more because their property is generally larger and developed more intensively.

The stormwater utility concept offers several advantages over the traditional financing by property tax revenues. Stormwater utilities provide a more secure revenue source for local stormwater management than property taxes. Because property tax revenues usually go into the general fund to finance a wide variety of local services, many programs compete for funding from such revenues. Without a dedicated revenue source, stormwater programs often do not gain priority in the local budget process and thus lack adequate funding. In addition, stormwater utilities allow a closer relationship between the charges and services provided than property taxes.

Stormwater utilities offer three major advantages over financing local stormwater programs from the general fund through property tax revenues. These three major advantages are that a stormwater utility:

1) Provides a dedicated, stable, and predictable source of funds for all facets of local stormwater management programs (capital improvements, operation and maintenance, and program administration);

2) Raises funds through charges based on a user's contribution to local stormwater runoff problems so a utility approach is often seen as more equitable to rate payers or the public; and

3) Provides an institutional mechanism to incorporate incentives (e.g., reduced charges) for implementation of on-site stormwater management.

KEY COMPONENTS AND ISSUES IN SETTING UP A STORMWATER UTILITY

To develop and implement a stormwater utility, each community must address a variety of legal, financial, institutional, and political issues. Key components and issues—legal, financial, institutional, and political—in setting up a stormwater utility (USEPA, 1994b) are summarized below.

Legal components

A combination of state enabling legislation and local ordinances is generally required to establish a stormwater utility, although the exact legal requirements vary according to the laws and precedents in each state. The major legal components in setting up a stormwater utility are enacting state enabling legislation, adopting a local stormwater utility ordinance, and avoiding legal challenges.

Enacting state enabling legislation

State enabling legislation must authorize the formation of local stormwater utilities. Many states already have such legislation either in general form, authorizing local governments to form public utilities, or specifically authorizing stormwater utilities.

Adopting a stormwater utility ordinance

Stormwater utilities are typically created by the adoption of a local ordinance. To assure flexibility in reviewing and adjusting stormwater program goals as well as rates charged by a utility, communities often adopt two ordinances. The first ordinance establishes the community's operational authority and stormwater management program and the second ordinance establishes the stormwater utility and its rate structure. An advantage of this approach is that when rates require adjustment, the ordinance authorizing the local stormwater program remains intact.

Avoiding legal challenges

To anticipate and avoid legal challenges, utility planners need an in-depth understanding of legal issues associated with stormwater utilities. Several stormwater utilities across the country have been challenged legally. Most legal challenges are related to the legality of imposing utility charges or the specifics of the rate structure. Legal challenges are often based on the grounds that a utility service charge is really a tax or that previously tax-exempt entities, such as churches or hospitals, also should be exempt from stormwater utility charges. To avoid legal challenges, it is important to distinguish the utility charge from the property tax by clearly establishing a direct relationship between the utility charge and stormwater management services provided by a utility.

Financial components

The ability of the utility approach to provide a dedicated, stable, and predictable source of revenue to finance local stormwater management services is a primary advantage of establishing a utility. When designed properly, a stormwater utility rate structure allocates costs among users according to services received. The major financial components in setting up a stormwater utility are:

- Estimating revenue requirements,
- Determining the rate base, and
- Developing the rate structure.

Estimating revenue requirements

Many stormwater utilities rely almost entirely on revenues from utility charges. To develop a rate structure that raises sufficient revenues to cover the full costs of a local stormwater program, utility planners must estimate the total costs of desired stormwater management services. Often, financial, economic, and engineering analyses are necessary to determine revenue requirements for the capital costs of constructing needed stormwater management facilities. Cost estimation also involves long-range planning for construction of needed stormwater management facilities.

Determining the rate base

In determining the rate base, utility planners must decide who will pay the utility charges and whether to allow any exemptions. Ratepayers are typically property owners that contribute stormwater runoff. Thus, many utilities include in their rate base only developed property, which usually contains impervious area. Although publicly owned or nonprofit properties are normally exempt from the property tax, stormwater utilities often include such properties in their rate base. This practice has withstood legal challenge—most notably in

Louisville and Jefferson County, Kentucky—where the court determined that utility charges were a fee, not a tax.

Developing the rate structure

Developing an appropriate rate structure is critical to establishing an effective stormwater utility. When designed properly, the rate structure allocates costs among users according to services received. The three basic elements of developing a stormwater utility rate structure are:

- Determining the basis for charges,
- Determining the billing unit, and
- Setting the rate.

Stormwater utility charges are usually based on an estimate of the amount of stormwater runoff contributed by a property. This contribution may be estimated, for example, by total impervious area on a parcel or a ratio of impervious area to total property area. The rate structure can also be tied to the intensity of development (e.g., as reflected by land use categories such as residential, commercial, or industrial).

Using impervious area as the basis for charges allows a utility to develop a uniform billing unit based on the amount of impervious area for the typical residential property and use that unit to calculate charges for other types of property. A common billing unit is the use of equivalent residential or runoff units (ERUs). An ERU represents the average impervious area associated with residential parcels (e.g., single family homes) in the utility service area. A utility develops an ERU by estimating the total impervious area of residential parcels and dividing this amount by the total number of residential parcels. These calculations usually are based on a statistical sample of residential parcels in the service area.

With the ERU approach, the billing unit represents an estimate of the impervious area associated with the average residential property. For example, an ERU may represent 2,500 square feet. The billing unit for all residential properties is one ERU. For parcels in other land use categories (e.g., commercial, industrial), the runoff potential is based on the number of ERUs associated with the impervious area of each parcel. The amount of impervious area on a nonresidential property is divided by the ERU square footage to calculate the number of billing units (ERUs) for each nonresidential parcel in the rate base.

Utilities that use ERUs as the billing unit generally set the rate per ERU. If a utility charges a monthly rate of $3.00 per ERU, for example, then all owners of residential properties, which represent one ERU, would pay a $3.00 monthly utility charge. Utilities using ERUs generally calculate stormwater utility charges for nonresidential property owners individually by calculating the number of ERUs associated with their nonresidential parcel and multiplying by the rate. A typical billing algorithm for nonresidential properties is: (total impervious area/ERU square footage) x (rate per ERU). Using this billing algorithm, for example, the monthly utility charge for a nonresidential property with an impervious area of 10,000 square feet would be $12.00, where the ERU represents 2,500 square feet.

Although the most common type of stormwater utility charge is based on the amount, or square footage, of impervious area on a parcel, other indicators or proxies for the actual volume of stormwater runoff from a property are used by some utilities. Other bases for stormwater utility charges include the area and proportion of impervious cover on a parcel, the intensity of development, and the type of land use. Recently, a few utilities have experimented with actual estimates of the volume of runoff or some estimate of the concentration of pollutants in runoff as the basis for charges. Examples of more complex stormwater utility rate structures are presented in the case studies below.

Experience with stormwater utilities shows that they are capable of providing financial self-sufficiency for local stormwater management programs at relatively nominal charges. Single family residential charges for most stormwater utilities currently range from $2.00 to around $6.00 per month. Some stormwater utilities establish initial rates at lower levels and schedule rate increases as the utility provides an increased level of stormwater management services. Communities may budget for contributions from the general fund to the utility over a certain time period to allow for a gradual transition to a fully established utility.

Institutional components

Institutional issues are also important to successful creation and implementation of a stormwater utility. Selected institutional issues discussed below are the appropriate administrative structure for local stormwater management, the role of public education and involvement, and credits as economic incentives for on-site stormwater management.

Determining an administrative structure for stormwater management

Most stormwater utilities are administered under public works departments or local departments of utilities that also provide wastewater or water services. To determine the most appropriate administrative structure for providing stormwater management services, each community must examine its stormwater management goals and specific functions (e.g., administration, planning, design and engineering, construction, operation and maintenance, regulation and enforcement, and billing and collection of utility charges) performed to provide those services.

Implementing public education and involvement programs

Public support is critical to establishing a successful stormwater utility because such support ensures that a utility will have adequate financial resources to perform stormwater management activities. Education and involvement programs for local elected officials and the general public help develop a clear understanding of the need for and expected benefits from a utility's activities.

Credits as economic incentives for on-site stormwater management

Stormwater utilities provide an institutional mechanism to incorporate incentives for implementation of on-site stormwater management through credits or reduced user charges. Providing such incentives creates greater flexibility by allowing each user to chose the least-cost option—paying the stormwater utility charge or implementing on-site stormwater management. A recent paper (Doll, Scodari, and Lindsey, 1998) provides examples of stormwater utilities with credits for on-site stormwater management, including credits for peak runoff controls, implementation of water quality BMPs, and proper maintenance of on-site stormwater facilities. Also discussed are issues associated with establishing credits as economic incentives to encourage prevention or reduction of stormwater runoff problems. As economic incentives, credits must be sufficient to induce changes in behavior; however, their impact on total utility revenues must be examined carefully.

Political components

Finally, political support is important to establishing a utility rate structure. The nature of local government is that key players in utility design and implementation are seldom the key players in local politics. In designing a utility rate structure, utility planners can attempt to minimize controversy by gaining the support of local elected officials.

As an example, in the City of Indianapolis, Indiana, considerable controversy arose over a proposed stormwater utility. A credit system was proposed to help overcome general opposition to new charges or taxes. Through a credit system, utility planners and local elected officials attempted to make the proposed stormwater utility charges more equitable and acceptable politically. The credit system in the final draft ordinance (Proposal No. 657, 1997) was a relatively complex approach to provide a reduction in stormwater user fees for nonresidential properties based on certain conditions. The draft ordinance outlined a two-tiered credit based on watershed area as well as the size of the on-site detention/retention basin. Efforts to establish a credit system for on-site detention/retention addressed concerns of nonresidential property owners and generally increased the perceived fairness of the proposed rate structure. It is now clear that inclusion of a credit system was not sufficient to ensure adoption of the stormwater utility and overcome other objections.

Despite significant efforts to gain political acceptance, the utility proposal was withdrawn pending completion of more detailed planning studies.

CASE STUDIES OF SELECTED STORMWATER UTILITIES

This section presents case studies of selected stormwater utilities. The selected utilities are Austin, Texas; Bellevue, Washington, and Boulder, Colorado (USEPA, 1994a).

Austin, Texas

In September 1982, the Austin City Council approved the first drainage fee charged on Austin utility bills. Revenues from the drainage fee were initially used to supplement general funds used for drainage-related activities. Historically, the drainage fee provided support for drainage-related activities of several city agencies, including the Department of Public Works and Transportation, Environmental and Conservation Services Department, and the Parks and Recreation Department. In September 1989, the City Council dedicated all drainage fee revenues to drainage-related activities. In September 1990, the City Council created the Drainage Fund as a dedicated account for managing the receipt and expenditure of drainage fee revenues. City Council action in September 1991 increased Austin's drainage fees from $1.30 per month for residential property and $14.04 per acre per month for commercial and industrial property to $3.32 per month and $35.83 per acre per month, respectively. These increases were approved to begin developing and implementing solutions to the water quality problems of Austin's urban watersheds and Town Lake.

When the Drainage Utility (DU) was established in November 1991, drainage fee revenues were fully dedicated to the Drainage Utility Fund. The drainage fee is assessed to all electric, water, or wastewater customers (except for properties owned by the state, county, and school districts) within the incorporated area of the city. In 1993, the drainage fee was $3.82 per household per month for residential customers and $41.23 per acre per month for commercial and industrial customers. The utility generated approximately $5.4 million in annual revenue from commercial and industrial customers, and $9.0 million in annual revenue from households, for total annual revenues of $14.4 million in 1993.

Most of the city's stormwater programs are funded by DU. Additional financing for some aspects of stormwater management comes from other sources, including annual storm sewer discharge permit fees, development fees, and federal grant funding for selected projects (e.g., development of innovative control structures for retrofitting high density urban core areas). Review of drainage or flood control plans by the Planning and Development Department is not funded by DU.

The urban retrofit program established by Austin's Urban Watersheds Ordinance has an estimated capital cost of $250 million over a 25-year period. Because this represented a substantial increase in capital expenditures, DU planned to issue revenue bonds to finance the construction and acquisition costs for drainage improvements under the urban retrofit program. The bonds would be repaid by drainage fee revenues.

Bellevue, Washington

When first established in 1974, the City of Bellevue's Storm and Surface Water Utility (SSWU) focused on examining various solutions to control flooding and preserve waterways. The utility selected an "open stream concept" using streams as the main conveyance system for stormwater runoff. This system uses regional, in-stream flood control facilities to attenuate peak flows for older development. The utility also manages the municipal storm drainage system. In addition, regulations require developers to provide erosion and sedimentation controls at all construction sites and on-site stormwater controls for new development. With successful flood control systems in place, the focus shifted to water quality controls including requirements mandated by the federal Clean Water Act. For the most part, SSWU's comprehensive effort to solve stormwater quality problems is preventive in nature, but the utility also recognizes the need for retrofitting and new capital improvements for treatment.

The City of Bellevue decided that the most equitable system of drainage service charges would be to base them on the estimated amount of runoff individual properties contribute to the surface water system. All properties are classified according to their intensity of development. Each classification is assigned a rate (per 2,000 square feet of property area), with rates in 1993 as follows: undeveloped ($0.17), light development ($0.99), moderate development ($1.23), heavy development ($1.83), and very heavy development ($2.46). Wetlands are also a class, however, wetlands are not charged due to their value in water quantity and quality control. The classification combined with the total square footage of the property determines the service charge, which is billed every two months.

Revenues grew slowly until rates were raised to fund the adopted Capital Improvement Program, which was initiated by issuance of $10 million of revenue bonds. Three major rate increases occurred in 1980 (70 percent), 1982 (90 percent), and 1986 (35 percent), and subsequent rate increases have remained in the single-digit category largely to cover inflation. Although the majority of SSWU revenue is from service charges, other revenue sources include clearing and grading permit fees, general facilities charges, and interest on fund accounts. Revenues from the utility service charges and these other sources cover the full costs of Bellevue's storm and surface water management program.

Single family customers made up 92 percent of the 24,000 accounts and contributed 45 percent of the revenue in 1993. An average single family household paid $16.44 every two months ($98 per year) for 10,000-12,000 square feet of property with a typical home. Tax-exempt properties are not exempt from the utility charges (Washington State highways and Bellevue streets are SSWU's two biggest ratepayers).

Boulder, Colorado

The Boulder Storm Water and Flood Management Utility was created in 1973 by Boulder City Ordinance No. 4749, which is codified in Title 11, Chapter 5 of Boulder's City Code. It serves an area of approximately 40 square miles and was created in the Utilities Division of the city's Department of Public Works and is under the control of the City Manager. Boulder's utility has no governing structure or officers, although it does receive input and guidance from the Utilities Advisory Board. The utility primarily serves as a mechanism to manage dedicated revenues from stormwater and flood management fees within the Utilities Division of the Department of Public Works. During the late 1980s, Boulder developed a "Comprehensive Drainage Utility Master Plan" (CDUMP) to address flooding and stormwater issues. In 1989, Boulder's Storm Water Quality Program was developed as a component of CDUMP to address water quality issues related to stormwater runoff.

Activities conducted by Boulder's Storm Water and Flood Management Utility are financed by user fees. All owners of developed property in the city must pay a monthly stormwater and flood management fee, which is determined according to the anticipated use of drainage facilities. Undeveloped parcels are exempt from the fee. The fee is calculated according to the following formulas:

> Fee = $4.40 x (parcel runoff coefficient/0.43) x (property area/7,000 square feet)
>
> Parcel runoff coefficient = ((0.9 x impervious square footage) + (0.2 x pervious square footage))/total square footage

The average residential charge is $4.40 per month (for < 15,000 square feet). It can range up to $5.40 (for 15 to 30,000 square feet) or $6.60 (for > 30,000 square feet). The stormwater and flood management fee is collected on the city's water and wastewater utility bills.

Annual revenues for 1993 from the stormwater and flood management fees were $2.5 million. The Storm Water and Flood Management Utility holds all fee revenues in a dedicated account and may make expenditures only for the following purposes: 1) development review, administration, stormwater quality, inspection, construction, installation, repair, maintenance, improvement, replacement, and reconstruction of drainage facilities in the city, and all other facilities necessary to handle stormwater runoff and floods in the city; purchase of land or easements that may be required to implement stormwater and flood management in the city; and repayment of any revenue bonds issued by the city to finance any of the above activities.

Boulder has issued a revenue bond, backed by the stormwater and flood management fees, to finance some of the utility's capital improvement projects. The utility spends about $1.3 million annually on capital improvement projects.

In addition to the stormwater and flood management fee, the Boulder utility charges a developer fee for the development of previously undeveloped property, annexation of developed property, and changes or additions to developed property. This developer fee is based on the square footage of the extended service area, or the utility may also allow a developer to build their own approved system extensions. Revenues from developer fees are used solely for the purpose of capital improvements, reconstructions, or expansions. Annual revenues for 1993 from these developer fees were $75,000.

CONCLUSION

Stormwater utilities are now well established as an effective and feasible financing option for raising the necessary funds for local stormwater management programs. Clearly, there is a large funding need for stormwater management programs to prevent and control the adverse water quality impacts of stormwater runoff in our nation's urban and urbanizing areas. Most of the key components and issues—legal, financial, institutional, and political—in setting up a stormwater utility are manageable. The critical component at the local level in setting up a stormwater utility is often political, where local elected officials and the public must make difficult choices among many needed local services. Once established, however, a stormwater utility provides a dedicated revenue source for stormwater management and is often seen as more equitable to rate payers or the public because charges are based on each user's contribution to local stormwater runoff problems. Stormwater utilities can generate substantial revenues and provide financial self-sufficiency for local stormwater management programs at relatively nominal charges.

ABSTRACT

Impairments to beneficial uses such as recreation, sediment dwelling organisms, and fish and wildlife habitats have been, in part, caused by discharges from sewage treatment plants (STPs), combined sewer overflows (CSOs) and stormwater. Municipalities in areas identified by the International Joint Commission as Areas of Concern (AOCs) are addressing these problems by conducting Pollution Prevention and Control Plans (PPCPs) and carrying out the recommended implementation strategy. Environment Canada's Great Lakes 2000 Cleanup Fund and the Ontario Ministry of the Environment have provided funding and technical assistance to conduct these PPCPs. Joint federal/provincial/municipal projects are also underway to develop and demonstrate lower cost technologies as alternatives to conventional options that are typically recommended in the PPCPs.

This paper highlights the findings of PPCPs conducted in the various AOCs and their status of implementation. In addition, demonstration projects related to low-cost innovative technologies aimed at reducing the costs of implementing the PPCPs are described.

KEYWORDS: pollution control planning, pollution prevention, stormwater management, CSOs, Great Lakes, Areas of Concern

INTRODUCTION

During the later part of the 1980s, Pollution Control Plans (PCPs) were carried out by many Ontario municipalities under Ontario's Beaches Improvement Program to develop cost-effective solutions for controlling the impacts of point sources (from STPs and industries), and non-point sources (CSOs and stormwater). The planning process followed is a means of integrating technical concerns and public input to arrive at cost-effective solutions that satisfy social, environmental and economic goals. Since 1990, greater emphasis has been placed on prevention aspects in addition to control, with a change in the name of the studies to Pollution Prevention and Control Plans (PPCPs). The names are used interchangeably in this paper.

The steps generally used in a PPCP are :

1. Assess loadings and relative receiving water quality impacts of the municipal effluents.
2. Evaluate the most appropriate pollution prevention and abatement measures for the STPs CSOs and stormwater discharges.
3. Conduct the study in conformity with the Class Environmental Assessment for Municipal Water and Wastewater Projects under the provincial Environmental Assessment Act.
4. Develop the Pollution Prevention and Control Plan to optimize environmental objectives and costs.

POLLUTION PREVENTION AND CONTROL PLANNING IN AOCs

As shown in Table 1, PPCPs have been completed in four AOCs while three are underway. The PPCPs for Belleville, Trenton and Severn Sound municipalities deal with stormwater only since there are no CSOs in these municipalities. STP effluents are of concern for Sarnia, Cornwall, Thunder Bay and Windsor, since these municipalities provide only a primary treatment level for their sewage. Pollution

Control Plans have been completed prior to the availability of federal funding for a few other municipalities with CSO problems in AOCs, , i.e. Hamilton-Wentworth in the Hamilton Harbour AOC, and Toronto area municipalities in the Toronto Waterfront AOC.

TABLE 1: POLLUTION PREVENTION AND CONTROL PLANS IN AOCs

Municipality/Area of Concern	**Municipal Effluents addressed in PCP**	**Status**
Sarnia/St. Clair River	CSO, SW, STP	Completed 1993
Cornwall/St. Lawrence River	CSO, SW, STP	Completed 1995
Thunder Bay/Lake Superior	CSO, SW, STP	Completed 1996
Windsor/Detroit River	CSO, SW, STP	Underway
Belleville/Bay of Quinte	SW	Completed 1996
Trenton/Bay of Quinte	SW	Underway
Severn Sound municipalities	SW	Underway

Beneficial use impairment attributed to municipal effluents include:

- degradation of benthos due to accumulation of heavy metals and organic chemicals in bottom sediments
- degradation of aesthetics caused by algae and floatables
- negative impact to fish and wildlife habitat (e.g. fish advisories, and poor aquatic habitat)
- limitations on recreational use of the receiving waters (e.g. beach postings)

City Of Sarnia Pollution Control Plan - St. Clair River AOC

The City of Sarnia (population: 74,200) is located at the southern edge of Lake Huron, on the shore of the St. Clair River. The city lies on the border between Ontario and the State of Michigan in the U.S.

Beneficial use impairments attributed to municipal effluents include degradation of benthos, limitations on recreational use and negative impact on fish and wildlife habitat. Restrictions on consumption of fish and wildlife exist because of high levels of mercury and polychlorinated biphenyls (PCBs) in the fish and wildlife.

As shown in Table 2, the STP contributes the greatest amount of suspended solids (SS), biological oxygen demand (BOD), phosphorus (P) and bacteria to the St. Clair River. For the local Sarnia waterfront, CSOs are the main source of bacterial pollution to the waterfront during wet weather. During wet weather, stormwater runoff is the main source of SS to the St. Clair R. The amount of P in stormwater is similar to that from the STP under wet weather conditions.

TABLE 2 : POLLUTANT LOADINGS - CITY OF SARNIA

	TSS	TP	BOD	Bacteria, (bMPN/1000 mL)
STP (dry weather)	263,300	6,800	526,600	54×10^6
STP (wet weather)	66,060	1,700	132,100	12×10^6
SW	258,300	1,200	23,280	1×10^6
CSO	33,370	625	9,900	2×10^6

Note: Loadings represent period from April 1 to October 31. Units: kg/rainfall season

The PCP recommended (1) upgrading of the primary STP to secondary treatment standard and year-round disinfection, (2) provision of more settling capacity (for the interim period till the secondary STP is built) to fully treat all flows and hence, eliminate bypassing of flows, (3) construction of 4 CSO tanks to achieve a 90% level of volumetric runoff control), (4) collection of stormwater flows into an interceptor pipe and conveyance to a stormwater pond.

The total cost of implementing the recommendations from the PCP was estimated at $48.5 million (1993$) STP upgrade cost - $29.2 million, 4 CSO storage tanks - $12.7 million)

Implementation of the recommendations is underway. In 1996, the City of Sarnia constructed one CSO storage tank at a cost of $4.73 million (funded under the joint Canada-Ontario Municipal Infrastructure Program). This tank was designed to handle the volume requirements of two-originally proposed tanks, realizing a cost saving of several hundred thousand dollars. The pre-design of the secondary STP has been completed. Detailed design and construction is expected pending the availability of sufficient funding resources.

Cornwall Pollution Control Plan - St. Lawrence AOC

The City of Cornwall,(population: approximately 47,000) is situated on the banks of the St. Lawrence River. The beneficial use impairment of the St. Lawrence AOC associated with municipal effluents as well as other point and non-point source discharges include impact to fish and wildlife (consumption restrictions, population degradation, deformities, tumours and habitat losses); beach closings, degradation of benthic communities and drinking water restrictions.

As shown in Table 3, the STP is the main source of pollutants during dry and wet weather. During wet weather, the TSS loadings from CSOs and stormwater are of the same order of magnitude as that from the STP.

TABLE 3 : POLLUTANT LOADINGS FROM CITY OF CORNWALL

	TSS	TP	BOD	Bacteria org/hr - fecal coliform)
STP (dry weather)	169,270	3,070	482,130	5.2×10^9
STP (wet weather)	66,770	2,225	69,550	5.1×10^5
SW	45,880	237	6,080	2.2×10^4
CSO	51,710	286	4,270	3.9×10^5

Note: Loadings represent period from April 1 to October 31. Units: kg/rainfall season

From the PCP, stormwater impacts would be more pronounced in the tributary drains that receive the stormwater rather than the St. Lawrence River itself. For example, one of these drains (the South Branch of the Raisin River) has a low baseflow. Hence, the additional stormwater with its relatively higher concentration of contaminants (in particular, total phosphorus, iron, zinc, mercury and fecal coliform) was likely contributing to reported impairment in water quality.

The PCP recommendations were prioritized as follows: implement CSO control measures followed by stormwater measures and then finally, upgrade the STP to secondary treatment. This prioritization reflected the need to first eliminate uncontrolled discharge of untreated sanitary wastes to the St. Lawrence River from the existing CSOs, thereby improving the quality of the nearshore waters. The stormwater measures would improve the water quality and aquatic habitats particularly in the tributary drains (South Raisin River and Grays Creek). Finally, the STP upgrade would further improve the water quality of the St. Lawrence River.

Recommendations for CSO control included (1) provision of a 17,500 m^3 underground storage tank and consideration of first flush storage and satellite high rate treatment to reduce the cost of storage, (2) continuation of ongoing program of on-lot flow reduction especially in subcatchments with high wet weather infiltration/inflow (I/I), (3) continuation of real time control with the Brookdale gate, (4) continuation of the City's water conservation strategy and (5) completion of sewer separation projects planned for selected subcatchments.

Recommendations for SW abatement included (1) continuation of existing stormwater best management practices (e.g. street sweeping and catchbasin cleaning, (2) enhancement of vegetation and flow distribution in the Fly Creek stormwater pond to improve its water quality function, (3) completion of a detailed feasibility study for stormwater quality control wet ponds in existing developed areas, (4) adoption of a comprehensive Stormwater Quality Discharge Control program for new development areas, (5) implementation of stormwater ponds wherever feasible for existing developed areas.

Recommendations for improving sewage treatment included (1) conduct a pilot testing program of secondary treatment options, (2) develop a detailed facility plan to refine capital cost estimates of secondary treatment options.

The total cost of implementing the recommendations from the Cornwall PCP was estimated at $44.3 million (1993$) (CSO storage tank - $11.0 million, STP upgrade - $31 million). Since the PCP was completed, an environmental study report identifying options for upgrading the Fly Creek Stormwater pond for quality control has been undertaken.

Thunder Bay Pollution Prevention and Control Plan - Thunder Bay AOC

The City of Thunder Bay (population: approximately 114,000) is situated on the west shore of Lake Superior. There are seven water courses in the study area. All of these and Lake Superior are considered important fisheries habitat or pathways to spawning grounds. Table 4 presents the pollutant loadings from the city's sewers. The results of the receiving water impact study of the PCP that CSOs and stormwater discharges were not significant sources of pollutant loadings in the area.

TABLE 4: POLLUTANT LOADINGS FROM CITY OF THUNDER BAY

	TSS	TP	BOD
STP(dry weather)	1,352,400	31,750	2,381,400
STP(wet weather)	67,620	1,566	119,070
SW	423,080	1,030	61,360
CSO	6,090	50	1,380

Note: Annual Loadings; Wet weather 5% of the time; Units: kg/year

The PCP study found that the objectives could be achieved by replacement of many of the CSO regulators and other O&M type actions. The overall recommendations of the PCP was set out in a 2 stage process (a short term PPCP and a long term PPCP.

The cost of the short term PPCP was estimated at $3.9 million. With the short term CSO control recommendations of replacement of 12 regulators and other O&M type actions, the CSO volume criteria of 90% volumetric runoff control could be met. Recommendations for the STP included conducting a pilot study to investigate treatment technologies for secondary upgrade to the STP and improving digester mixing. Pollution prevention measures recommended increasing the scope of routine catch basin cleaning/street sweeping, and downspout disconnect and public education programs.

Total estimated cost of the long term PPCP recommendations for the collection system was $15.5 million (excluding the STP upgrade). The long-term PPCP includes collection system management in the context of controlling and managing excess wet weather flows, considerations for future development and elimination of basement flooding. Recommendations for the collection system included provision of a 8760 m^3 storage tank (est. cost $5.4 million), new storm sewer construction and providing an additional pumping station. The estimated $30 million upgrade of the STP to secondary treatment would be pending the results of the pilot study which was initiated in 1996.

Windsor Riverfront Pollution Control Planning Study

This study consists of three phases. The Phase I work (completed in 1995) determined the quantity and quality of the municipal effluents discharged under wet and dry weather conditions to the Detroit River. The pollutant loadings are shown in Table 5. The study also estimated the impact of the municipal effluents on the river. The City of Windsor is served principally by combined sewers, with practically no separated systems. Storm relief sewers have been installed in some areas to relieve flooding in the combined sewer system - these are considered to be CSOs.

TABLE 5: POLLUTANT LOADINGS FROM THE CITY OF WINDSOR

	TSS	TP	BOD
STP	812,600	20,000	1,253,000
STP Bypass	55,700	1,000	86,000
Storm Relief	640,900	8,000	131,000
CSO	885,000	8,000	279,000
Industrial	37,500	-	-

Note: Annual Loadings; Units: kg/year

It is worthwhile to note that the above loadings account for 1% to 5% of the contaminant loadings to the river in this area - the remainder being discharged from the Detroit area.

Phase 1 determined that Windsor's municipal effluents had minimal impact on the Detroit River. Since no bathing beaches are present in the immediate areas of the discharges, recreational use is not impaired. Consequently, the objective adopted for the study was to meet the minimum requirements of the MOE CSO policy - that is, that 90% of the wet weather flow from the CSO system is to receive at least primary treatment. Phase II of the study, completed in 1997, evaluated options for meeting this CSO objective.

It is proposed that a short term program be initiated to address operational concerns, pollution prevention and non-structural control measures. Long term control measures being considered include 1) construction of storage facilities to detain wet weather flows for eventual treatment at the West Windsor STP, and 2) satellite treatment using retention treatment basins (or some other high rate treatment method such as vortex separation).

Because of site constraints that will limit the use of high rate treatment at some of the CSO locations, only part of the system can be controlled using this method. Control costs for storage alone, using underground tunnel storage and conveyance, are $61 million, rising to $148 million with the inclusion of storm relief flows. Control costs for use of retention treatment basins for part of the area, along with a smaller storage tunnel are $48 million, rising to $93 million with the inclusion of storm relief flows. All options include an increase in primary treatment plant capacity to increase the dewatering rate for the sludge from the storage tanks.

Phase III, underway in 1998, will present long term control options to the public, including the Remedial Action Plan Public Advisory Committee, to input into the preferred option.

City of Belleville Pollution Control Plan - Bay of Quinte Area of Concern

Bacteriological contamination of surface waters in the Bay of Quinte has impaired beneficial use related to recreational activities in the Bay. The bacterial contamination is attributed primarily to stormwater runoff.

The PCP for the City of Belleville quantified and located the sources of bacterial contamination under both dry and wet weather. Under dry weather, some of the storm outfalls are occasionally contaminated.

However, the level of contamination is quite variable. For those sewers that were consistently contaminated, the source was identified and the problem tributary lines were isolated. Sanitary cross-connections and/or sewer leakages were suspected to be the cause of bacterial contamination in these lines

During wet weather, bacterial contamination occurs in the receiving waters of the Moira River, increasing by approximately an order of magnitude compared to dry weather periods. These elevated bacterial concentrations lead to contamination of east Bayshore of the Bay of Quinte within the City of Belleville and a beach (Riverside Beach) within the Moira River.

The high levels of bacteria are attributed to washoff of bacteria-laden sediment from urban surfaces, and suspension and transport of sediments that accumulate within the storm sewers during events. For the Riverside Beach, however, pigeons residing under the highway bridge at this location are suspected to be the source of contamination since the contamination occurs during both dry and wet weather.

A stormwater control plan was developed for the City of Belleville. Core components were (1) a source control program, (2) a centralized stormwater retrofit treatment and (3) a project by project stormwater control and treatment. Recommendations related to source control included street sweeping/catchbasin cleaning, identifying/eliminating sources of dry weather storm sewer contamination (sewer cross-connections), minimizing runoff from existing industrial and commercial properties, pet-litter control, public education and minimizing runoff volumes as a principle to be applied to new development and to road/sewer reconstruction projects.

For (2), the recommendations consist of installation of end-of-pipe stormwater treatment to treat existing outfalls, where opportunities exist. For the project-by-project stormwater control and treatment, a stormwater control policy was recommended that sets out guidelines and procedures for reviewing the design of drainage systems for all new development and redevelopment projects, as well as road and sewer improvement projects. This policy is intended to ensure that, on each project, all opportunities are utilized to reduce stormwater volumes an stormwater contamination.

Disinfection, using ultraviolet irradiation, was recommended for consideration, only for those areas of high recreational use.

Specific recommended control measures included (1) continued surveillance of the storm sewer system for bacterial sources, (2)following the recommended stormwater control policy, (3) construction of end-of-pipe stormwater quantity/quality ponds for specific outfalls, (4) implement bird control program (at the Highway 401 bridge) for reducing/eliminating the pigeon population and a public information program to discourage feeding of gulls and waterfowl. Estimated cost of the control measures was $3.18 million.

Pollution Control Plan - City of Trenton

The Trenton PCP, like that of Belleville's, was initiated to address bacterial contamination within the Trent River and the Bay of Quinte at Trenton. Phase 1 was completed in 1997. The results of the monitoring program indicated that bacterial quality (under dry weather conditions) had substantially improved since earlier studies. This improvement was due to the City of Trenton's ongoing effort to upgrade sewers and eliminate sanitary-to-storm cross-connections. Under wet weather conditions, there remains bacterial contamination of the Trent River (south of Dixon Drive Bridge to the mouth of the river). The main cause appears to be contaminated discharges from the City's storm sewers.

Phase 2 of the PCP, currently underway, is aimed at identifying the source of this wet weather bacterial pollution, and monitoring the effect of corrective actions. Corrective actions include recent elimination of cross connections in the system, proposed cleaning of sewers to flush out sediment. Wildlife, such as racoons, is also suspected of contributing to the bacteria levels in the stormwater discharges. Phase 2 will also address options with respect to phosphorus load control. Phosphorus loads from Trenton are estimated at 1,000 kg/year. Ultimately the PCP will provide a long-term strategy for stormwater pollution control from the City of Trenton.

R0025072

Severn Sound Remedial Action Plan Urban Stormwater Study

Impairments caused by stormwater in the Severn Sound AOC were problems associated with eutrophication and beach closings and effects of toxic contaminants on fish and benthic communities. Rough 1993 cost estimates for achieving a target of 20% reduction in phosphorus loadings was $35 million. The PCP was therefore initiated in 1996 to provide more definitive costs and options for managing stormwater in this AOC. The study encompassed 4 municipalities - the Town of Midland, the Town of Penetanguishene, the Township of Tay and the Township of Severn.

The PCP identified the annual pollutant loads entering into Severn Sound. A planning level model (Retrofit Stormwater Management Practices) allowed various stormwater management options to be evaluated for the entire Severn Sound area, as well as the individual municipalities. The sequence of stormwater management options takes into account source control measures firstly, followed by end-of-pipe treatment.

As a result of the PCP, loadings estimates for phosphorus to Severn Sound has been revised from 3,300 kg/year to 1,368 kg/year. A 15% reduction of phosphorus loading is achievable with best management practices. A 20% reduction of phosphorus was considered to be uneconomical. Estimated cost for the 15% reduction target was $4.3 million.

TECHNOLOGY DEVELOPMENT AND DEMONSTRATION

The total estimated cost for implementation of the PCPs for the seven cases described previously amounts over $330 million. Much of these costs are associated with the need for upgraded STPs, storage tanks for CSOs and stormwater ponds. Many municipalities need stormwater controls to be retrofitted or added to existing drainage systems in developed areas, which requires new technologies. Environment Canada GL2000 CUF, in partnership with the Ministry of Environment and municipalities, is also supporting the evaluation of technologies (described below) that have the potential to reduce the costs of implementing these PCPs.

Conventional secondary treatment plants that use activated sludge can convert to step-feed operation during wet weather to reduce bypasses and overflows. The conversion in many cases can be made with minor modifications to the process flows. In a demonstration of the procedure at the Woodward Ave. STP in Hamilton Ont., modification costing only $132,000 (1991) reduced secondary bypassing during storm flows over a ten month period by 97% (Chapman, 1998)

For CSO control, high rate treatment could provide substantial cost savings compared to sewer separation or storage and central treatment. In a 1992 study, the costs were estimated at $107 million for satellite treatment using high rate processes, $441 million using the storage and central treatment option and $3.7 to $5.9 billion for sewer separation for AOCs. The high rate treatment option is being evaluated in a pilot study initiated in 1994 (Averill et al, 1997). High rate treatment processes evaluated to date include the Storm King vortex solid separator (with and without chemicals), microscreening, parallel plate separators and tertiary filters as a polishing unit. Disinfection of CSOs treated by the effluents from the vortex separator and other unit processes was also evaluated. Key findings are (i) for the CSOs encountered, the vortex unit was able to meet the MOE's requirement of 90 mg/L TSS at a loading rate of 5 - 10 m/h, (ii) using a polymer coagulant resulted in substantially higher loadings (in excess of 40 m/h), (iii) similar loading rates could be achieved with a pilot rectangular tank, suggesting that tank geometry was not an important factor. The project has evolved into a full-scale demonstration project in which the effectiveness of the polymer coagulant is being evaluated in a CSO/stormwater tank in Toronto.

Real-time control of a sewer system is a means to take advantage of existing excess storage in a sewer system (resulting from a large sewer system, or of under utilized, or oversized sewer elements). Installation of a system of sensors, automatically operated control gates and pumps, with a computer management system can take advantage of this excess storage and reduce overflows. This may reduce control costs by up to 30%, based on European experience. A demonstration study is underway in Hamilton-Wentworth has developed the necessary software to control the extensive network of combined sewers and storage tanks (Vitasovic et al, 1993). Actual demonstration of the system is expected in 1998. The system is expected to result in improved performance in controlling overflows and reductions in capital construction of additional storage or treatment components.

Technologies using low cost measures for stormwater treatment are also under evaluation through the Stormwater Assessment Monitoring and Performance Program (SWAMP) supported by a partnership of Environment Canada GL2000 CUF the Ministry of Environment, Ontario Ministry of Transportation, Toronto and Region Conservation, and municipalities. This program is currently evaluating a number of technologies applicable to stormwater systems, including a stormwater pond performance assessment, a stormwater pond retrofit to improve water quality, underground tank performance, exfiltration and filtration systems (discussed below), flow-balancing systems (discussed below), and oil/grit separators.

In Etobicoke, an exfiltration system (constructed in 1993) is under evaluation (D'Andrea, 1998). Storm drainage is diverted to perforated pipes installed in the same trench as the conventional storm sewer. The system has great potential for reducing the costs of stormwater treatment, since it will add only 10 to 20% to the cost of sewer replacement (when road reconstruction is being carried out) and be less costly than alternate storage or treatment schemes. Since the system is built in the right-of-way, no land need be purchased, which makes the method attractive for controlling existing problems in built-up urban areas. The system performance to date has shown the system will exfiltrate up to 63 mm of rainfall. Optimization of the design is currently underway. Other aspects under evaluation include pollutant removal, groundwater transport of pollutants, and maintenance requirements.

In Scarborough, the Dunkers Flow Balancing for control of stormwater will be evaluated in 1998 (Mack-Mumford, 1998). The system uses an embayment that is sectioned off into treatment cells for removing suspended solids. Plastic suspended curtains suspended act as the cell walls. A low-cost alternative to an underground storage tank, the capital cost of the Dunkers system was $3 million versus $22 million for a storage tank.

In a separate study carried out in Scarborough, Ont., a watershed planning approach was developed to evaluate retrofit measures for existing urbanized areas (Li, 1997). In the demonstration carried out on Centennial Creek, watershed goals were translated into specific targets for reduction of total suspended solids by 50% and runoff volume by 25%. A number of different measures were then screened for applicability in the area. Retrofit measures that would fit into the municipality's capital works budget for rehabilitation and replacement of roads and sewers were included such as the exfiltration system discussed above. In addition, downspout disconnection, oil/grit interceptors, stormwater pond retrofits and new stormwater ponds to be constructed on municipal property were evaluated. A multi-efficiency model that accounted for the suspended solids reduction for both treatment measures (e.g. ponds) and infiltration measures was used to assess overall performance.

SUMMARY

Pollution prevention and control plans conducted in municipalities in AOCs have provided hard data on pollutant loadings and options to minimise these loadings from the various municipal sources (STP effluents, CSOs and stormwater). The municipalities in the AOCs now have an implementation strategy to minimize the municipal pollution to the Great Lakes. The costs of the implementation strategies are substantial. Opportunities for reducing these costs may arise from the technology evaluation projects on lower cost alternatives currently underway. Retrofit technologies that can be implemented in existing urbanized areas are important for AOCs to address existing problems. Environment Canada Great Lakes 2000 Cleanup Fund continues to provide support for these technologies.

ACKNOWLEDGEMENTS

The authors wish to acknowledge the following agencies and municipalities for their assistance in

PUBLIC INVOLVEMENT STRATEGIES FOR URBAN COMMUNITIES

William L. Hurt, PR Networks, Inc.

PR Networks, Inc. 400 Renaissance Center, Suite 2250, Detroit, MI 48243 U.S.A

ABSTRACT

Utilities contemplating projects that will affect the lives of the general public (short or long term) in many instances have a mandated requirement to also inform the public. This process, normally called public involvement, can contain any combination of these components: public information, education, and/or participation.

In many situations, utilities are not thoroughly aware of how these component parts impact their project(s) within the communities serviced. Moreover, in today's diverse yet often segregated communities it is critical to understand how communities receive, interpret and act upon messages.

This manuscript will seek to provide the strategies necessary in developing effective and successful public involvement campaigns specifically directed toward urban markets. The manuscript will address such issues as:

- Public relations v. public involvement
- Public involvement that meets the urban community's need
- Audience identification
- Partnership development for successful public involvement
- Selection of appropriate communication techniques/vehicles to deliver your message
- What to do when your community will not cooperate

The methodologies are general for application in other municipalities seeking to inform and engage their publics.

KEYWORDS

Target audiences/stakeholders/publics, CSO, public involvement, public participation, public information.

INTRODUCTION

The public involvement component of the Detroit Water & Sewerage Department's (DWSD) Long Term Combined Sewer Overflow (CSO) Control Program is a requirement set forth in the CSO provisions of the current National Pollutant Discharge Elimination System Permit (NPDES), issued by the Michigan Department of Environmental Quality (MDEQ) to DWSD.

The primary objective of the public involvement program is to inform local customers, elected officials, the press and broadcast media, and special interest groups about projects that will affect and impact their lives, and to solicit their input in the process.

The following is a partial listing of additional activities associated with projects of this nature:

- formulating a strategic approach
- creating a project identity
- reviewing and revising the media/presentation kit
- setting up an advisory coalition
- establishing a project workgroup
- researching and reviewing communication tools and public involvement activities previously conducted including surveys, wholesale customer meetings and partnership sessions.

In Detroit, the strategic public involvement plan had eight component audiences.

- Wholesale customers
- Retail customers
- Community Organizations
- Environmental Groups
- DWSD Employees
- Media
- Business leaders
- Political officials

Each audience, required a different strategy because of the information and how it should be presented. (A more detailed review of these audiences is listed separately in Audience Identification.)

The overall objectives of our communication efforts were to:

- Provide approved information to the various audiences in a timely and easily understandable and professional manner. Compile and interpret responses and make recommendations.
- Position department as an effective utility making a positive impact on issues of importance to its customers.

This paper presents methodologies and results of the City of Detroit's Combined Sewer Overflow Control Public Involvement Program.

METHODOLOGY

The very first task to accomplish in constructing a meaningful public involvement program is to gain a clear understanding of the differences between public relations and public involvement.

Briefly, the basic practice of public relations involves assuring that your publics perceive you as you wish to be perceived. While, public involvement provides a basis for shared decision-making power.

As a part of the public involvement process, a determination must be made if one or both of its component parts will be applied. The component parts are *public information and participation*. In the normal course of a public involvement program, the application of public information and participation may vary. The key is to understand when to apply each.

Public information is a one-way communication process- telling a story or providing other pertinent knowledge about the program. It is not important here that any feedback is received. Public participation on the other hand does as it name states-- involve the public's participation in the process. Participation can vary from a limited one-time occurrence to on-going. This is why the determination on the type and level of public involvement must be made at the beginning during the strategic planning stage.

To assist in constructing a public involvement program that will meet the needs of urban communities, ask and answer these questions during the planning stage:

- Why conduct public involvement?
- What are the benefits of involving the public?
- When is public involvement necessary?
- How to include the public in the process
- What level of involvement is appropriate to reach the desired outcome?
- Which public should and/or need to be involved?
- Can we define the importance of the program to the community?

R0025078

Answers could include the following:

Why Conduct Public Involvement Programs

Prioritize issues
Build credible relationships
Is required for many publicly funded projects
Public becomes part of decision making process
Expand solutions and understanding of solutions

Benefits of Involving the Public

More effective and responsive decisions
Broader acceptance and commitments
Saves time and money

When is Public Involvement Needed

The decision will affect your public unequally
The decision is a change of policy or service
The decision can't be made without public support
To build support with regulatory agencies
To build support with your customers

How to Include the Public/ Level of Involvement

One time meeting for specific closed-end decisions
On-going public involvement process
- Public meeting
- Collateral development
- One-on-one meetings
- Ad hoc advisory committee
  (Community influentials)
- Toll free information hotline

Define Importance of Program to the Community

Explain all aspects of the program
Why the program must be undertaken
Community's role
Be responsive to community concerns

Which Publics to Involve

Whose help do you need to show this is a legitimate decision and process?
Who can disrupt the process?
Who stands to gain or lose the most?
Who has the skills, contacts and experience to help the process?

In urban areas, these questions take on added importance due in part to the diversity of culture and population.

AUDIENCE IDENTIFICATION

One of the first lessons we learn in the study or communications is "Know Your Audience". This rule takes on added significance when structuring messages for urban environments. Your audience is also referred to as "stakeholders" because they have a direct and/or indirect stake in the public involvement process.

Stakeholders are comprised of internal and external publics. They may enter or have access to the process at varying stages. However, knowing who they are or represent may be the most underrated and least understood facet of the process. In urban communities, the stakeholder profile should reflect the ethnic diversity present in each city. It is therefore likely that a series of tailored messages may be needed.

Typically, stakeholder groups will consist of:

- rate payers/users
- affected residents and associates
- regulators and elected officials
- special interest groups
- internal public
-

Two specific groups-affected residents/associations and interest groups are highlighted here for discussion.

In Detroit, to effectively reach these groups, we used a strategy commonly referred to as "push-pull". We identified influentials who had credibility within the community and neighborhood groups, religious and civic associations and politics. Once identified, we sold them on our plan and enlisted their assistance in our efforts to deliver our message to the community. Community meetings were held at recreation centers, churches, schools, block club leader's homes and any other place where people would gather. As a result, we were able to communicate our message and not get side-tracked by non-related issues that residents might wish to debate.

Listed below is a profile on each stakeholder group identified for DWSD's public involvement program.

Wholesale Customers

This group has very specific concerns that could be addressed through "Wholesale Customer Meetings".

Messages that are important to this group include:
- Wastewater sites
- Alternatives
- Meter accuracy
- Water quality
- Public health issues
- The plan
- Wastewater treatment

Communication vehicles may include any of these:

1. Wholesale customer meetings
2. One-on-one & small group meeting
3. Speaker Bureau
4. Newsletter

Retail Customers (Residents/Users)

Objective

To educate the city's residential and business rate payers on the necessity for and benefits of the plan and accompanying construction.

To generate comments and input from these groups that may be of benefit to the city.

Methodology

The most efficient and cost-effective method for reaching large numbers of customers at one time would be to develop messages primarily for mass media (if the budget permits). Included here could be a mix of broadcast (primarily radio with some television) and print (community papers). If not, then community meetings are recommended. A secondary communication vehicle might include direct mail. Information of most interest to this group include benefits and/or quality of life issues.

A question and answer sheet on the project could be a good introduction to the project for retail customers. Public service announcements and a toll-free telephone hotline should also be developed and then promoted on radio and television as needed.

Other possible opportunities exist using customer service personnel. A hotline number and limited program information on a wallet sized card will allow them to answer basic questions with the public.

Possible Outcome

A) The public-at-large is provided any and all relevant information needed to be informed and educated in a timely way.
B) The utility can be positioned as proactively addressing water quality issues for all its customers.
C) A more informed public can respond one of two ways. The first and preferred response would be to accept the information with no controversy or opposition. The second and more likely response which will occur is one of some level of initial anxiety depending on how information is reported. There will be some who will be upset over cost, others will question the perception of how it will affect "their" community. This can be resolved by staying "in touch" with the community.

Community Organizations

Objective

To educate and enlist these groups to act as channels through which information can be distributed.

Methodology

Community groups like business leaders are ideal situations to use a speaker's bureau. Community organizations include churches and religious organizations, community based and civic organizations, and educational institutions.

Apart from a speaker's bureau for use at community meetings, schools, etc., these organizations can be excellent conduits to get information out to the community. Introduction of new programs, ideas and other messages can be targeted by using those in leadership positions to sell through our position.

Possible Outcomes
A) When "tapped" into properly, these groups can become additional salespeople for the project, and be available to give support at community meetings.
B) If not sought out and lobbied, some could pose serious problems because of their ability to impact community decision making.

Environment Groups

Objective

To present information in a way that addresses environmental impact concerns on the utility's plan and implementation.

Methodology

Although environmental groups will want information on rates and meter accuracy, it is believed that the issues of water quality, public health, alternatives, wastewater treatment and the long-term plan will be their "bread and butter" issues.

It will therefore be necessary to fashion information in a similar format as for the residential customers. The focus should be on the end-results; how the environment will be enhanced functionally and aesthetically.

The primary communication tools to be used in addressing this group consists of one-on-one & small group meetings, brochures and other collaterals, and a speaker bureau.

Possible Outcomes

A) If the information is received and it responds to the questions of interest/concern for these groups, a working majority buys into the utility's vision and plan, and then works with the utility by lending their support to the project.
B) Because of their size many are (small and neighborhood oriented) some of the more outspoken groups have a single issue that needs addressing. If the issue(s) can be identified and responded to, the smaller groups may not be much of a concern.
C) Use a tie-in of some sort with their issues and create a presentation for public (primarily school) use to help educate other publics.

DWSD Employees

Objective

To inform all staff with emphasis on field and customer service employees with an overview of the mechanics of the plan for the purpose of directing public inquiries to the appropriate response channels.

Methodology

Working closely with the utility's public relations division, design a "crib sheet" of basic information that employees can use if approached by the general public. This crib sheet will have in bullet format, questions and answers about the project. It will also have the toll-free hotline number that will be given for additional inquiries.

Possible Outcomes

A) Field and customer service employees will become an informal speaker's bureau as well as a distribution channel for information.
B) As a part of this methodology, a flow chart showing how information would be responded to should be created.
C) All employees will on some level become knowledgeable about the plan and its execution. As a result, employees will have some ownership in the final product.

R0025082

Media

Objectives

To provide in a controlled manner information about the plan and any related construction.

To identify and use those mediums and individuals that will be supportive voices for the project. Moreover, to identify and develop a strategy to minimize media opposition.

Methodology

The most direct method to build a support base is to be proactive in managing the media. The initial approach is to schedule editorial visits with local newspaper editors and "beat" writers. These one-on-one sessions provide for relationship building.

Additionally, reporters are always looking for information, therefore, the utility can become a conduit of information that tells the utility's story. It also opens up opportunities to position the utility in a positive way.

A media kit using current information is another tool that allows media access to information.

Important to media will be the development of a speaker's bureau and crisis/issue management plan. Both should be ready to be employed at a moment's notice.

Possible Outcomes

A) Media has to be viewed as a two-headed serpent and treated as such. The initial approach would be to enlist them as an ally, however, one should always be mindful that your interests are usually not the same. Information has to be controlled and channeled through a single voice to the media.
B) The public relations division will need to direct the majority of media contact. Therefore, the contractors' efforts should be in synergy with the utility.

Business Leaders

Objective

Educate and enlist these influentials as a support base for the project.

Methodology

The focus here will be on-on-one personal contacts with groups such as the Chamber of Commerce, civic associations and ethnic associations. These are the most probable audiences where a speaker's bureau can be used.

Possible Outcomes

A) Business leaders can use their position to pull-through our information to various audiences,
B) Employee-based education programs and information can be implemented, focusing on preventive and ecology friendly behavior of workers.

Mayor's Office and City Council

Objective

Provide timely updates and information on the progress and status of the plan.

Methodology

The department accompanied by the project administrator should provide the briefing to the city's administrator and/or their designated staff.

A strategy to inform other political officials(city and suburban) will evolve from the direction given by the administration.

Possible Outcomes

A) In Detroit, the process called for the administration to carry information to city council; DWSD personnel along with the contractor are available to answer specific questions before council.
B) Council members are approached and informed individually by a team consisting of a lead individual from the administration, DWSD and the contractor.

DEVELOPING PARTNERSHIPS

An often used formula for creating successful partnerships begin by developing trust between the participants. As discussed in audience identification, DWSD created a strategy that allowed for input and comment at different stages and with a variety of individuals. Another ingredient in establishing successful partnerships include having a firm understanding of the public involvement strategies and the desired outcomes sought.

Public Involvement Strategies

1. Clarify objectives
2. Confirm commitment
3. Understand roles, responsibilities and resources available
4. Determine the opportunities to influence the decision-making process
5.
    - Frame the problem
    - Identify stakeholders
    - Confirm the problem
    - Determine the criteria for a good solution
    - Identify potential solutions
    - Evaluate alternative solutions, identifying the trade-offs
    - Recommend decision to decision maker

5. Prepare appropriate methods and materials to meet objectives

Desired outcome

- Only involve public if they have a legitimate role
- Public Involvement comes with no guarantees
- Public is a resource to managers, not a surrogate
- Effectiveness of program, not efficiency
- Give all stakeholders opportunity to be involved
- Involving public does not equal decision up for vote
- Not everyone wants to be involved

COMMUNICATION TECHNIQUES/VEHICLES TO DELIVER MESSAGES

There are two types of people who travel. The first type are those who are not concerned with how they get from point "A" to point "B". They are normally only thinking of getting to their destination. The vehicle or mode of delivery is secondary. Then there are those who carefully plan their trip, taking into account potential detours, delays or other external factors that could affect their trip. In most situations, it is the prudent planner that enjoys the trip as much as getting to their destination. So it is also for the utility that is conducting a public involvement program. The trip itself is critical to reaching the destination or goal. In order to reduce the detours and delays, an inventory of available resources is appropriate. Vehicles that can deliver messages include:

- Billing inserts
- Logos, letterhead and mascots
- Door hangers
- Newsletters
- Fact sheets & brochures/literature drops
- Specialty items-placement, table tents
- Displays at community events
- Speakers Bureau presentations to groups
- Public events such as water week, river rescues, storm drain stenciling, tours
- Survey (telephone, mail, personal, door-to-door)
- Public meetings
- Information phone line (hotline)
- Advertisements- television, radio, print, billboards
- Media kits
- Press releases
- Television and radio interviews & talk shows
- Newspaper inserts or special sections
- CD-ROMS, Videos, Web Site, Slides

These vehicles may be used together or as a stand alone, depending on the audience. Urban residents vary in how they receive information. Choosing the correct "vehicle" to deliver the message is sometimes more important than the message when dealing with these communities.

WHAT TO DO WHEN THE COMMUNITY WILL NOT COOPERATE

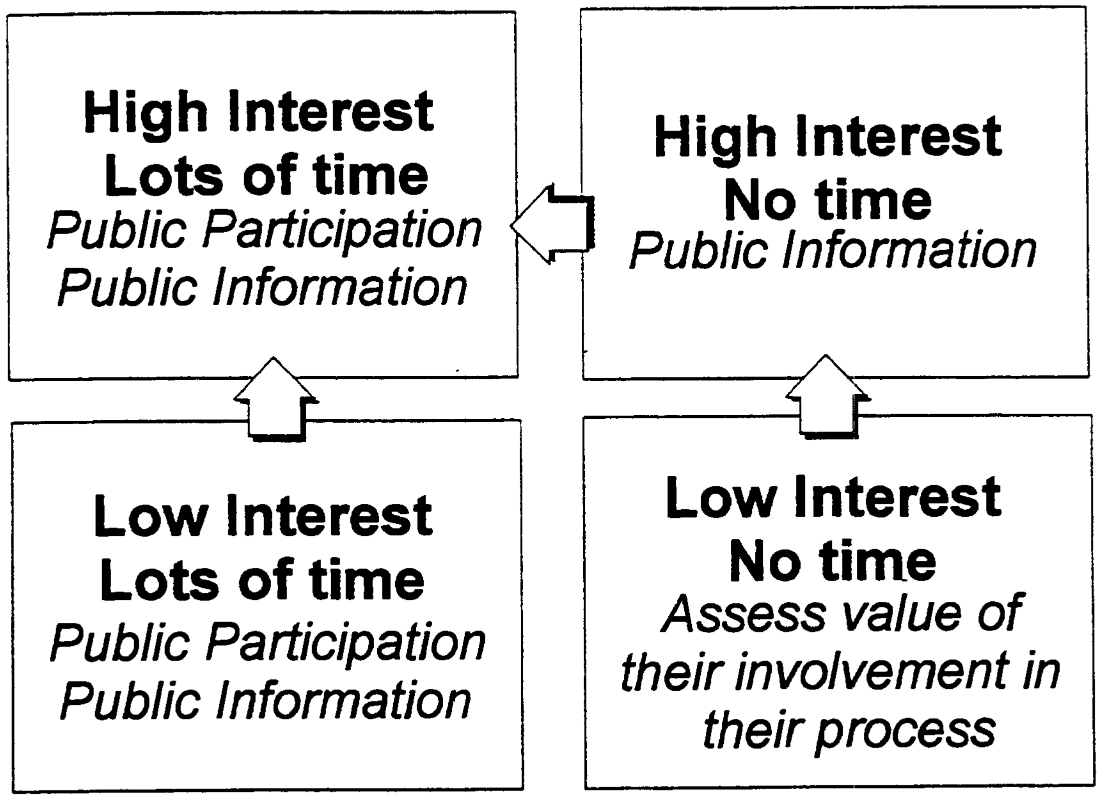
Community cooperation is the glue that holds a successful program together. Therefore, when the community will not cooperate, the original strategy should be reviewed. For example, we discussed earlier that it should be determined whether a program was information or participation driven. Knowing this could prevent lack of cooperation from the community. People may not be cooperating because they:

1) do not fully understand the process and their role or responsibility
2) may not be directly impacted or affected by the process, so it has little or no value, or
3) they simply do not wish to be involved in the process.

The following chart highlights where people should ideally be in the public involvement process.
In addition, if it can't be determined that the problem exists as described in example one or two above, leveraging the relationships established with the influentials i.e. ministers, community leaders, may be appropriate.

The public involvement process is constantly changing, people enter and exist at varying stages of the process, creating a on-going learning curve. To overcome indifference, and non-cooperation remember one very important phase "patience is a virtue and the virtuous are rewarded in the end".

Public Involvement Technique for Different Levels of Time and Interest



CONCLUSION

A successful public involvement program will follow this basic recipe:

1) Develop a strategy/plan and set up obtainable objectives
2) Identify stakeholders
3) Identify all issues that directly/indirectly impact plan; create message(s)
4) Build trust by using influentials
5) Determine level of involvement desired
6) Establish a program identity with corresponding collaterals
7) Staff with adequately trained personnel
8) Measure results throughout the process

The methodologies presented in this paper will have a wide spread and long lasting positive impact on public involvement in urban communities regardless of their size.

Success Achieved in Reducing Sanitary Sewer Overflows Using the Program Management Approach

By
Rosanne W. Cardozo, P.E.
Program Manager, Montgomery Watson

William M. Brant, P.E.
Deputy Director, Miami-Dade Water and Sewer Department

Anthony J. Clemente, P.E.

ABSTRACT

After the Miami-Dade Water and Sewer Department (the Department) was hit with enforcement actions from the state and federal government to address wastewater facility capacity issues, the Director of the Department quickly realized that an organized and highly focused approach was needed to successfully comply with the requirements of the enforcement actions, to lift the County's building moratorium and to reduce the occurrence and volume of sanitary sewer overflows (SSOs). Montgomery Watson was brought on board to provide program management services for the Department on its $1 billion wastewater improvements program.

Through this program management approach, the Department has achieved a 56 percent reduction in the occurrence of wet weather SSOs over a three year period, and has seen a 66 percent reduction in the total volume of SSOs. The Department has also met more than 800 milestones set forth in the enforcement actions, many of which carry stipulated penalties of up to $10,000 per day for noncompliance. Moreover, a fast-track collection system improvement program resulted in the early removal of building moratoriums covering Miami-Dade County.

This program management approach has also provided the Department a savings in time and money, a solution to peak staffing needs, instantaneous expertise in wet weather and management issues, a uniform approach in implementing hundreds of projects and a single point of responsibility in ensuring the success of the program.

This paper will provide details on the success of the program management approach in addressing Miami-Dade's SSO challenges.

INTRODUCTION

The Miami-Dade Water and Sewer Department is the largest water and wastewater utility in the Southeast United States and serves a population of over two million located within a 600 square mile service area. The Department owns, operates and maintains over 2,400 miles of gravity sewers (up to 72-inch diameter), 640 miles of force mains (up to 102-inch diameter) and 906 pump stations. The three regional wastewater treatment plants (WWTPs) operated by the Department have recently been upgraded from a permitted capacity of 298 million gallons per day (mgd) to the current treatment capacity of 355.5 mgd.

As is common with most utilities of this size, the Department has had difficulty in controlling overflows from the sanitary sewer system, especially during wet weather events. The occurrence of these overflows drew the unwanted attention of the state and federal regulatory agencies. Over a two year period, the Department negotiated two separate Settlement Agreements with the State of Florida, and two Consent Decrees with the federal government. These enforcement actions required $1 billion in improvements to be made to Miami-Dade's wastewater facilities over a ten year period.

THE CHALLENGE

The Department was faced with some unique challenges in implementing this $1 billion improvements program. The Department had to comply with multiple enforcement actions imposed by two separate regulatory agencies that contained extremely short project completion schedules and costly penalties for not meeting the schedules. The enforcement actions also mandated a moratorium on development within the County until a large amount of the improvements had been completed. This building moratorium outraged land developers who were heretofore enjoying a fast-growing, highly profitable boom in the area of land development. The residents of the County were also outraged when their water and sewer rates more than tripled, when their streets and landscaping were torn up, and when traffic jams became the norm due to road closures. The Department was also faced with an enormous amount of work in addition to their day-to-day responsibilities, minimal staff, limited experience in addressing wet weather issues of this magnitude and a collection system that was in desperate need of repair.

PROGRAM MANAGEMENT TEAM ORGANIZATION

Confronted with these difficult issues, the Department quickly made the decision to engage Montgomery Watson to assist them in the management of this program. Montgomery Watson and its subconsultants founded the Program Management Team (PMT), which was structured to act as an extension of the Department. A 10,000 square foot office filled with a staff of 75 people was established adjacent to the Department's main office. The PMT provided the following services:

- coordination of design consultants;
- planning, design review, permitting and material procurement;
- construction management;
- developer coordination;
- multi-agency coordination;
- regulatory reporting and negotiation assistance;
- creation of a Small Contractor Development Program to increase small and minority business participation on construction projects;
- project scheduling and cost control;
- document control;
- technology transfer/training;
- and public relations/information.

THE PROGRAM

A program of improvements was established to improve the Department's management of SSOs and to satisfy the requirements of the enforcement actions. These improvements ranged from changes in operation and maintenance of the collection system to capital improvement projects, as detailed below:

- Wastewater treatment plant improvements to include an increase in treatment capacity of 67.5 mgd, the installation of odor control facilities, an optimization of plant operations.
- Construction of a regional pump station and force mains, including a subaqueous 102-inch, 5 mile force main.
- A comprehensive program was developed to monitor and inspect the 906 pump stations. The operating hours of the pump stations are monitored via elapsed time meters to determine if there are operational or capacity problems. Each pump station is also field inspected on a weekly basis, and is repaired and/or upgraded if required. To date, almost 500 pump station projects have been identified as requiring upgrade, of which, 400 pump station projects have been completed.
- A Supervisory Control and Data Acquisition (SCADA) system is being installed on all 906 pump stations to better monitor operations and identify any periodic or chronic maintenance problems.
- An aggressive Infiltration/Inflow (I/I) reduction and sewer rehabilitation program is well underway. The entire 2400 miles of collection system is being evaluated and rehabilitated as needed to minimize I/I and to improve the structural integrity of the system. Program activities include 100 percent television inspection, smoke-testing, flow metering, installation of manhole inserts, and sewer/manhole repair and replacement.
- An ordinance has been enacted which requires municipalities that discharge to the Department's wastewater facilities to implement a similar comprehensive wastewater collection system improvements program. A provision of the ordinance also requires the owners of privately-owned laterals to correct any defects.
- A grease trap ordinance was enacted to control the discharge of grease and oil from industrial and commercial users into the collection system. It was determined that the majority of pipe blockages which caused overflows, occurred due to an abundance of grease build-up.
- The development of a comprehensive sewer model and peak flow study will be utilized to refine operation and maintenance procedures to achieve optimal transmission capacity of the collection system. This model will also be used to evaluate the impact of I/I rehabilitation projects, and proposed system modifications to further address wet weather capacity issues.
- A comprehensive maintenance tracking system capable of tracking maintenance activities, equipment histories, and scheduling preventive maintenance activities has been developed. Emphasis has been placed on preventive maintenance, which has served to reduce the need for unscheduled maintenance.
- A computerized spare parts inventory management system is being utilized to ensure that a sufficient supply of routine and critical spare parts are in stock to satisfy scheduled and crisis related collection system maintenance requirements. Through this process, equipment inventories have been successfully reduced by several million dollars.

- An SSO database and contingency plan have been developed to track and minimize the quantity and volume of SSOs discharging to surface waters. The weather is monitored continually, and upon notification of an impending severe storm event, Department personnel are quickly mobilized to aid in the emergency transfer of flows away from highly sensitive areas in the collection system. In the event of a spill, investigation crews are also dispatched to correct the problem and clean the area.
- An ongoing water conservation program serves to educate the public about the importance of water conservation, and aids low-income residents through the installation of ultra low flow toilets and showerheads in their homes in order to reduce their water usage charges.

The Department has also implemented the following programs that are not required by the enforcement actions, but which serve to improve the operation and maintenance of the collection system.

- A long-term corrosion control program to include the lining of existing force mains and replacement of sewers subject to corrosion.
- The development of new design standards to minimize the potential for I/I and corrosion within the collection system.
- The installation of standby power generators at major pump stations to minimize operation interruptions.
- The development of a Geographical Information System (GIS) to aid in operating and maintaining the collection system.
- A scheduled sewer cleaning program for sewers that experience frequent grease buildup and blockages.
- An intensive cross-training program for personnel to enable them to better maintain and operate the collection system.

PRELIMINARY RESULTS

The Department has completed over 65 percent of the program improvements and is more than satisfied with the preliminary results of the program. The Department has:

- met the terms of the enforcement actions to date and has not had to pay any stipulated penalties;
- eliminated dry weather capacity SSOs and significantly reduced the quantity and volume of wet weather SSOs;
- created a more reliable, structurally sound collection system;
- improved customer service;
- appeased the developers by minimizing the duration of the building moratorium;
- grown small/minority construction businesses within Miami-Dade through the Small Contractor Development Program (59 percent of pump station projects were awarded to SCDP contractors);
- established an excellent relationship with the regulatory agencies, who now acknowledge that Miami-Dade has a model program; and,

- has successfully educated the public on the value of the program improvements and related issues through different media presented in English, Spanish and Creole.

CONCLUSION

Through this program management approach, the Department continues to be successful in reducing its SSOs and in meeting the requirements of the enforcement actions. Moreover, this approach has allowed the Department to maintain its focus on providing good customer service throughout the implementation of this massive improvements program.

CALCULATING INFLOW IN COMPLEX HYDRAULIC NETWORKS WITH PUMPED FLOW INPUTS AND BYPASSES

John S. Gresh, P.E., RJN Group, Inc.
Frank T. Torre, RJN Group, Inc.
Atlanta, GA

RJN Group, Inc., 3230-L Peachtree Corners Circle, GA 30092

ABSTRACT

When performing flow metering for evaluation of infiltration/inflow levels in a sanitary sewer system, meter locations should be selected to avoid manipulation of data between upstream and downstream meter sites to obtain net flows within a defined area. Sites also should be selected to avoid the impact of force main discharges upstream of the meter because analysis of the inflow components from pumped flow data is more difficult. This paper will examine a large scale metering project in Gwinnett County, Georgia. The county is served by multiple wastewater reclamation facilities, which receive flow from approximately 130 pumping stations. Various pump stations and treatment facilities have bypass structures, which send excess flow beyond the capacity of the facility to an alternative downstream facility. This introduced additional difficulty into an analysis effort that was daunting by its sheer size alone.

KEY WORDS

Flow metering, bypasses, inflow, data analysis

INTRODUCTION

A unique aspect of this wastewater system is that the collection lines and customers are often located away from the treatment facilities best equipped to handle the flow. The county Department of Public Utilities has employed a strategy of pumping flow from the sewersheds with limited treatment capacity to those within the county with available capacity. Some of the newer pumping stations have been designed to allow flow to by-pass to older treatment facilities, while "shaving off" peak flows to newer facilities in alternate sewersheds. The combination of multiple pumped flow inputs and four major by-pass points provided challenges when choosing meter sites and analyzing data. These features of the Gwinnett County system are illustrated on figure 1.

The metering project for Gwinnett County was designed to provide countywide data for the winter 1997 monitoring season. Data from 101 temporary sites was collected. Select meter sites were subject to the effects of pumped flow inputs because the large number of sites, pumping stations, and network layout prevented this condition from being avoided in every case. Four locations were monitored to track by-pass flows. Although it is always preferable to analyze flow meter data which is independent from other locations, this is rarely feasible. In particular, the calculation of peak flows to obtain inflow quantification is complicated at these sites. Pumping stations act to dampen peak flow effects, which are otherwise clearly observed in a gravity flow scenario.

METHODOLOGY

A variety of challenges exist when conducting analysis of flow data from meter locations subject to upstream pumped flow and by-passes.. These include:

- The shape of the pumped flow hydrograph is not the same as that of a gravity flow sewer hydrograph.

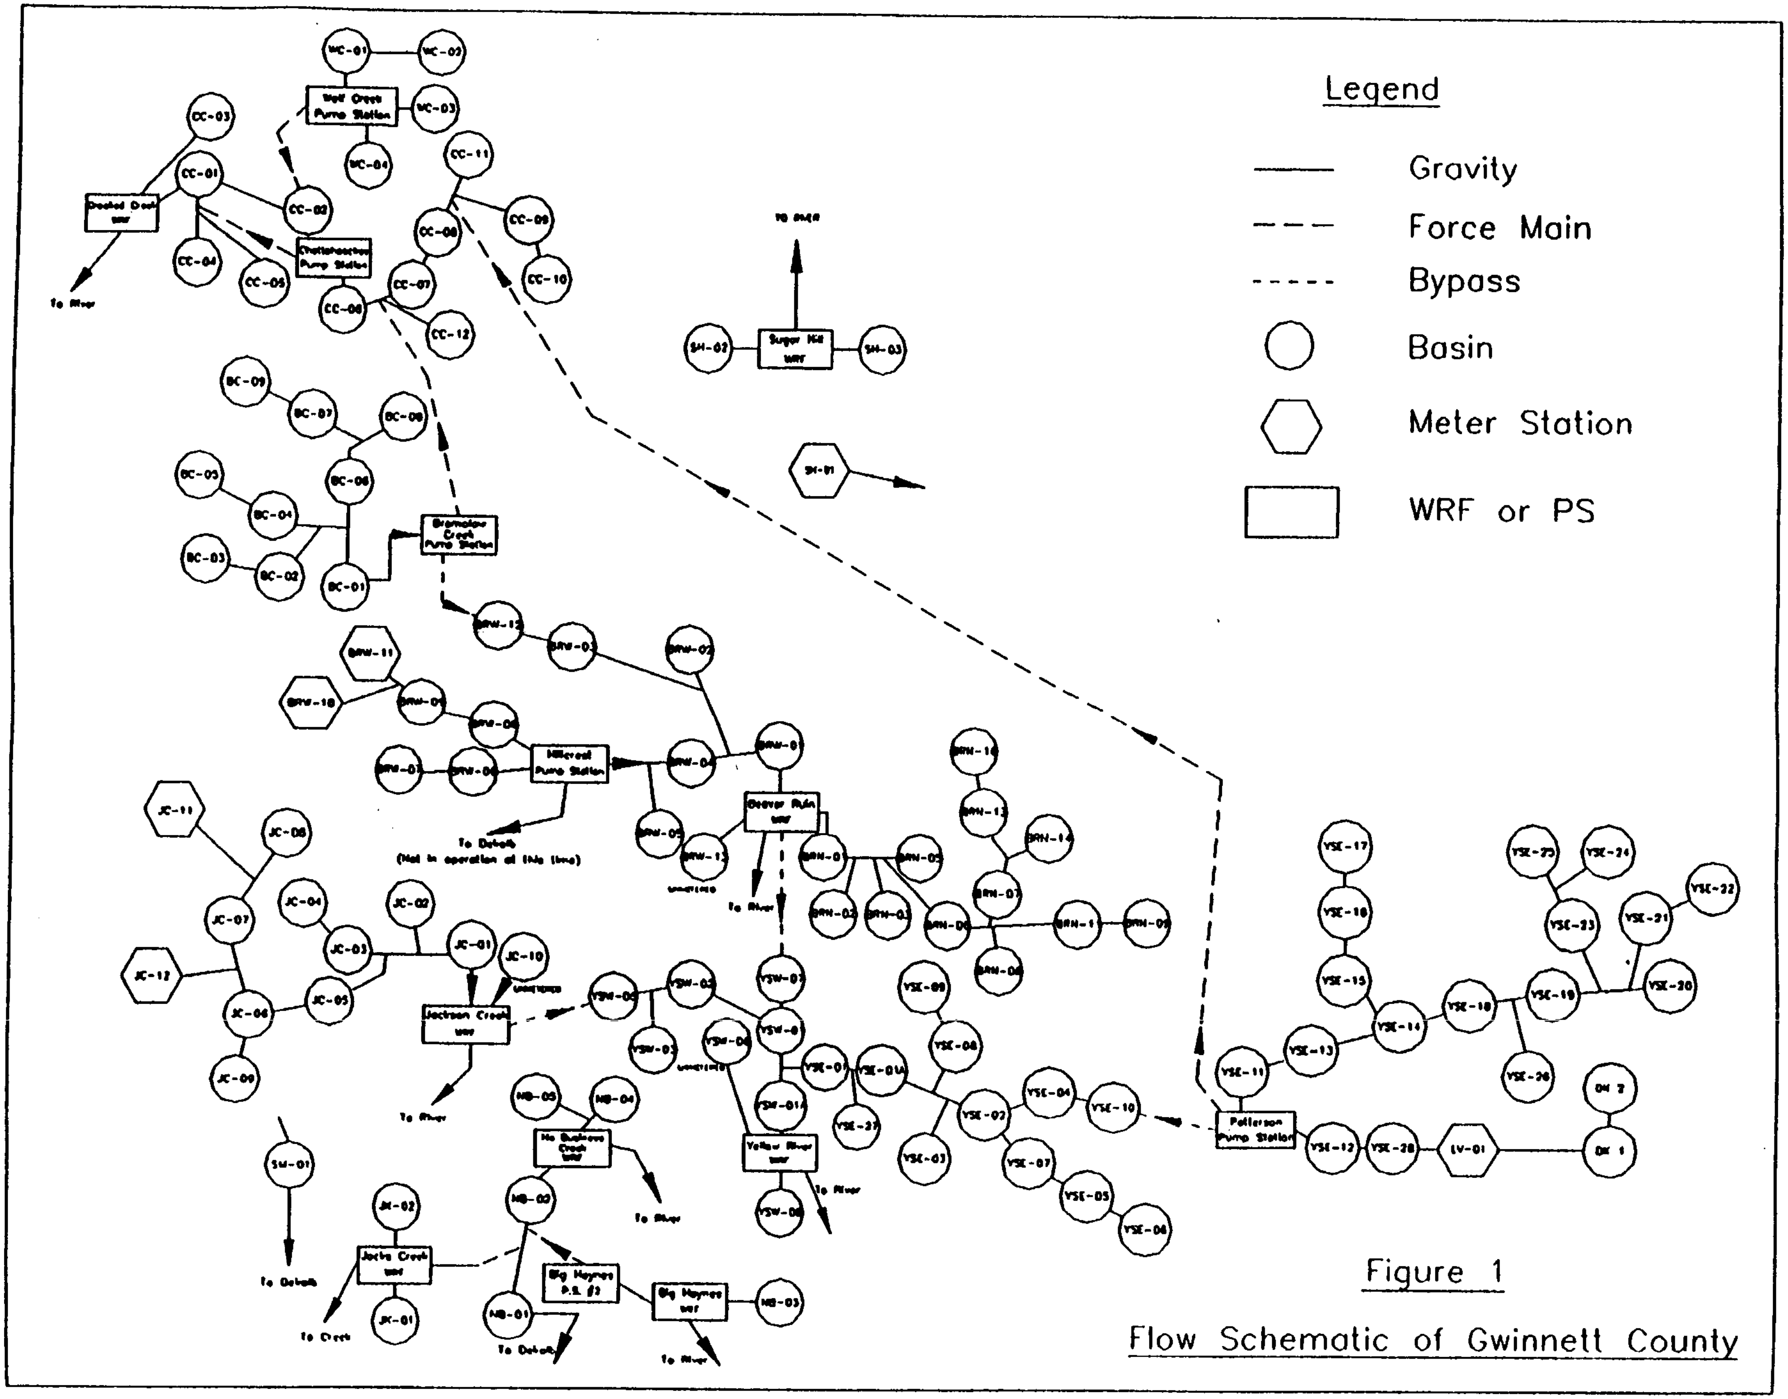

Figure 1

Flow Schematic of Gwinnett County

- The point in time of peak flow from an upstream site is extended because of wet-well detention times.
- By-passed flows are not predictable and may vary without respect to inflow related events.

Inflow in a sanitary sewer system is defined as extraneous flow that is a direct result of stormwater runoff. Inflow may enter the sewer from a variety of sources including; downspouts, area drains, storm sewer cross connections, and manhole covers. Inflow replaces valuable system capacity in collection networks and treatment plants and may cause sanitary sewer overflows (SSO) if present in sufficient quantities. The determination of inflow rate is made by comparing the antecedent, dry-day conditions at a given meter site with peak flow recorded at the meter site during a rainfall event. The rainfall during the peak 60-minute rainfall intensity was plotted against peak inflow for a variety of storms to determine the relationship between the data sets. For example, if the wet-day flow rate at the peak period is 4,690 liter/minute (L/m), or 1.75 million gallons/day (mgd), and the corresponding dry-day flow at the corresponding time is 3,943 L/m (1.50 mgd), the inflow is expressed as the wet-day flow rate minus the dry-day flow or 657 L/m (0.25 mgd).

Several techniques were applied to facilitate inflow analysis in light of the limiting factors mentioned above. These included:

- Averaging data over known pumping cycles.
- Differential time adjustment to match peak flows between upstream and downstream locations, and
- Graphical hydrograph comparison for data verification and cumulative effect analysis.

Data Averaging

Data may need to be averaged over the normal pumping cycle when picking a point to analyze for inflow in the case of a pumping station with constant speed pumps. The hydrograph produced by pumped flow does not mirror the actual flow in the system upstream of the pump station. The observed peak is limited by the maximum capacity of the pump not the actual flow that would otherwise be observed. (In many cases, the pump capacity will exceed the peak inflow rate tributary to the station.) What will occur is that the frequency of pumping increases during wet-weather. The minimum (pump off) and maximum (pump on) rates will not vary, but the peaks will be closer together with respect to time. Therefore, the data must be averaged over a period of time during the storm event. It is not practical to select a discreet data point.

Differential Time Adjustment

The analyst should account for the time difference between peaks observed at connecting meters, based on the distance between sites, and whether or not they are connected by gravity sewer or force main. For situations where pumped flow inputs occur, the length of sewer and the flow velocity can be determined to estimate travel time. This travel time can be significant if the pumped flow originates from a long distance away. The travel time is subtracted from the time the peak is observed at the downstream meter. The peak comparison can then be made for the same storm event at equivalent times.

Graphical Comparison

An effective means to analyze interrelated sets of data is by graphical superimposition to detect observable time of concentration differences in upstream flow inputs, including pumped flow and by-passed flow. This technique allows for analysis of storm inflow effects at the desired meter location while accounting for the influence of the upstream inputs. The downstream hydrograph can be viewed as a composite of the upstream hydrographs. In this way, choosing the peak inflow point for the analyzed meter site was done after accounting for the upstream peaks finally flowing past the meter site. This technique is used in conjunction with differential time adjustment to pick the time of peak inflow. Once the true peak point is established, then the upstream inflow values are subtracted from the desired downstream meter location. The difference is the amount of inflow attributable to the drainage area in question, and not upstream sources.

RESULTS

Data Averaging

Initially, data was collected regarding pumping stations to determine whether or not they were supplied with constant speed or variable speed pumps. This information assists the analyst when interpreting the flow data. An example of a meter site subject to upstream pump station influence is illustrated in figure 2. The upstream pump station serves a residential area and is supplied with constant speed pumps. The graph represents flow data averaged over 5-minute intervals. Longer pump run times produce higher flow rates at expected times such as mid-moming and early evening. The general shape of the graph depicts a typical diumal hydrograph; however, the effects of pumping are also apparent from the continuous oscillation of flow throughout the day. This makes picking the true flow peak difficult. In this case, the data was graphed using 15-minute averages. This produced a smoother graph with an obvious peak at 11:25 p.m., as shown in figure 3. The preceding dry-day flows are superimposed to show the expected flow rates during dry conditions. The dry-day peak flow for comparison was determined to be at 11:35 p.m. after examination of tabular 5-minute data. This point accounts for pumping. This example produced a wet-day flow of 2847 L/m (1.083 mgd) and a dry-day flow of 1698 L/m (0.646 mgd). The net difference is 1149 L/m (0.437 mgd), which is the inflow for this location.

Differential Time Adjustment

The peak hourly intensity for the rainfall event in the above example began at 10:15 p.m. After allowing for detention time in the wetwell, a clear peak can be observed in figure 3. This peak is not shifted radically, occurring about one hour after the peak rainfall intensity. It is important for the analyst to understand the nature of the collection system upstream of the meter site. In this case, the pumping station has approximately 1,400 linear feet of force main which discharges about 6,000 linear feet upstream of the meter location. It is known that the gravity sewer velocities in this portion of the system range from 0.61m/s (2 ft/s) to 1.22 m/s (4 ft/s). this would produce a time of concentration of 40 to 80 minutes. The peak was observed at 11:25 p.m. and is consistent with the known collection system criteria.

Graphical Comparison

Figure 4 illustrates how superimposition on a common scale of wet-day/dry-day and upstream/downstream meter data helps the analyst to interpret inflow effects. The feature that is initially obvious is the shift of inflow peaks from the upstream, by-pass meter at site BRW-12 to the downstream meter at BRW-03. The BRW-12 site measures flow by-passed from an upstream pump station at Bromolow Creek. This effect is consistent with the known conditions of the system and serves as a verification check of the data from both locations.

It is also observed that anomalies in flow can occur from by-pass sites. These types of sites can have broad variations based on either the mode of operation of the pumping station or treatment plant just upstream. In this case, BRW-12 shows a dry-day flow spike at roughly 6:30 p.m. This would skew the inflow results downward if this point was chosen as a dry-day reference. It was helpful to use these points, however, to determine the differential time adjustment between sites.

For this example, rain effects are very noticeable at each site. Dry-day and wet-day flows track closely until the peak storm intensity occurs at 2:15 p.m. Both curves then begin a pronounced increase. The peak is observed at BRW-12 at approximately 4:15 p.m., reflecting the relatively large drainage area to this meter. The peak at BRW-03 is shifted to approximately 5:15 p.m., reflecting the separation between sites. The calculated gross inflow at site BRW-12 is 1,632 L/m (0.621 mgd) and 4,101 L/m (1.560 mgd)

at site BRW-03. The net flow from BRW-03 is 2,469 L/m (0.939 mgd). Table 1 shows the data values extracted from the graphs for inflow analysis.

Table 1. **Inflow Computation Example Data**

	Peak Wet-day Flow (A)			Peak Dry-day Flow (B)			(A)-(B)
Meter Location	Rate (L/m)	Date	Time	Rate (L/m)	Date	Time	Inflow (L/m)
BRW-03	7,313	2/21/97	17:35	3,212	2/20/97	17:05	4,101
BRW-12	3,912	2/21/97	17:35	2,279	2/20/97	17:05	1,632
				Net Inflow at BRW-03			2,469

DISCUSSION

If data for a meter site which is subject to pumped flow inputs is not averaged, it is possible to pick a data point on the downside of a pump cycle, giving an inaccurate result. With respect to differential time adjustment, it should be noted that small pump stations or overdesigned stations may have a large impact on inflow analysis because of relatively long wet well detention times. It is important that the analyst understands the exact nature of upstream pump stations to assess probable detention times. Typical inflow analysis requires a minimum of three to four measurable storms to generate an inflow to rainfall intensity relationship. When plotted on log-log paper, the points will form a line from which a linear regression analysis can be performed. The level of confidence of data correlation is improved with additional data points. When dealing with the effects of pumped or by-passed flows, it is desirable to obtain additional data points to improve the fit of the inflow-rainfall intensity curve. This helps mitigate the potential error introduced when interpreting pumped flow data.

CONCLUSIONS

Although meter sites may be chosen to avoid pumped flow or other irregular inputs, they cannot be avoided in all cases. The techniques described in this paper provide approaches which the data analyst may employ to account for the unique flow patterns produced by pumped flow and by-passed flow inputs.

AN INTENSIVE FIELD SAMPLING PROGRAM IN SUPPORT OF A NUMERICAL TOXICANT FATE AND TRANSPORT MODEL AND RISK ASSESSMENT OF THE DUWAMISH RIVER AND ELLIOTT BAY, WASHINGTON

ABSTRACT

The Duwamish River and Elliott Bay urban estuary, located in Seattle, Washington, is an important natural and economic resource for the Puget Sound region. A field sampling program was undertaken in the winter of 1996-97 to provide data to support a toxicant fate and transport modeling effort and risk assessments on combined sewer overflow (CSO) discharges in the Duwamish River and Elliott Bay system. Results of this CSO Water Quality Assessment will provide decision makers with information integral to long-range CSO control planning.

The field program sampled conventional parameters, bacteria, trace metals and organic compounds in matrices including the water column, sediments, CSO discharges and fish and invertebrate tissues. Water column and sediment samples were collected weekly, with daily water samples collected for the three days following CSO events. CSO samples were collected by automated samplers. Biological samples were obtained through a number of methods, including fishing and trawling. A special study with transplanted and wild mussels documented differences in tissue chemical concentrations encountered in dry and wet seasons. Surveys were undertaken to characterize differences in the benthic community proximal and distal to a CSO.

A number of specialized sampling and analytical techniques were used . Organic concentrations were too low to detect using our traditional sampling and laboratory methods. Semi-permeable membrane devices were deployed to assess water column concentrations of organic compounds, these samplers estimate the average concentration of organic compounds over time. Low level mercury sampling was also employed to estimate mercury concentrations in the water column.

water quality, combined sewer overflows, field sampling program, Duwamish Estuary

INTRODUCTION

The King County CSO Water Quality Assessment for the Duwamish River and Elliott Bay was funded in 1995. Its purpose is to provide information for making decisions about the future of the CSO control program in King County. The State of Washington has adopted a long-range standard for CSO control equivalent to no more than one overflow per discharge point per year in an average rainfall year. The long-range planning process for wastewater treatment in King County has estimated the cost of achieving this standard to be $600,000,000.

The primary question, on the part of county decision makers, is: What is the significance of risks caused by CSOs and how can the region most effectively address these risks? Evaluating these risks will provide decision makers with information for optimizing the CSO program through prioritization of current and future CSO control projects.

The Water Quality Assessment was designed to answer these questions using both the US EPA Ecological Risk Assessment Framework (EPA, 1996) and the Water Environment Research Foundation (WERF) protocols for Ecological Risk Assessment (WERF, 1996). Risks to people are being assessed within the framework of ecological risk but using the EPA Human Health Risk Assessment Guidelines (EPA, 1989). The first objective of the Water Quality Assessment was to understand the existing conditions of the Duwamish River and Elliott Bay in terms of level of risk to aquatic life, wildlife, and people who use these water bodies. A second objective was to understand the significance of CSO stressors compared to those of other sources.

The purpose of the field sampling program for the Water Quality Assessment was to provide empirical data that could be used in the human health and ecological risk assessments and to calibrate the toxicant fate and transport model. The field sampling program was integral to addressing the first objective of the Water Quality Assessment - the risks to human health, aquatic life, and wildlife from existing conditions in the Duwamish River and Elliott Bay.

COMBINED SEWER OVERFLOWS

Combined sewer overflows or CSOs, are discharges of untreated sewage and stormwater released directly into surface waters during periods of heavy rainfall (King County 1995). Combined sewers, those which carry sanitary sewage and storm runoff in a single pipe, are found in much of metropolitan Seattle. Because combining systems was the standard engineering practice, all of Seattle's sewers built from 1892 until the early 1940s were combined sewers. As newer sewers were installed in Seattle, storm water was separated from household, commercial, and industrial wastewaters.

Combined sewer overflows serve as safety valves for the sewage treatment system. In combined systems, the trunk sewers and interceptors have fixed capacities. During periods of heavy rainfall, wastewater volumes may exceed the capacity of the sewer pipes to convey the wastewater to the treatment plant. To prevent damage to the system and to prevent sewers from backing up into homes, combined sewers are designed to overflow. Typically, overflows are designed to discharge to rivers and marine waters where the flushing action of tides and currents can disperse pollutants.

City of Seattle and King County (formerly Metro) overflows occur within the study area in both the Duwamish River and Elliott Bay. From 1981 to 1983, nearly 2.4 billion gallons of untreated sewage were discharged from this system each year. As a result of control efforts, this volume was reduced to 1.8 billion gallons per year by 1994 (King County 1995).

PROJECT METHODOLOGIES

The methodologies for ecological and human health risk assessment designed by the US Environmental Protection Agency (USEPA 1989; 1992; 1994; 1996; and the Water Environmental Research Foundation (Parkhurst et al. 1996) are being used to describe risk that may be occurring to aquatic life, wildlife, and people who use the Duwamish River and Elliott Bay, and how the risk could change with control of CSOs.

A model that predicts the concentrations of chemical stressors and other potential changes in the water body will drive the risk assessment. The model is essential to predict conditions in the estuary if CSOs are eliminated. The model also provides a way to fill gaps in data on current conditions. The modeling effort is supported by a sampling program that allows model calibration and detailed characterization of the physical, chemical, and biological stressors entering the Duwamish River/Elliott Bay ecosystem. This paper will describe the various components of the field sampling program which provided the input to the water quality model and risk assessment.

STUDY AREA DESCRIPTION

The Water Quality Assessment study area, shown in Figure 1, includes the Green-Duwamish River from just upriver of the East Division Reclamation Plant (Renton Sewage Treatment Plant) downstream to where it enters Elliott Bay, a distance of approximately 24 kilometers (km). The study area also includes the portion of Elliott Bay east of an imaginary line drawn from Duwamish Head north to Magnolia Bluff.

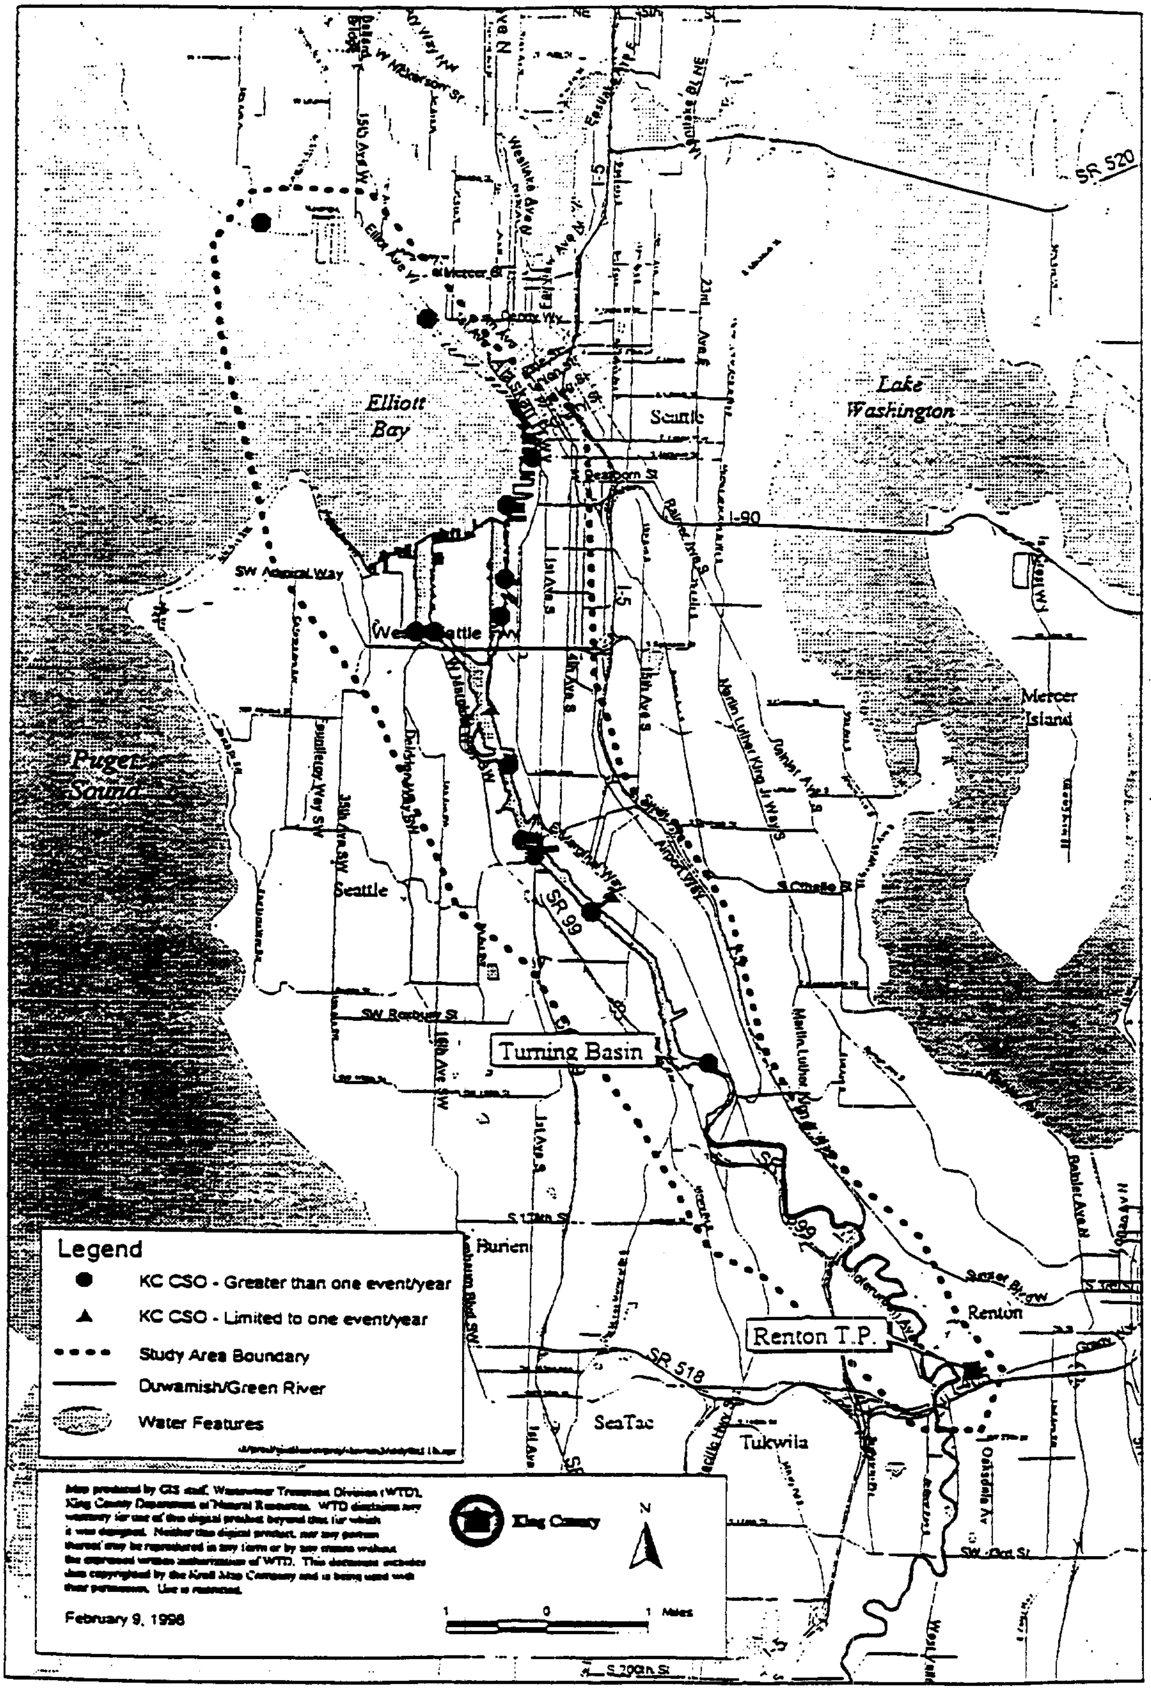

Figure 1. Water Quality Assessment Study Area

The lower Duwamish River is a highly industrialized, salt-wedge estuary influenced both by river flow and tidal effects. At its mouth, the river splits into the East and West Waterways, flowing around Harbor Island into Elliott Bay. The river is considered an estuarine system, exhibiting both marine and fresh water characteristics. During periods of normal river flow, the salt wedge extends upriver approximately 13 km with its terminus or "toe" near the navigational turning basin. From the turning basin upriver to the Renton Sewage Treatment Plant, the river flows through areas of light commercial and residential uses.

The lower portion of the Duwamish River, below the turning basin, has been straightened, dredged, and rip-rapped to facilitate navigation and commerce. Upriver of the turning basin the river continues to flow through its historic channel. River depths range from approximately 17 meters (m) near the mouth to less than a meter in some areas of the upper portion of the study area. Bottom sediments range from coarse sand to fine silt depending on sediment sources and river hydrodynamics. River flows are largely controlled by releases from the Howard Hansen dam, located in the upper Green River watershed. Summer flows, gaged at Auburn, Washington are in the range of 7 cubic meters per second (cms). Winter flows average approximately 45 to 55 cms with peak flows greater than 150 cms during storm events.

Elliott Bay, approximately 21 square km in area, forms the western boundary of the commercial core of Seattle. Land use surrounding the bay is mainly marine-oriented industrial and commercial with marine traffic on the bay heavy at all times of the year. The bay opens to the main basin of Puget Sound to the east.

Depths in the bay on the western edge of the study area range from 150 to 180 m while depths near the Seattle waterfront are in the range of 10 to 20 m. The open portion of Elliott Bay is dominated by Puget Sound marine water masses with the fresh water lens from the Duwamish River occupying the upper 5 m. Natural shorelines with intertidal zones are present along the northeast and southwest shores of the bay. In the commercially developed portions of the bay, piers and rip-rapping have replaced natural shorelines. Bottom sediments in the bay range from fine sediment to coarse gravels and cobble.

FIELD SAMPLING PROGRAM FOR THE WATER QUALITY MODEL

The field sampling program for the water quality model generated data from three matrices; CSO effluent, receiving water, and sediment. These data will be used to model the chemical, physical, and microbiological characteristics of the Duwamish River and Elliott Bay during both storm and non-storm conditions. All sampling and routine analytical work was performed by staff of the King County Environmental Laboratory.

CSO Effluent

Effluent samples were collected during discharges from five CSO locations. At two of the locations, sequential and composite autosamplers were placed side-by-side at the outfall structure. The placement allowed comparison of effluent chemical and microbial concentrations at various times during the discharge event (sequential sampling) to concentrations over the entire duration of the event (composite sampling.

At the third location, three composite autosamplers were placed with the sampling intakes at three different depths in the effluent stream. This placement allowed comparisons of concentrations at the bottom, middle, and surface of the effluent stream.

Placements at the fourth and fifth locations included, respectively, side-by-side sequential autosamplers to provide replicate sampling for field quality control and a single, composite autosampler.

Intake lines for the autosamplers were placed in the wet well at each location. Sampling events were triggered by flow conditions monitored by King County's computerized flow-monitoring system SCADA (Supervisory Control And Data Acquisition).

CSO effluent was routinely analyzed for the following conventional parameters: chemical oxygen demand, total organic carbon, volatile suspended solids, ammonia nitrogen, nitrate/nitrite nitrogen, and total suspended solids. Chemical oxygen demand, total organic carbon and volatile suspended solids provided an estimate of the organic content of the CSO effluent. Analysis of the various forms of nitrogen allowed evaluation of the contribution of these nutrients to receiving water from CSO effluent. Conventional parameters measured in the field included temperature, conductivity, and pH.

Metal parameters included the following thirteen priority pollutant metals: antimony, arsenic, beryllium, cadmium, chromium, copper, lead, mercury, nickel, selenium, silver, thallium, and zinc. Analysis of these samples was performed by ICP-MS (inductively coupled plasma mass spectroscopy) to obtain the lowest-possible detection limits. The samples also were analyzed by ICP (inductively coupled plasma optical emission spectroscopy) for calcium and magnesium to allow a hardness calculation since fresh water quality criteria for metals are hardness normalized.

To obtain the lowest possible detection limits for mercury, a separate low level mercury study was also undertaken for CSO effluent and receiving water. Sampling methodologies followed guidelines specified in EPA Method 1669, the "clean hands/dirty hands" technique. Collection of a greater number of field QC samples allowed evaluation of the final quality of the data. Low level mercury analysis by Cold Vapor Atomic Fluorescence was performed by Brooks Rand, Inc. of Seattle, Washington.

Organic parameters included all of the priority pollutant base/neutral/acid (BNA) extractable semivolatile organic compounds with the addition of caffeine and coprostanol, two compounds which act as tracers for the sewage component of CSO effluent.

Fecal coliforms were routinely analyzed in CSO effluent samples as an indicator species for other pathogens.

Receiving Water

Receiving water samples were collected from 21 stations in the Duwamish River and Elliott Bay to evaluate the chemical, physical, and microbiological characteristics of receiving water during both storm and non-storm conditions. Samples were collected over two 26-week periods.

At most stations in the river and bay, samples were collected from two depths; one meter below the surface and one meter above the bottom (or a maximum depth of 20 m at the deeper stations). Sampling at two depths allowed an evaluation of the differences between the overlying fresh water and the salt water at each station. At very shallow stations samples were collected only at a depth of one meter. Samples were collected weekly except in the event of storm conditions causing a significant discharge at two or more of the target CSOs. During storm conditions, samples were collected at all 21 locations daily for a period of three days following the CSO discharge event.

Routine receiving water samples were collected either from the King County Environmental Laboratory's research vessel *Liberty* or from shore. In non-navigable areas, receiving water samples were collected from bridges. Samples collected from bridges employed Van Dorn or Niskin bottles lowered by rope to the water surface. Sample bottles were lowered to a depth of approximately one meter below the surface and the closing mechanism tripped to facilitate the collection of a discrete sample.

Samples collected from the *Liberty* used Niskin bottles deployed on a hydrowire. The Niskin bottles were lowered on the hydrowire to depths of one meter below the surface and one meter above the bottom (or 20 meters in depth) simultaneously at each station.

Receiving water was routinely analyzed for the following conventional parameters: total organic carbon, volatile suspended solids, ammonia nitrogen, nitrate/nitrite nitrogen, and total suspended solids. Where the receiving water is fresh, analysis of chemical oxygen demand was also performed. Conventional parameters measured in the field included dissolved oxygen, temperature, conductivity/salinity, and pH.

Fresh and marine receiving water was analyzed for the same suite of metals mentioned above by ICP and ICP-MS. The salinity and dissolved solids concentration of marine water, however, imparted a high degree of interference to the ICP-MS analysis. Special sample preparation was conducted on marine receiving water samples prior to analysis. The sample preparation consisted of a "reductive co-precipitation" process which both removed chloride and other dissolved solids interferences as well as concentrating the sample to improve detection limits.

BNA compounds (including caffeine and coprostanol) were analyzed for every fourth set of receiving water samples. Grab sampling did not prove to be the most successful method for detecting organic constituents and routine analysis was done to confirm that these compounds were not present above standard detection limits.

Receiving water samples were routinely analyzed for fecal coliforms.

In addition to the receiving water sampling scheme described above, separate sampling tasks were undertaken for the evaluation of trace-level organics and mercury.

To obtain the lowest possible detection limits, special sampling events for the collection of mercury samples were undertaken in association with Brooks Rand, Inc. of Seattle, Washington. Sampling from the *Liberty* employed a peristaltic pump and Teflon® tubing to allow virtually hands-free collection of water samples *in situ*. This minimized contamination either from sampling equipment or the environment. Sampling from shore employed a Teflon® bailer and associated deployment equipment. Special precautions outlined in EPA Method 1669 were followed and several field QC samples were collected, including tubing blanks, atmosphere blanks, filter blanks, and bailer blanks. Sampling equipment was supplied and Cold Vapor Atomic Fluorescence analysis of mercury was performed by Brooks Rand.

Organic compounds are difficult to detect in ambient receiving water samples collected as discrete grabs. To better understand the existing organic compound concentrations in receiving water, semipermeable membrane devices (SPMD) were employed to collect time-integrated water samples. The SPMD were, essentially, pre-cleaned polyethylene sheets which accumulated organic compounds over time. The SPMD concentrate non-polar or lipophilic compounds over a specified time period. Resulting data can then be used to estimate the average receiving water concentrations by applying compound-specific partitioning coefficients. SPMD analysis was performed by Battelle Marine Sciences Laboratory in Sequim, Washington. Analytical parameters included polynuclear aromatic hydrocarbon (PAH) compounds, chlorinated pesticides, polychlorinated biphenyl (PCB) Aroclors®, and PCB congeners. The SPMD were deployed at two locations in the Duwamish River for a period of two weeks. SPMD were attached to a rope-float-anchor assembly which was deployed and retrieved as quickly as possible to minimize contamination. To assess possible contamination by airborne organic compounds, a trip blank was exposed to the air for the same amount of time as one SPMD during deployment and retrieval.

Sediment

Sediment samples were collected from five locations in the Duwamish River for a period of 18 weeks. At one CSO location, sediments were collected weekly for the entire 18 weeks. At a second CSO location and at an in-river reference location, sediments were collected weekly for a period of 14 weeks. At two other in-river reference locations, sediments were collected weekly for a period of four weeks. At each location, a single sample was composited from 10 sediment grabs, laid out on a 5-m square grid. Samples were collected from the top two centimeters (cm) at each grab station. Sediment samples were collected from the *Liberty* using a modified, stainless steel Van Veen grab sampler. The grab sampler was lowered on a hydrowire and, upon retrieval, the sample was visually inspected for acceptability. If acceptable, a 200 cubic centimeter aliquot was collected from the sample using a stainless steel cookie cutter and placed in a stainless steel bowl. An aliquot was collected from each of the subsequent nine grab stations and the sample thoroughly homogenized before placement in sample containers. Oxidation-reduction potential, was measured in each of the ten individual grab samples with an electronic meter.

Sediment was routinely analyzed for particle size distribution, total solids, total organic carbon, ammonia nitrogen, and total sulfides. Particle size distribution and total sulfide analysis was performed by AmTest, Inc. of Redmond, Washington. Analysis of total solids allowed sediment organic and metal data to be normalized to dry weight. Some organic data are also normzalized to organic carbon, based on the results of the total organic carbon analysis.

Sediment analysis also included those metals regulated under the State of Washington Sediment Management Standards (Chapter 173-204 WAC) which include arsenic, cadmium, chromium, copper, lead, mercury, silver, and zinc as well as the remaining priority pollutant metals (antimony, beryllium, nickel, selenium, and thallium). The mineral metals, aluminum and iron, also were analyzed to provide a potential method for normalizing other metal concentrations to local geological conditions. Organic forms of metals, including butyltin isomers and methyl mercury, were also analyzed in sediment due to their potential toxicity through bioaccumulation. Methyl mercury analysis was performed by Frontier Geosciences, Inc. of Seattle, Washington.

Sediment samples were analyzed for all organic parameters specified in the Sediment Management Standards. These parameters include the BNA compounds and PCBs.

FIELD SAMPLING PROGRAM FOR THE HUMAN HEALTH AND ECOLOGICAL RISK ASSESSMENTS

The field sampling program for the ecological and human health risk assessments generated two types of data; chemical concentrations present in fish and shellfish tissue and abundance of benthic infaunal organisms. These data will be used directly in calculations used to ascribe risk to human health and the ecological receptors established as risk assessment endpoints for the WQA project.

Bioaccumulation of Chemicals in Fish and Shellfish

Chemical concentrations present in fish and shellfish from the Duwamish River and Elliot Bay were evaluated through two studies.

An *in situ* bioassay using transplanted mussels was conducted twice near several CSO outfalls and in-river reference stations. Mussels were collected from a "clean" baseline location and transplanted into the Duwamish River and Elliott Bay for a period of one month, both during wet and dry season river-flow conditions. Mussel tissue was analyzed and chemical concentrations will be compared between transplanted mussels, ambient or wild mussels, and mussels from the baseline sampling location.

Chemical analysis of various fish and shellfish tissue was conducted on samples collected by Washington State Department of Fish and Wildlife personnel as part of their Puget Sound Ambient Monitoring Program work. Tissue was collected from English sole, quillback rockfish, Dungeness crab, spot prawn, and numerous small fish. In addition, samples of squid and benthic invertebrates were collected by King County personnel for chemical analysis. Tissue samples were resected, homogenized, and analyzed by King County personnel. All tissue collection was performed following methodologies suggested in *Recommended Guidelines for Sampling Marine Sediment, Water Column, and Tissue in Puget Sound* (PSEP, 1996).

All tissue samples were analyzed for the thirteen priority pollutant metals mentioned above in addition to butyltin isomers. Tissue samples were also analyzed for BNA compounds (including caffeine and coprostanol), PCBs, and percent lipids and total solids. Analysis of total solids and percent lipids allowed normalization of tissue chemical data to dry weight and lipid content, respectively.

Fecal coliforms were analyzed in tissue samples collected from wild mussels located near one in-river CSO. Baseline samples were collected prior to a discharge event and additional samples were collected following the discharge event. In addition to fecal coliforms, mussel tissue samples were analyzed for viruses, salmonella, and *Yersinia* bacteria.

Abundance and Diversity of Benthic Infauna

Numbers of species present in benthic sediment in an area influenced by a CSO were compared with similar data from an in-river reference area. Additional comparisons between the impacted and reference sites were made by employing standard reference species numbers and other indices developed by the Washington State Department of Ecology for Puget Sound. In addition to the benthic analysis, the sediment samples were analyzed for chemical and physical characteristics.

Sediment samples were collected near a CSO outfall and at an in-river reference station. Both sampling sites included a transect of five grab stations. Samples were collected by Striplin Associates personnel assisted by King County personnel. Sample collection followed methodologies suggested in *Recommended Guidelines for Sampling Marine Sediment, Water Column, and Tissue in Puget Sound* (PSEP, 1996) and *Recommended Protocols for Sampling and Analyzing Subtidal Benthic Macroinvertebrate Assemblages in Puget Sound* (PSEP, 1987).

In addition to the taxonomic analysis, the benthic sediments were analyzed for the physical and chemical analyses mentioned previously. This analysis provided data regarding the chemical and physical nature of the sediment in which the benthic organisms reside.

SUMMARY

Completion of the field sampling program has provided the project team with a large volume of high-quality data with which to model toxicant fate and transport in the study area as well as perform human health and ecological risk assessments, thus meeting the initial goals of the field sampling portion of the project. The field data, in addition to hydrodynamic data, have been used to successfully calibrate the toxicant fate and transport model for 19 chemicals of potential concern as well as fecal coliform bacteria. One-year model simulation runs have been completed and the output has been submitted to the risk assessment team. Ten-year model simulation runs and the risk assessments are scheduled to be completed during the summer of 1998.

In summary, during the course of the King County Water Quality Assessment project, over 13,000 analyses were performed on nearly 2,000 water, sediment, and tissue samples. Challenges to this intensive field sampling program included mobilizing field and analytical staff during storm events, development of new field and analytical methodologies, and management of sample throughput and large database.

ACKNOWLEDGMENTS

Several staff of the King County Environmental Laboratory were instrumental in the success of this sampling and analytical program, investing both time and expertise to develop new methodologies and manage the sheer volume of samples and resulting data. They include Ben Budka, Marc Patten, and Jean Power of the Environmental Services Unit, Bob Kruger of the Conventionals Laboratory, Diane McElhany of the Trace Organics Laboratory, John Rowan of the Trace Metals Laboratory, and Debbie Turner of the Microbiology Laboratory.

SEASONAL CHARACTERIZATION OF STORMWATER QUALITY IN AN URBAN RESIDENTIAL AREA

Amy M. Schofield, Boston Water and Sewer Commission*
Lisa D. Eggleston, P.E., Eggleston Environmental

*** BWSC, 425 Summer Street, Boston, MA 02210**

ABSTRACT

The Residential Stormwater Monitoring Project was initiated by the Boston Water and Sewer Commission in March of 1997. The purpose of the project was to characterize the seasonal variation in the quality of stormwater discharged from a low-density residential area. The project included precipitation monitoring, stormwater quality sampling and quantification of flows at a single manhole location for up to five storms per season for a period of one year, surface stormwater quality sampling at five gutter locations, and inspection and sampling of dry weather flows in storm drains. Based on the data collected event mean concentrations and loading estimates were calculated and compared with earlier data, and recommendations were developed for stormwater quality improvements for the project area and for future stormwater monitoring projects.

INTRODUCTION

The Boston Water and Sewer Commission is statutorily responsible for maintaining storm drainage systems in the City of Boston. The Commission currently maintains 92 major and 98 non-major storm drain outfalls. Approximately one quarter (11 square miles) of Boston is served by separate storm drains. The remainder is served by combined sewers or separate storm drains which discharge to combined sewers.

The Commission completed a two-part NPDES Stormwater Permit Application (Permit Application) and submitted it to EPA in 1993. As part of the application the Commission collected stormwater quality and flow data during a four-month period for five representative land use areas in Boston. Annual pollutant loadings were calculated based on an event mean concentration for each parameter. Inherent in the calculations was the assumption that pollutant concentrations do not vary significantly throughout the year. While this assumption is reasonable for some parameters, others may be subject to seasonal variations due to specific activities occurring within drainage areas during certain times of the year, as well as the effects of temperature and other climatic conditions on pollutant levels.

The Commission initiated the Residential Stormwater Monitoring Project in March of 1997. The purpose of the project was to characterize the seasonal variation in the quality of stormwater discharged from a low-density residential area. Low-density residential is the primary land use in the separated areas of Boston. The study area is an 84 acre area located in the West Roxbury neighborhood of Boston. The study area is part of a larger 484 acre drainage area tributary to Bussey Brook which is located in the Charles River Watershed. A small portion of the study area and most of the larger drainage area are located in the neighboring town of Brookline. The area was monitored during preparation of the Commission's Permit Application. Topography in the drainage area is relatively flat, with an average slope of five percent. Land use in the study area is primarily single-family residential with two-family houses interspersed. Of the 523 housing units in the study area, 369 or 71 percent are single-family and 29 percent are two-family. The Thomas J. Hynes Field, a public park about 6-1/2 acres in size, and the Lyndon Elementary School are also located in the study area. The average single-family home lot size is about 1/8 of an acre. Taking road surfaces, driveways and parking areas into account, as well as roof drains which are hydraulically connected to the drainage system, impervious area in the study area is estimated to be about 37 percent.

Storm drains vary in size from 10-inches in the drainage area's upper reaches to 60-inches at each of the two parallel outfalls. Theoretically, flows from the study area can discharge through either outfall. However, most of the flow discharges through one outfall due to the configuration of the drainage system and siltation in the other discharge pipe.

METHODOLOGY

To characterize stormwater runoff quality and reflect seasonal variations in weather patterns and pollutants, the Commission attempted to sample up to five storms per quarter for a period of one year. At least two of the storms sampled per quarter were to meet the representative "base case" storm criteria set forth in EPA's NPDES Stormwater Sampling Guidance Document (EPA 833-B-92-001, July 1992). For Boston the representative storm criteria were determined to be as follows:

Antecedent dry weather:	3 days (72 hours)
Rainfall:	0.4 to 1.0 inches
Duration of rainfall:	6 to 18 hours

Up to three additional storms, which did not meet the base case storm criteria were to be sampled each season under varying antecedent conditions. The storm criteria were modified for the winter season, since it was expected that much of the precipitation would be in the form of snowfall, and runoff would be in the form of snow-melt.

Flow/Precipitation Monitoring

To monitor flow in the drainage area, an automatic area/velocity flow meter was installed in the same storm drain manhole monitored during the preparation of the Commission's Stormwater Permit Application. To enable remote retrieval of data, the flow meter was telemonitored via a telephone service line connected to a nearby telephone pole. It was programmed to provide continuous readings at five-minute intervals and record precipitation in one-hundredths of an inch at all times during the project.

To measure local volume and intensity of rainfall in the study area, a precipitation monitoring station was established on the roof of a nearby establishment. The precipitation monitoring station was equipped with a tipping bucket rain gauge with a data logger and associated software. The rain gauge was programmed to operate continuously at five-minute intervals throughout the duration of the project. The rain gauge was not equipped to record accumulated snowfall.

Weather was monitored continuously throughout the project through the *INTELLICAST Boston Weather* internet web site, the NOAA weather (radio) station, and the National Weather Service.

Stormwater Quality Monitoring

The automatic composite sampler used for the project was connected to the telemonitored flow meter in order to allow remote activation during storm events. EPA's Stormwater Sampling Guidance recommend flow-weighted composite samples collected during a representative storm for the first three hours, or for the duration of the storm if less than three hours long. For this project, the decision was made to extend the compositing period to four hours in order to obtain data which were more representative of average New England storm conditions.

Composite samples collected from the sampling manhole were analyzed for total dissolved solids (TDS), total suspended solids (TSS), biochemical oxygen demand (BOD), chemical oxygen demand (COD), nitrite/nitrate-N, ammonia-N, total kjeldahl nitrogen (TKN), organic-N, total phosphorus, chloride, and total and soluble cadmium, copper, lead, zinc and sodium. Total cyanide was analyzed during the winter quarter (January through March), since cyanide is commonly used as a road salt anti-caking agent, and soluble metals were included to enable evaluation of potential toxicity to aquatic biota. Parameters for analysis were selected based on the following criteria:

- o they were present at elevated concentrations in samples collected for the study area during the preparation of the Stormwater Permit Application (bacteria);
- o they are pollutants of specific concern in developing management controls (bacteria, solids);
- o they are pollutants of specific concern in evaluating receiving water impacts (soluble metals, bacteria);
- o they are expected to demonstrate seasonal variability in concentrations (BOD, nutrients, bacteria, solids, metals, cyanide).

Consideration was given to monitoring for pesticides. However, since all of the pesticides detected in samples collected during the preparation of the Permit Application are no longer being manufactured, pesticides were not included in the project parameters.

In addition to composite samples, grab samples were collected from the monitoring manhole to be analyzed for pH, temperature and conductivity and bacterial sampling for fecal coliform, fecal strep and *E. coli*. The grab samples were collected between one and two hours after the start of the storm to avoid skewing the data from first flush effects and to ensure contribution from tributary land surfaces. Oil and Grease (O&G) samples were collected at the outfall, not at the monitoring manhole since collection of the sample directly into the sample container, as protocol requires, could not be done without entering the manhole during wet weather. Also collected were surface runoff samples from gutters situated at five representative locations throughout the drainage area to be analyzed for fecal coliform, fecal strep and *E. coli*. The fecal strep measurement was included primarily for use in determining the fecal coliform/fecal strep (FC/FS) ratio. Two of the gutter sampling locations, the VFW Parkway site and the site at Carlson Circle, were also sampled for O&G. The purpose of this sampling was to assess the contribution of pollutants from surface runoff. Samples were collected between one and two hours after the start of the storm from the deepest part of the surface flow as it approached catch basins.

Dry Weather Inspections

Once during each project quarter, the outfall, monitoring manhole and up to 10 additional manholes in the drainage area were visually inspected during dry weather. Dry weather was defined as three continuous days with less than 0.1 inches of precipitation. Where observed, dry weather flow was measured using a portable velocity meter, and grab samples were collected for on-site analysis of temperature, pH, conductivity, chlorine (residual), copper, surfactants and phenols using a CHEMetrics storm drainage field test kit. Where sanitary sewage contamination was suspected, grab samples were collected and analyzed for fecal coliform, fecal strep, *E. coli*, ammonia-N and fluoride. These tests and further inspection of manholes and dye testing of houses in the study area by the Commission revealed twelve sanitary sewer connections to storm drains in the drainage area, eight of which were located in the study area. Two of the eight in the study area were located in the Town of Brookline. It is interesting to note that despite the sanitary sewer connections to storm drains in the drainage area, no evidence of sanitary sewage was observed at the outfall during previous monitoring for the Permit Application, nor during the course of this project.

Six of the sanitary sewer connections in the study area, including the two in Brookline, and the two sanitary sewer connections outside the study area were corrected by the beginning of the third (fall) quarter. The two remaining sanitary sewer connections in the study area required special engineering to eliminate, and thus were not scheduled for correction until after the conclusion of the monitoring project. Dry weather inspections conducted in the third and fourth quarters of the project confirmed correction of the eight sanitary sewer connections.

RESULTS/DISCUSSION

Flow/Precipitation Monitoring

Upon installation in April of 1997, the flow meter measured base flow in the storm drain at about 1.5 inches. The base flow gradually decreased over time down to about 0.2 inches by the end of the dry summer quarter, and gradually rose again to about 1 inch during the wetter winter quarter, indicating that the base flow is primarily due to residual runoff and groundwater infiltration.

On close inspection of the first quarter data, regular daily flow increases were observed which corresponded to the daytime hours, when people were most likely using water in their homes. This suggested that at least a small portion of the base flow was due to the existence of sanitary sewer connections to storm drains in the study area. Sanitary sewer connections to storm drains in the study area were confirmed during dry weather inspections and subsequently eliminated as described in the previous section.

Precipitation in Boston was significantly below average during the first three quarters of the monitoring project (April through December). For 1997 overall, average precipitation was 8.43 inches below normal. January through March of 1998 were fairly wet but very mild. Of the 54 storm events occurring during the monitoring period, only eight met all three of the storm criteria established by the Commission at the beginning of the project.

Given the lack of rainfall during the previous months and the insufficient number of storms meeting the storm criteria, the Commission decided midway through the summer quarter to modify the storm criteria in order to capture more storms events. The criteria were relaxed to include any event with more than 0.3 inches of precipitation rather than the previously required 0.4 inches, and a minimum storm duration of four hours. Antecedent conditions were reviewed on a case-by-case basis to determine the suitability of an event for monitoring.

As winter approached the Commission developed special criteria for sampling flows in the drain under varying winter conditions, i.e. after a road de-icing and sanding event or following snowpack melting. However, lack of snowfall in the winter of 1998 prevented much sampling under such specific conditions. The resultant monitoring events included two mixed precipitation events with associated deicing activity, and two winter rain storms.

Based on precipitation and flow data, runoff coefficients were calculated for all precipitation events exceeding the base case minimum precipitation volume of 0.4 inches. The event runoff coefficient was calculated as the portion of precipitation that resulted in runoff, i.e. total runoff volume divided by total precipitation volume. Total precipitation volume was calculated as the total precipitation multiplied by the land area in the study area. Runoff coefficients for this project ranged from 0.03 for a 0.97 inch precipitation event (0.52 in/hr maximum intensity) to 0.28 for a 2.74 inch precipitation event (0.03 in/hr maximum intensity). Runoff coefficients for the winter months were notably higher, possibly due to saturation of the water table or due to frozen ground. Overall the runoff coefficients were consistently lower than those calculated for the Commission's Stormwater Permit Application, even for similar size storms, and they were significantly lower that the coefficient calculated for the area based on EPA's Guidance Manual for Part 2 Applications.

Although 1997 was a very dry year, it is unlikely that this alone would account for the low runoff coefficients demonstrated in this study. The Commission attributes the differences in the runoff coefficients to the use of a different rain gauge location (in closer proximity to the study area) than was used for the Stormwater Permit Application, use of a different, more accurate flow meter, different placement of the meter probe in the drain pipe, and installation of a flow control structure in the drain pipe to improve the accuracy of low flow measurements. Since a portable velocity meter was used to confirm the accuracy of the flow meter, the coefficients calculated for this project are believed to be the most accurate.

Water Quality Data

Stormwater quality data was obtained for 10 storms during the monitoring period. This was only half of the 20 planned at the onset of the project. Of the storms sampled only two met all of the storm event criteria established for the program. Sample Mean Concentrations (SMCs) for conventional pollutants in the composite samples collected from the monitoring manhole are shown in Table 1. Event mean concentrations (EMCs) calculated for the Nationwide Urban Runoff Program (NURP) and EPA's Freshwater Acute Water Quality Criteria are included in Table 1 for comparison purposes.

The relatively large (0.84 inches) storm on November 22, 1997 was sampled twice; once within the first four hours of the storm and a second time after the storm had peaked and rainfall had begun tapering off. The purpose of this sampling protocol was to evaluate the validity of using composite sampling data collected in the first several hours of a storm event (per EPA's sampling protocol) to represent event mean concentrations applicable to the entire runoff volume for the event.

Total Suspended Solids

The storm event on August 13, 1997 exhibited elevated TSS levels in comparison to the August 20-22, 1997 event. This is likely due to the high intensity of the rainfall occurring during the composite sampling collection, resulting in more scouring of pervious and impervious surfaces.

Deicing Parameters

Sodium, chloride, total dissolved solids (TDS) and total suspended solids (TSS) were higher during the late fall and winter storm events after snow storms requiring road de-icing and salting. Cyanide was also detected in composite samples collected on January 23, 1998 and February 12, 1998 after previous storm events required roadway de-icing. Since cyanide was not detected in samples collected during the spring and summer months for the Permit Application it is believed that its presence in the runoff is limited to the deicing season.

Toxic Metals

Copper and zinc exceeded the 1986 EPA Freshwater Acute Ambient Water Quality Criteria in 40 percent and 50 percent of the samples respectively, based on total recoverable metals concentrations. However it is EPA's current policy, as stated in its October 1, 1993 "Metals Policy" memorandum, to recommend the use of the dissolved metal concentration to set and measure compliance with water quality standards, because the dissolved metals concentration more closely approximates the bio-available fraction of metal in the water column. Table 1 also lists the EPA acute toxicity criteria expressed as dissolved metals concentrations, derived using the conversion factors that were subsequently published in the EPA's "Conversion Factors for the Calculation of Dissolved Freshwater Aquatic Life Criteria for Metals" (U.S. EPA, 1995). Comparison of these adjusted criteria with the dissolved metals concentrations measured in the project indicates only one exceedance of the zinc criterion and none of the copper criterion. It should be noted however, that EPA's criteria are hardness-dependent, i.e., the toxicity of the metal is a function of the hardness (expressed as $CaCO_3$) of the water, and EPA's criteria presented in Table 1 are based on moderately hard water (100 mg/l as $CaCO_3$). As a result they may underestimate the toxicity of metals in the softer surface waters typical of New England.

Besides sodium, zinc was the only metal to demonstrate any degree of seasonal variation with the concentrations in samples collected in the fall and winter deicing seasons being higher than concentrations in the summer. Sources of zinc include automotive fluids, tire wear, metal corrosion, paint and deicing salts.

SMC = Event Mean Concentration
NA = Not Available or Not Analyzed
ND = Not Detected
NC = Not Calculated

With respect to individual metals concentrations, cadmium was not detected in any of the runoff samples and does not appear to pose a threat to receiving water quality.

The SMCs of lead measured were significantly lower than those reported in the NURP study and, to a lesser extent, lower than the concentrations measured in the same drainage area during preparation of the Permit Application five years earlier. This trend is consistent with other more recent stormwater investigations and is directly attributable to the decreased use of lead in gasoline. None of the SMCs measured exceeded the acute toxicity criteria for lead.

Nutrients

Concentrations of nitrogen and phosphorus were generally comparable to the NURP EMCs and the Permit Application data for the drainage area. Except for the generally higher concentrations of these parameters in samples collected on August 1, 1997, seasonal variations were not significant. It is possible that the higher concentrations on that data were attributable to summer landscaping activities. However, the conditions were not repeated in any other monitoring event during the spring or summer.

In comparison to other events monitored, high levels of TKN and organic nitrogen were observed in the composite sample collected on November 11, 1997. The concentrations of other forms of nitrogen or of associated parameters were not unusual in this sample. No explanation is evident for this one incident of high TKN and organic nitrogen.

Bacteria

Table 2 shows the results of the wet weather bacterial monitoring at the monitoring manhole and at three of the five of the gutter sampling locations. The results of the bacteria sampling conducted during the storm on November 22, 1997 were not included since the data produced was highly inconsistent, and discussions with the laboratory director indicated that the samples may have been mislabled.

Notes: (1) Concentrations based on grab samples
NA = Not Available or Not Analyzed

The Massachusetts Class B Water Quality Standard for fecal coliform bacteria is a log mean of 200 colonies/100 milliliter (ml). Massachusetts does not have a standard for either fecal strep or *E. coli.* However, the EPA recommended criterion for freshwater bathing beaches is 235 colonies *E. Coli* organisms per 100 ml. In urban runoff, fecal coliform concentrations frequently exceed water quality standards, with typical warm weather concentrations in the 10,000 to 100,000 colonies per 100 range (NURP, 1983). The medan fecal coliform concentration for all the NURP sites was around 21,000 colonies per 100 ml.

As indicated by the data presented in Table 2, fecal coliform concentrations measured in the study area were consistent with the NURP data, although they frequently exceeded the Massachusetts standard. The fecal coliform concentrations measured during preparation of the Permit Application were significantly lower. However, it has been concluded that the Permit Application bacterial data were subject to laboratory error.

Concentrations of bacteria were significantly higher during the warmer summer months, as compared to samples collected during the colder fall and winter months. This was not surprising since it is known that bacteria will survive longer under warm conditions. Antecedent conditions also appear to impact bacterial concentrations, since the two events preceded by only one day of dry weather (October 27, 1997and January 7, 1998) had the lowest concentrations relative to the season. The highest concentrations of bacteria were observed in the surface grab samples collected at the Hynes Field. Observations made during visits to the park and conversations with local residents indicated that the park is a common destination for dog owners in the neighborhood. This strongly suggests that pet waste is a major contributer of bacterial contamination to the stormwater runoff in the project area.

Oil and Grease

Higher concentrations of oil and grease were observed at the surface location which receives runoff from the VFW Parkway as compared to the Carlson Circle site. The VFW Parkway is a highly traveled, four-lane roadway while Carlson Circle is a residential side street. The concentration of oil and grease was below detection in the samples collected during the two events with only one day of antecedent dry weather (October 27, 1997 and January 7, 1998). This is likely due to most of the accumulated oil and grease O&G having already been washed off the road surfaces.

Pollutant Loadings

The two sets of samples collected at different phases of the same storm on November 22, 1997 yielded significantly different results. Pollutant concentrations were consistently lower in the composite sample collected later in the storm. Only nitrate and TKN increased in the later sample, possibly indicative of nitrification processes taking place. These results indicate that the use of composite data from the first several hours of a larger storm event to represent the event mean concentration could result in an overestimation of pollutant loadings due to the more dilute concentrations which occur later in a storm event.

FINDINGS/CONCLUSIONS

Runoff coefficients calculated for this project and for the Commission's Permit Application were significantly lower than the value calculated using the method recommended in EPA's Guidance Manual for Part 2 Applications. Since the runoff coefficients calculated for this project were based on metered flows, they are believed to be the more accurate, thus suggesting that the EPA method overestimates runoff coefficients, particularly for smaller storms.

It appears that EPA's storm criteria are too restrictive for the Boston area. Due to weather conditions few of the storms (only eight of all fifty-four) occurring during the monitoring period met the initial storm criteria of 0.4 to 1.0 inches of rainfall, 6 to 18 hour storm duration and 72 hours of antecedent dry weather. Of the ten storms sampled, only two met the initial storm criteria. It should be noted however, that 1997 was a particularly dry year in Boston and precipitation was much lower than average.

Seasonal variations in pollutant concentrations occurred most frequently in parameters that are associated with winter deicing practices.

Comparison of the two data sets collected on November 22, 1997 indicated that the use of composite data from the first several hours of a larger storm event to represent the event mean concentration could result in an overestimation of pollutant loadings since significantly more dilute concentrations occur later in a storm event.

Although the bacterial concentrations in samples collected from the monitoring manhole and the gutter locations were similar to concentrations reported in NURP, most samples exceeded Massachusetts' water quality standards for Class B waters. While some of the bacterial contamination in the samples taken from the monitoring manhole can be attributed to the influence of the two remaining sanitary sewer connections to upstream drains, it is unlikely that the surface runoff grab samples were contaminated with human waste. Thus it appears that the Massachusetts standard for Class B waters is unrealistically high for urban stormwater runoff.

The highest concentrations of bacteria were measured in the surface grab samples collected at the Hynes Field, where local residents are known to bring their dogs. Thus, it was concluded that the primary source of bacterial contamination in the drainage area is urban runoff that had come into contact with deposited pet waste.

The FC/FS ratio for all of the bacterial samples collected in this program were greater than unity, and most were greater than four. Ratios greater than four typically suggest human sources, while those less than 0.7 indicate non-human (animal) sources. Since it is unlikely that the surface runoff grab samples collected in this program were contaminated with human waste, the data suggest that the FC/FS ratio is not a good indicator of bacterial sources in stormwater.

The concentration of oil and grease were below detection in the samples collected during two events that had only one day of antecedent dry weather October 27, 1997 and January 7, 1998), indicating that the previous storms had washed all the accumulated oil and grease off the road.

RECOMMENDATIONS

Stormwater Management

The Boston Public Works Department (PWD) is responsible for roadway de-icing and street cleaning in the City of Boston. The Commission will encourage the PWD to closely monitor and modify its de-icing practices and minimize use of de-icing agents and sand. PWD should also be encouraged to conduct more frequent street cleaning in the study area to remove street deposited automobile fluids, oil and grease, sediments, leaves, litter and accumulated pet waste.

The City of Boston's Animal Control Unit is responsible for enforcing the city's dog fouling ordinance, Section 16-1.10A of the Boston City Ordinances. Fines are $50.00 for failure to remove dog waste. The Unit should be encouraged to upgrade its surveillance and enforcement efforts in the study area.

The City's Parks Department has already installed signs at Hynes Field to inform residents of the repercussions of failing to clean up after their pets. In addition the Commission has asked the Parks Department to consider installing mutt-mitt dispensers to assist dog owners in collecting wastes.

The Commission should encourage town officials in Brookline to implement activities similar to those described above to improve stormwater quality in the drainage area which lies in Brookline.

Future Monitoring

The Commission was surprised at the initiation of the program to discover several sanitary sewer connections to the storm drains in the study area, especially since there had been no evidence of sanitary sewage contamination in the monitoring manhole or at the outfall during preparation of the Permit Application. In the future dry weather inspections of manholes in any drainage area to be monitored will be conducted prior to initiating the monitoring program.

Strict adherence to the criteria established by EPA restricted the number of storms suitable for sampling. More flexibility in the storm criteria established for future programs must be allowed, if a sufficient data base is to be developed.

The results of the dual sampling on November 22, 1997 suggest that the use of composite data collected during the first several hours of a larger storm event to represent the event mean concentration could result in an overestimation of pollutant loadings. In order to obtain composite samples that are more representative stormwater quality for the entire storm event, composite samples should be collected over a longer duration.

Future stormwater monitoring programs should include analysis for soluble metals, since EPA's current policy, is to recommend the use of the dissolved metal concentration to set and measure compliance with water quality standards. In addition the hardness of the stormwater should be monitored during future sampling, since the toxicity of the metals is a function of its hardness.

Additional sampling under winter conditions should be conducted to evaluate the effect of various conditions on stormwater quality, i.e. after road de-icing and sanding events, following extended periods with snowpack and during melting. Additional monitoring for Cyanide should also be conducted to obtain a more complete database.

ABSTRACT

Water quality monitoring programs have recently been completed in two metropolitan areas within the United States. One program was designed to assess the effects of sanitary sewer overflows (SSOs) on receiving waters. The other program was to determine the impact of combined sewer overflows (CSOs) on a local river. The experiences during these major water quality monitoring programs have proved that: (1) Detailed planning prior to the beginning of the program will minimize logistical problems; (2) The mobilization of sampling staff for a wet weather event when multiple entities are involved can wreak havoc on the program; (3) Several meetings with laboratory staff prior to the program can help set the proper course for laboratory analyses during the course of the program; (4) Constant reliability checks are necessary to prevent instrument drift and to assure that representative data are being collected; and (5) Opportunities for innovation can lead to pleasantly surprising results. This paper will relate in more detail the lessons learned during the course of these sampling programs. The paper will also present techniques and innovations developed for collecting and analyzing water quality data.

KEYWORDS

monitoring, sampling, SSO, CSO, overflows, DO

INTRODUCTION

Many programs repeat common mistakes, which lead to the collection of large quantities of data that provide very little benefit. This paper will serve as a guide for municipalities who are in the process of beginning a water quality monitoring program. An outline will be presented for the design and implementation of a monitoring program which ensures the collection of sufficient data to adequately characterize both the collection system discharges and the receiving water impacts. Additionally, techniques for reviewing and assessing the quality of the data collected will be described. Data analysis methods currently in use in the United States and abroad are compared, and several emerging technologies are discussed.

METHODOLOGY

Before undertaking any activity to mitigate collection system discharges into receiving waters, it is imperative that the effects of those discharges on the receiving waters are understood. A well designed and executed water quality monitoring program can help engineers assess these effects. Figure 1 displays a flow chart for designing a water quality program.

Program Design

The first step in the design of a monitoring program is to define the goals of the program: What information do you want to obtain from the monitoring program? The answer to that question will determine the level of detail in your subsequent monitoring program, and the type, accuracy, and frequency of data to be collected. Other factors in determining the objectives of the monitoring program include:

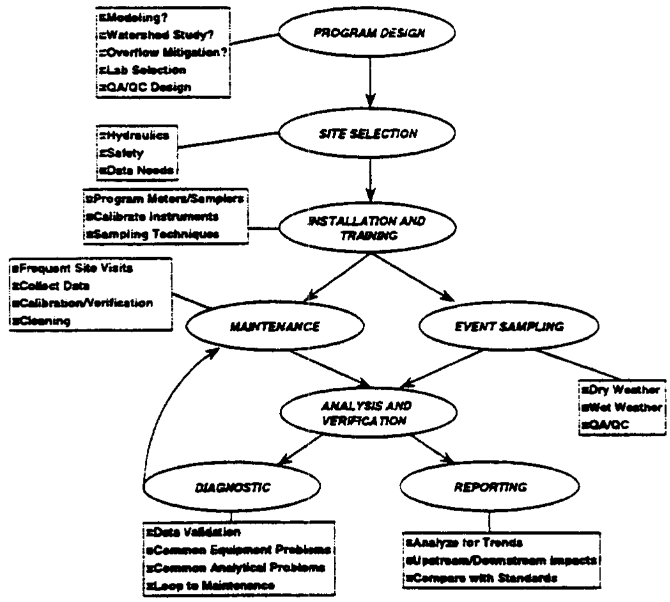
- State and local regulations
- Designated uses of receiving waters of interest

Defining the goals of a water quality program lays the groundwork for determining the components of the sampling program. A defensible monitoring program will have, at a minimum, the following components:

- Dry weather sampling,
- Wet weather sampling, and
- Continuous water quality monitoring.

Figure 1

WATER QUALITY MONITORING PROGRAM



Dry weather sampling determines the background conditions in the receiving waters. Wet weather sampling in the receiving waters and at the points of discharge from the collection system will determine the system response to storm events. Continuous water quality monitoring, primarily for dissolved oxygen (DO) and temperature, will provide useful data on the health of the receiving waters during both dry and wet weather conditions.

During this planning process, it is important to look for opportunities for innovation. For example, the CSO monitoring program used both biological monitoring and sediment monitoring data to contribute to aspects of the project objectives. Biological monitoring was performed to address regulatory issues and requirements for their system. Both lab and in-stream toxicity tests were performed to determine acute and chronic effects of CSO discharges. Sediment sampling assessed metals in the receiving water. Sediments from both the CSO structures and the receiving waters were analyzed for the same parameters to try to identify potential contamination resulting from CSO discharges. The use of these types of analyses can provide a more complete picture of the monitored system's response to wet weather discharges.

Another innovation was the use of long-term dissolved oxygen monitoring. In both the CSO and SSO programs, continuous water quality monitors were employed to show the effects of overflows on receiving waters. In the SSO program, the DO probes were installed and maintained for nearly six months. The data collected from these meters indicated that dissolved oxygen (DO) concentrations at less than the 5 mg/L state water quality standard were not caused by SSO discharges but by the diurnal fluctuations in dissolved oxygen. Further, there was no measurable response of the receiving water systems' monitored DO during storm events where SSO discharges were occurring.

Finally, QA/QC protocols for the water quality monitoring program will ensure that all samples collected are representative of the waters they were collected from and that the quality of the data is quantified. The QA/QC program should include both a field sampling component and a laboratory component to ensure a high degree of confidence in the data collection and analysis. Sampling QA/QC protocols typically call for:

- Field blanks to evaluate whether there was any cross contamination occurring that was attributable to sampling equipment or practices,
- Field duplicates to evaluate the sampling process with respect to the repeatability of the results,
- Trip blanks to measure cross contamination during transport, field handling, and storage, and
- Equipment blanks to measure the adequacy of the decontamination of sampling equipment after its use.

Because sample analysis is expensive, it is common practice to collect a full compliment of blanks, and then only analyze the field blanks. If the analysis indicates no problems with the field blanks, then the other blank samples may be discarded (Keith).

Site Selection

Once the goals of the monitoring program are clearly defined, the site selection process can begin. Often monitoring sites are located in a haphazard manner, leading to installations which are difficult to sample or which are not strategically located to meet the goals of the program. Another common flaw is to begin overflow monitoring without an accurate understanding of the collection system hydraulics, especially when monitoring overflows from sanitary sewers. A detailed understanding of the collection system topology is required in order to locate sampling points where they will best collect data to meet the defined goals. Key hydraulic points such as pump stations and diversions should also be taken into consideration, as these elements can have a significant effect on the monitored hydraulics and the discharge quality. Local knowledge of chronic problem areas can also assist the engineers in planning the monitoring program.

The final step in the site selection process is to perform field investigations to determine the adequacy of the selected sites. The adequacy of a sampling site is based on three factors:

- The data needs of the monitoring program,
- The feasibility of sampling and flow measurement, and
- The sampling crew safety concerns.

In order to quantify total loads from overflows and in receiving waters, accurate flow data is required in conjunction with quality monitoring throughout the event. Keep in mind that, for most analyses, it is important to characterize *relative* differences; the actual flow rate or volume is not as important. Hydraulic factors to take into consideration when assessing the candidate sites are siltation or heavy debris buildup in the overflow pipe, complex hydraulics such as 90-degree bends or multiple inflows in receiving water sites, and pump station influence. The use of automatic flow measurement equipment should be investigated at the candidate locations. This can significantly improve the quality of the data collected while minimizing the staff necessary at each location. Receiving water flow data can be obtained from USGS gaging stations located near the monitoring sites. Automatic flow meters were successfully applied at all stream monitoring sites in the SSO monitoring program.

Consideration should also be given to sampling logistics when determining monitoring locations. Most sampling programs involve coordinating with a large field staff, analytical laboratory staff, and the weather. Since the concern of most monitoring programs is wet weather water quality, it is important that sites are selected such that sampling teams can be notified and respond in time to sample the entire event. Clustering sites can allow the use of one team to sample a number of sites, provided the sample intervals are adequately spaced (e.g., half-hour sample intervals). Sites should be located within a short drive of the lab(s) in order to minimize travel time and ensure that samples meet the required holding times.

Staffing

Teaming with client and even regulatory agency staff can provide unexpected benefits and can contribute greatly to the success of a sampling program. The obvious benefit of using these groups is the cost savings in the overall program, as they will minimize the reliance on in-house staff. Even more important, however, is the sense of ownership and cooperation achieved when working with client staff, and also with regulatory agency representatives. Involving state or local agency personnel provides an excellent opportunity for them to observe the actual sampling techniques and conditions. During the SSO program, members of the state regulatory body participated in field staff training and actually mobilized for a number of sampling events. When presenting the results of the program, the agency staff had a better understanding of how the data was collected, and the actual site locations and conditions under which the data were collected.

Similar teaming was performed with the state regulatory agency during the CSO program. Biological sampling as part of the CSO study was tied in to an existing study being performed by the state agency. This resulted in the sharing of data, and sampling was actually split between the client staff and the agency staff. The result was a greater spirit of cooperation between the client and the regulatory agency.

Teaming with client staff can also be an educational experience. The client provided nearly 75 percent of the staff for the CSO sampling program. This was originally set up as a cost saving measure; however, it led to a greater understanding of the system and its effects on the receiving waters by the client staff. A senior staff member actually mobilized and collected samples at a CSO outfall.

The mobilization of sampling staff for a wet weather event can wreak havoc on the program. This is particularly vexing when multiple entities are involved. For instance, the CSO sampling program required the consideration of the union call-out procedures of the City staff. Early in the SSO sampling program, field sampling performed by an environmental sampling services firm limited the flexibility that exists when using your own staff or sub-consultants. In either case, make sure that call-out procedures and points-of-contact are clearly defined *before* beginning the monitoring program, and are documented so that all parties have a clear understanding of their responsibilities and expectations.

Finally, involve the contract laboratory with the sampling effort early in the program. Lab staff can be used as runners for sample pick-up. In the SSO program, the lab provided space onsite for sampling equipment, and served as the staging area for all sampling events. This type of service ensures "buy-in" in the program by the lab staff.

Installation and Training

Prior to the beginning of the sampling program and after final site selection, all monitoring locations should be visited and prepared for the upcoming sampling events. Staging areas should be defined and clearly marked to assist the sampling teams. Because receiving water sampling typically occurs at bridge crossings, the location where the samples are to be taken should be identified with a mark on the bridge rail.

Corresponding flow measurements will be necessary at the wet weather sampling locations. Most flow measurements can be determined by using a portable velocity meter; however, it may be possible at some locations, particularly the overflow locations, to install automatic flow measurement devices. If manual flow measurements are performed at the receiving water monitoring sites, measurement points along the cross-section of the channel should be clearly marked on the bridge rail. Regardless of the flow measurement technique in the receiving waters, full surveys of the cross-section will need to be completed in order to define the geometry of the channel.

Any equipment such as automatic samplers and flow monitors must be installed before training of the field crews. This equipment can greatly assist in the collection of wet weather data by providing a much more consistent data set than can be achieved using human labor. The sampling requirements for bacteria usually do not permit the use of automatic samplers to collect samples during the wet weather events. However, in the SSO monitoring program, automatic samplers were used successfully to perform the sample collection. Bacteria requirements were addressed through the use of selective grab samples during the course of the event.

Training sessions in proper sample collection, handling and submission, and general field procedures must be conducted for all field staff. Specific emphasis should be placed on QA/QC issues as well as upon health and safety. All field crews should receive additional training in instrument calibration, receiving water sampling, and overflow sampling. As part of the training for the SSO sampling program, field crews mobilized to their actual monitoring site and performed many of the functions that would be done during a sampling event. This gave field crews the opportunity to:

- Get to know their assigned sites,
- Become familiar with the SOPs and sampling techniques, and
- Become comfortable with all procedures and functions that would need to be performed during an event.

Field crews should be provided with a field manual as part of the training effort for ready reference. The manual contains Standard Operating Procedures (SOPs) for all facets of field work on this project. The field manual serves as an on-site trouble shooting tool if the sampling team has a question about which parameters to sample for and when, how to calibrate the DO meter, etc. Sampling and equipment operation SOPs present the field protocols in simple, "cookbook" procedures. These SOPs provide the field staff with guidance while performing all functions of the sampling program. At a minimum, the field manual should contain the following items:

- Definition of wet or dry weather sampling event (i.e., 72 hour period of dry weather followed by threshold rainfall amount to qualify for wet-weather event; 72 hour period of dry weather to qualify for dry-weather event).
- Step-by-step procedures for collecting, documenting, storing, and transferring samples from stream and overflow sites.
- Timetable for sample collection during sampling events. This will include sampling frequency, parameters to be sampled for, and frequency of blank and duplicate submission.
- Calibration and maintenance of field instrumentation.
- Decontamination procedures for sampling equipment and instrumentation.
- Health and safety issues including protective clothing and equipment, emergency procedures, the phone number and route to the nearest hospital, and a list of phone numbers of project management personnel.

Monitoring and sampling activities present a variety of potentially hazardous situations. Safety protocols should be developed and included in the field manuals to present procedures and required equipment that are to be implemented to minimize this potential. These protocols can include all applicable company, local, state, or federal regulations. However, it is the responsibility of each individual worker to comply with all applicable regulations. All staff involved in the monitoring program should read and understand these procedures prior to commencing work.

Routine Maintenance

Routine maintenance requirements will vary depending on the scope of the monitoring program and the type (if any) of equipment utilized. Most monitoring programs will use continuous monitors for DO and temperature as well as flow meters in the monitored overflows and sometimes in the receiving waterbodies. Continuous monitoring relies on sensitive equipment installed in a hostile environment. Constant reliability checks are necessary to prevent instrument drift and to ensure that representative data are being collected. Typical maintenance activities include:

- Frequent site visits to ensure automatic equipment operation and to collect data,
- Routine calibration and verification of probes and flow meters,
- Periodic review of sampling techniques.

During any site visit, field data should be collected to compare with the recorded data. The comparison of field measured data to the continuous probes is used to indicate drift in the measurement of dissolved oxygen occurring in continuous monitors. Possible causes for observed drift may include build up of bacterial growth on the sensor membrane or low batteries. However, a rigorous maintenance schedule adhered to throughout the deployment of the monitors can control and enhance the operation of the continuous probes. Monitor locations should be visited and cleaned twice a week. Monitors should be calibrated and the membranes replaced every two weeks. Note that membrane wear is more likely to occur when the sondes operate in water temperatures in the 25-30° C range.

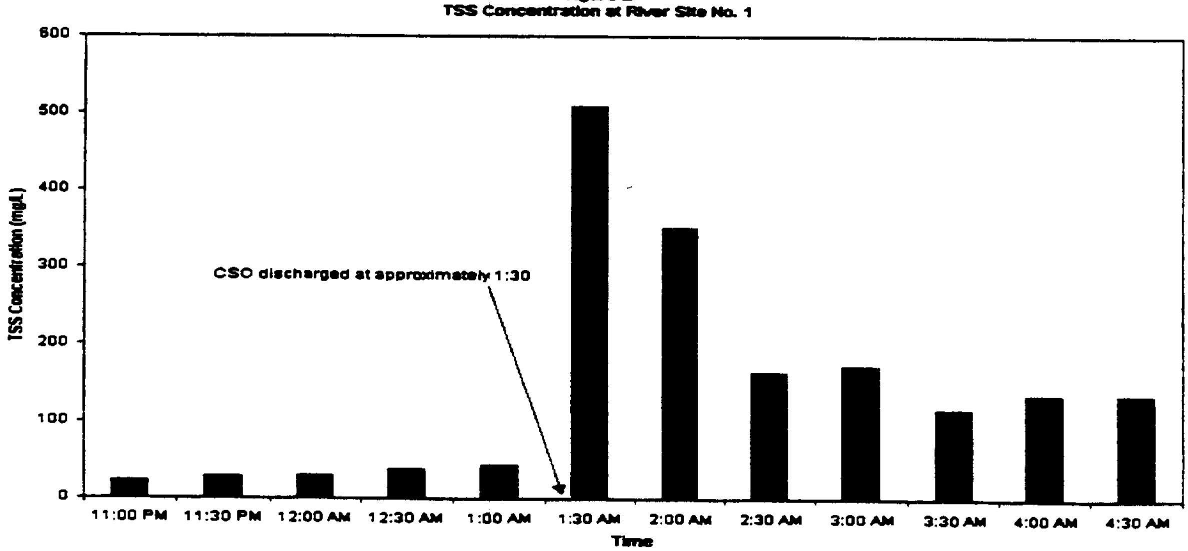
Data collected from any equipment should be frequently reviewed during the course of the program. This will assist in the detection of potential problems early in the program so that corrective action can be taken. In many cases, alternative methods of obtaining data may need to be explored due to particular site conditions.

Event Sampling

Because of the small number of samples and the flexible collection time, dry weather sampling requires only one team of two people. However, wet weather sampling requires many more samples as well as flow measurements. Therefore, sampling teams of two people for each of the monitoring sites should be used whenever possible.

Monitoring programs often rely on composite samples or post-storm event samples for stream wet weather response characterization. Experience gained during both the SSO and the CSO sampling programs proved that discrete samples taken before, during, and after the storm event provide a complete picture of stream response as well as overflow characteristics. Figure 2 displays a storm event pollutograph (monitored concentration versus time) at a receiving water sampling location monitored during the CSO program. As can be seen, the full response of the system can be analyzed using this sampling technique. Composite samples or post-storm event samples would have masked this response pattern, which may ultimately lead to the under-design or over-design of overflow control measures.

Figure 2
TSS Concentration at River Site No. 1



During each wet weather event, every sample location will have a unique sample matrix listing all samples to be collected. An example of a receiving water sample matrix is shown in Table 1. This matrix assists the sample teams in collecting all samples and completing all measurements. As the sample team collects each sample, that box of the matrix is checked, and the time is recorded. The field supervisor for each event will monitor sample times throughout the event.

Detailed field notes should be taken for all sample events. Obvious observations often become very important later on in a study. Any unusual or atypical conditions must be noted. Standard field forms can be developed for each site, and should include at a minimum:

TABLE 1
EXAMPLE SAMPLE CHECKLIST

Receiving Water Sample Location												
Event Begin Time:			Event End Time:									
				In-Stream Measurements								
Number	Time	Discrete Sample	Fecal Grab	DO			Temp			pH		
1	0											
2	30											
3	60											
4	90											
5	120											
6	150											
7	180											
8	210											
9	240											
10	270											

- Date and time of sample, and sample station identification
- sample preservation
- date of last rainfall
- name/initials of sampler
- water and air temperature
- noticeable odors, oil sheens, water color, etc.

Analysis and Verification

Review and evaluate analytical data immediately upon receipt from the lab to facilitate corrective actions if any were deemed necessary. Specific QA/QC screening procedures that should be followed as part of the data review effort include:

- Field blank data review to ensure that field blanks do not exhibit concentrations greater than the detection limit for the parameter being tested.
- Duplicate sample review to ensure that duplicate samples have reported concentrations within 25% of each other.
- Range checks to evaluate whether observed concentrations are within expected range.
- Internal consistency checks (e.g., TKN>NH_3, BOD>CBOD, and dissolved oxygen < saturation).

Blank sample results give an indication of any contamination that may have occurred during the sampling process. The relative percent differences between results of duplicate samples provide an indication of analytical precision. Range checks provide a comparison of monitored data to historical data. Internal consistency checks provide an indication of the quality of the analytical procedure followed by the lab.

It should be noted that these criteria should be defined at the beginning of the monitoring program. Further, there may be instances where data not meeting the criteria stated above would still be valid, useable data. For instance, monitored dissolved oxygen concentrations can exceed expected DO saturation values for a given temperature where the streams monitored are highly productive and experience exposure to sunlight.

If any of the data points fail to pass the above screening level checks, the data in question should be investigated. The investigation of failed data points includes at a minimum:

- Review field notes for possible explanation of the anomalous result.

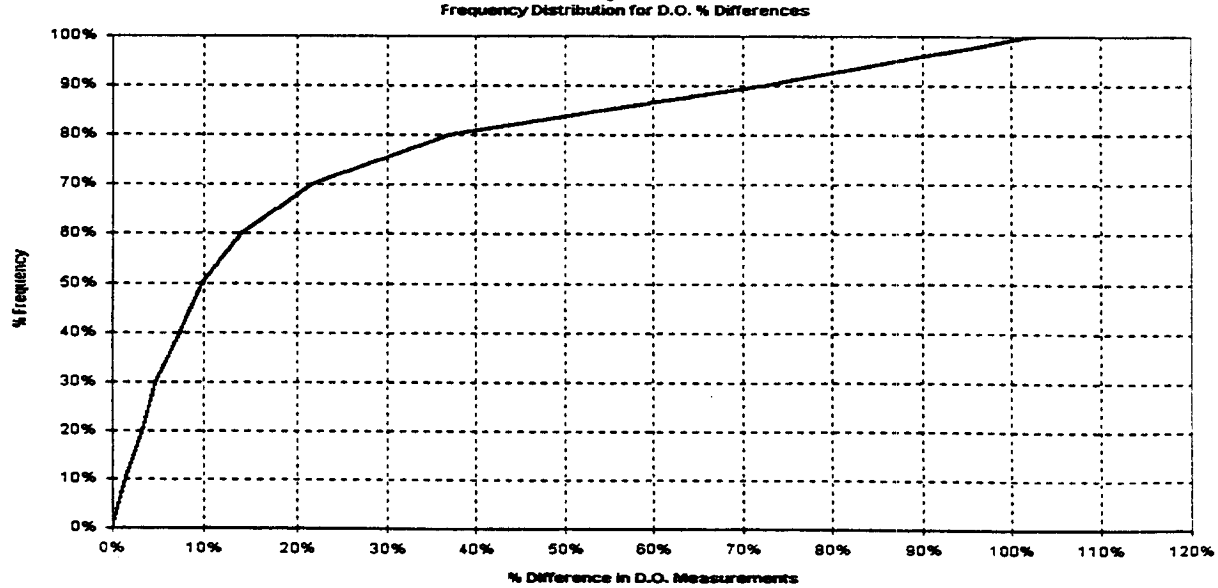
- Check for transcription error. Was the sample properly identified in the field notes, on the chain of custody, and on the lab report?
- Check with the laboratory for:
  - ⇒ Reporting error - was the result correctly transferred from bench sheets to report?
  - ⇒ Sample ID - Was the sample properly identified during the analysis?
  - ⇒ Equipment performance - did the equipment used for analysis achieve acceptable performance criteria?

If the investigation reveals any questionable results on the part of the lab, a re-analysis should be requested for the parameter in question. Any questionable results will be flagged so that future analyses are conducted with an awareness of potential problems associated with that data point(s).

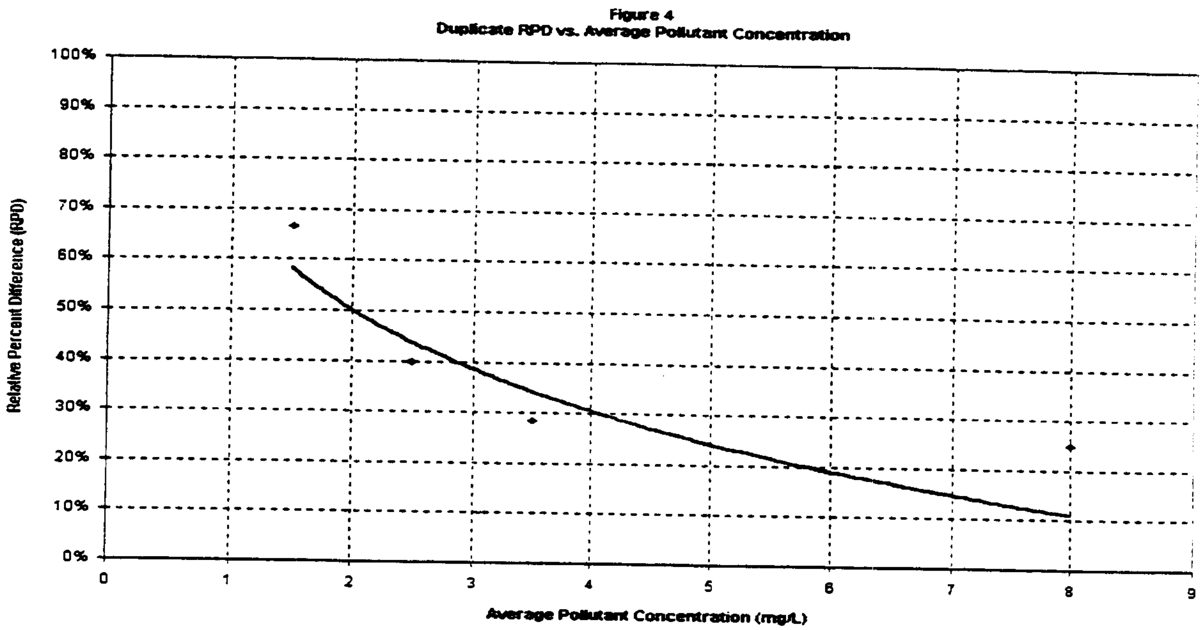
Figure 3 presents a typical technique for assessing the operation of continuous dissolved oxygen probes. The figure displays a frequency distribution for the differences between field-measured and monitor-measured dissolved oxygen observations. This type of analysis can provide an indication of the reliability of the continuous monitor. By maintaining data such as this on a routine (typically weekly) basis, staff can quickly detect potential equipment problems and can help guide the routine maintenance of the sondes.

Frequent analysis of the analytical results is also recommended. Be sure to get a fast turnaround time from the laboratory, as this can affect future analyses. Figure 4 presents a technique for reviewing analytical sampling results. This figure displays the relative percent difference (RPD) versus the average monitored constituent concentration. The RPD value represents the percent difference for duplicate sample results and provides an indication of analytical precision. As can be seen on Figure 3, the greatest RPD values are at the lowest observed concentrations. This may be of concern, depending on the nature of the monitoring program. However, if the goal is to accurately quantify when high concentrations are occurring, then this graphic indicates that analytical precision is greater at the higher concentrations, thus giving greater confidence in those results.

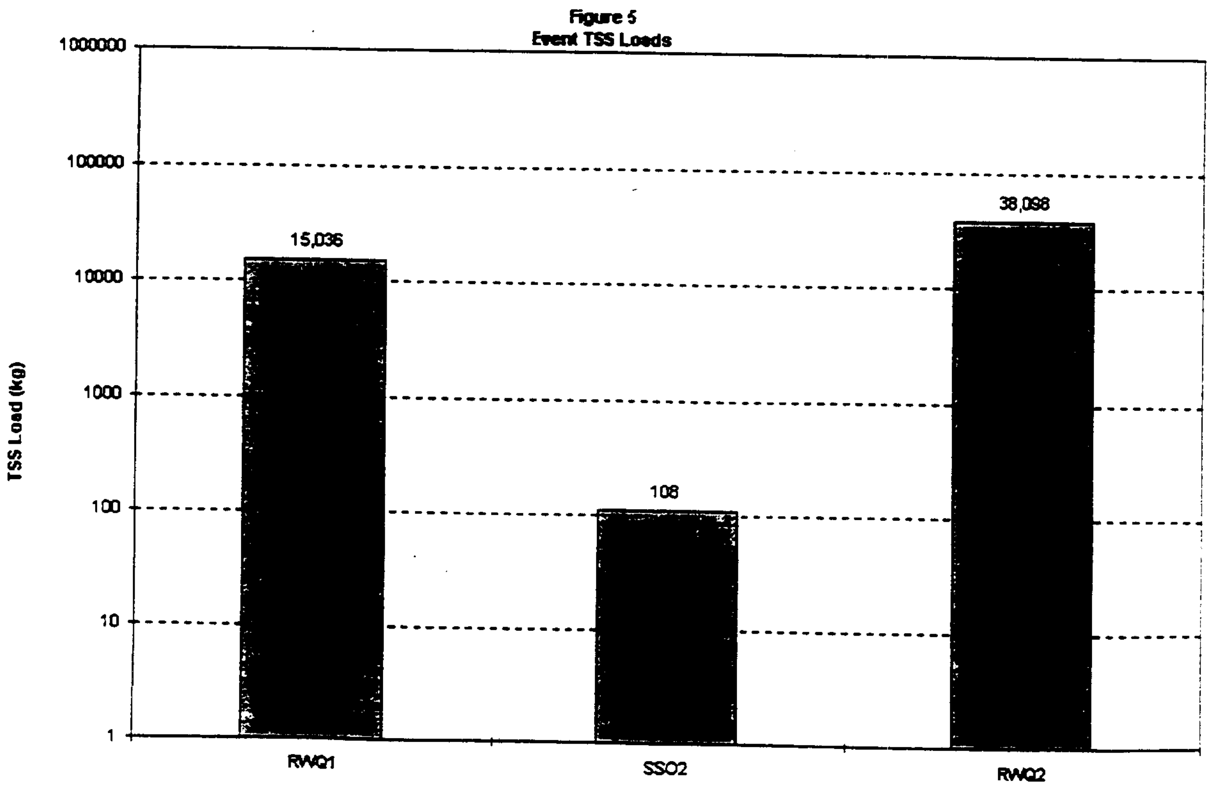
Figure 3
Frequency Distribution for D.O. % Differences



R0025128



Analysis of the discrete monitoring data from both the receiving waters and the overflow discharges also provides some insights. Comparisons of upstream and downstream receiving water monitoring data can indicate whether overflows actually effect the receiving water quality. Figure 5 shows an example of this type of analysis.



Note that the data displayed in Figure 5 is on log scale. This was done so that the comparatively small SSO loads would show when compared to the receiving water loads. The monitoring data displayed in

Figure 5 indicate that, compared to the downstream site (RWQ2), the SSO loads represent less than 0.5 percent of the TSS loading. Further, the graph indicates that SSO loads are less than 0.5 percent of the increase in load from the upstream site (RWQ1) to the downstream site.

CONCLUSIONS

The experiences during these major water quality monitoring programs have provided the following insights:

Plan Ahead: Detailed planning prior to the beginning of the program will minimize logistical problems. During the SSO program, detailed standard operating procedures (SOPs) were developed. During a dry run session, sample crews mobilized and sampled according to the SOPs.

Logistics Can Kill: Staffing of a sampling program can make or break it. Use the opportunity to build relationships with client and regulatory agency staff. The CSO sampling program effectively involved staff from both groups early and often, which led to benefits at the end of the program. Note that mobilization of sampling staff for a wet weather event can wreak havoc on any program, but especially when multiple entities are involved. For instance, the CSO sampling program required the consideration of the union call-out procedures of the City staff.

Know Your Laboratory: Do not assume the laboratory understands the goals of your program or the nature of the samples that they will be receiving. Several meetings with laboratory staff prior to the program can help the laboratory to determine proper detection limits for the analyses as well as plan for the necessary dilutions. Be sure to get a fast turnaround on wet weather lab results, as this can affect future analyses.

Maintain Equipment: Continuous monitoring for DO and temperature relies on sensitive equipment installed in a hostile environment. Constant reliability checks are necessary to prevent instrument drift and to assure that representative data is being collected.

Look for Innovation Opportunities: The CSO program performed sediment sampling in both the receiving river and in the collection system. These comparisons provided useful insights into the contribution of metals from the CSOs. The SSO program used continuous dissolved oxygen monitors in conjunction with discrete overflow monitoring data to show that SSO discharges were not responsible for the non-attainment of the DO water quality standards.

Analysis: Use upstream and downstream monitoring sites to assess the effect of overflows on receiving waters. Comparisons made between monitored overflow loads and monitored receiving water loads can provide insight into the receiving water response and the overall effect of overflow discharges. For example, monitoring during the SSO program revealed that SSO discharges represented less than one percent of the monitored loads in the receiving waters.

ABSTRACT

Evaluation of flows entering the Detroit Water and Sewerage Department (DWSD) collection system from outlying suburban areas requires high quality continuous flow monitoring at a number of key inflow locations. As part of a large scale collection system management project, the method of dye dilution was selected to investigate the accuracy of existing flow meters and evaluate new meters installed under the project. The dye dilution method for flow rate estimation involves the addition of a small, constant stream of fluorescent dye into a sewer and measurement of dye concentration at a downstream location after the dye has been thoroughly mixed across the sewer cross section. A mass balance calculation on the injected dye can then be used to determine the flow rate in the sewer.

This paper describes results of a detailed laboratory investigation and field implementation of the fluorometric dye testing technique. In particular, the potential for interference due to abrupt changes in suspended solids and background fluorescence was observed, indicating the need for monitoring of suspended solids in virtually all field testing scenarios. A field technique for flagging potential interference by continuous monitoring of light absorbance at the rhodamine WT excitation wavelength was developed.

A comprehensive error analysis was also performed, describing the magnitude of error introduced by variability in injected dye flow rate, fluorometer variability, error in standards curve preparation, temperature correction, travel time error, and variability in background fluorescence and suspended solids. In general, the majority of error introduced in a typical dye test is related to preparation of standards curves and variation in suspended solids and background fluorescence. A thorough understanding of the theory and potential sources of error in dye testing makes it possible to minimize the key sources of error and perform highly accurate flow rate estimates. The accuracy, portability, and flexibility of the dye testing technique makes it a highly useful method for evaluation and improvement of metering accuracy.

INTRODUCTION

As part of a system-wide evaluation of the accuracy of large meters in the Greater Detroit Regional Sewer System (GDRSS), a rigorous dye dilution testing technique was developed and tested under a detailed laboratory investigation and field implementation procedure. This paper presents highlights of the laboratory study and field work, and concludes with some general guidelines for high-quality dye testing and meter evaluation.

THEORY

A dye dilution test is performed by adding dye to the sewage flow at a constant rate, allowing the dye to mix completely with the sewage flow, and measuring the diluted dye concentration at a downstream location. A mass balance on all fluorescing materials in the system can then be used to estimate the sewage flow based on the degree of dilution observed at the downstream sampling point. Such a mass balance is given by:

$$Q_o C_B + Q_i C_i = (Q_o + Q_i) C_o \quad (1)$$

R0025131

where:
Q_i = Injected flow rate
C_i = Injected concentration
C_o = Concentration in mixed (output) flow
C_B = Background concentration
Q_o = Output flow rate to be measured

Expression (1) can be rearranged as:

$$Q_o = \frac{Q_i C_o - Q_i C_i}{C_B - C_o} \tag{2}$$

C_o can be assumed to be very small relative to C_i, so that:

$$Q_o = \frac{Q_i C_i}{C_o - C_B} \tag{3}$$

The analysis technique used in this study eliminates the effect of background fluorescence by using standards prepared from sewage samples. In such a case, a mass balance can be performed on rhodamine dye only, removing C_B from the above development. In this case,

$$Q_o = \frac{Q_i C_i}{C_o} \tag{4a}$$

or

$$Q_o = Q_i D \tag{4b}$$

where D is the measured dilution of injected dye, defined as $D = C_i / C_o$.

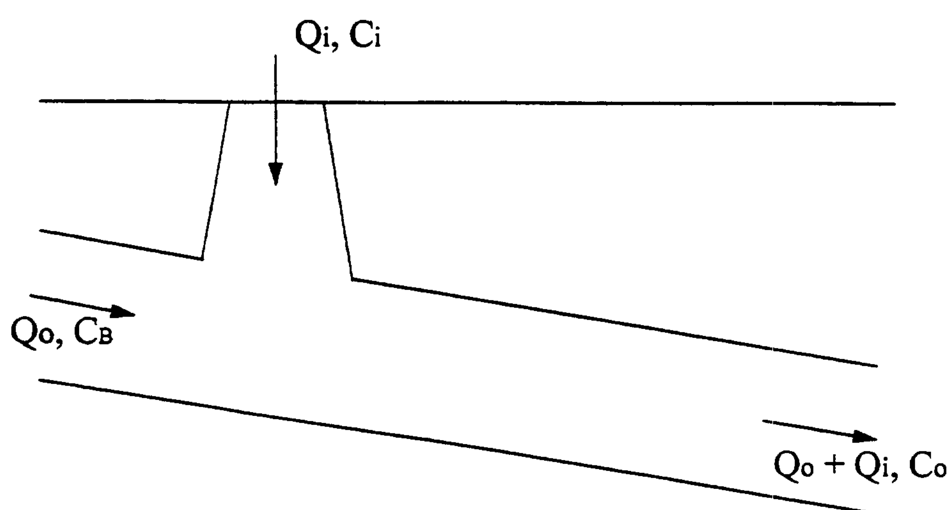

Figure 1. Dye test schematic

LABORATORY INVESTIGATION

Prior to implementing rhodamine dye testing in the field, a laboratory investigation was performed to refine the analytical technique used for measuring dye concentrations, quantify the expected sources of error, and develop a standard testing protocol. Issues explored in the laboratory investigation included:

- variability in the measurement of fluorescence
- variability in dilution preparation and standards curve preparation
- bias or variability due to temperature correction
- variability due to suspended solids fluctuation
- variability or bias due to changes in background fluorescence
- potential effects of poor mixing or non-conservative dye
- consistency of dye injection

While each one of these issues can have a great influence on dye testing performance, space considerations will limit us to a subset of the list given above. This paper will focus on the error involved in standards curve preparation, the importance of temperature correction, and the potential influence of suspended solids and background fluorescence on flow rate predictions. For all investigations reported here, a Turner Designs model 10-AU fluorometer was used for analysis of rhodamine WT concentrations.

Standards Curve Preparation

As noted above in the development of the dye testing equations, the rhodamine dye analytical technique employed in this study involves preparation of standards curves from site- and time-specific sewage samples in order to account for background fluorescence and possible effects of suspended solids. Standards curves are prepared by performing serial dilutions of dye to known concentrations and developing plots of known concentrations vs. measured fluorescence.

A laboratory study was conducted to identify the optimal range over which concentration measurements can be made using the rhodamine WT fluorescence technique. Standards were prepared for several concentration ranges in order to identify the point at which concentration and fluorescence no longer exhibit a linear relationship. Figure 2 shows plots of the standards curves for concentration ranges in the: (a) 0-200 ppb range, (b) 0-500 ppb range, and (c) 0-1000 ppb (1 ppm) range. The fluorometer was respanned for each of the concentration ranges explored. The lower of the three ranges exhibits high linearity, as is claimed in the manufacturer's specifications for the Turner model 10-AU for analysis of rhodamine WT. Extending to the 500 ppb range results in a departure from linearity at higher rhodamine concentrations. The observed nonlinearity is most clearly demonstrated in the 0-1000 ppb standards curve. Even a relatively small deviation from the best fit line as shown in 2b will result in a large increase in the error associated with concentration prediction. For this reason, 200 ppb was identified as a reasonable upper limit for precise concentration measurements.

Standards curves prepared at very low concentrations (0-2, 0-0.2 ppb) in distilled water also showed high linearity, with some increase in scatter at the lowest (<0.1 ppb) ranges. However, a more restrictive low-end constraint in sewer flow rate measurement applications is the presence of background fluorescence, which can obscure low rhodamine concentrations. Measured background fluorescence in samples of sewage collected throughout the GDRSS has generally been in the range of 0.2 to 1.0 (expressed as ppb of rhodamine WT). A factor of 20 times this range gives an effective lower limit of approximately 20 ppb for measurement of rhodamine concentrations. As long as measured fluorescences are significantly greater than background levels, background fluorescence variability will have little impact on measured concentrations.

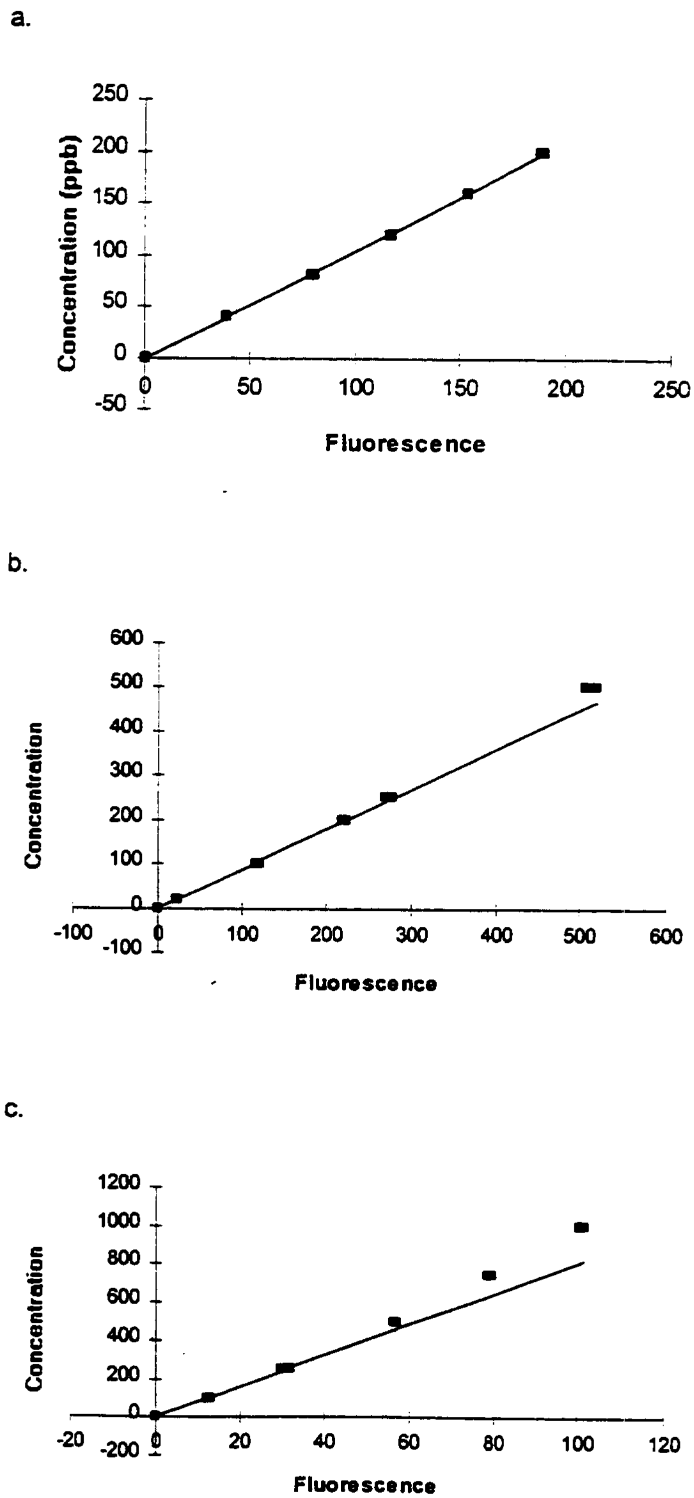

Figure 2: Standards curves for (a) C=0-200 ppb, (b) C=0-500 ppb, (c) C=0-1000 ppb

Reduction of data by regression of a standards data introduces error in the estimation of concentration, due to errors in fluorometric analysis and dilution preparation. The amount of error associated with data scatter can be quantified using the standard error of the estimate produced by the regression. For a regression of the form:

$$y = mx + b \tag{5}$$

the standard error of the estimate is related to the standard error of the regression by:

$$s_{y^*} = s\sqrt{\frac{1}{n} + \frac{n(x^* - \bar{x})^2}{n\sum x_i^2 - (\sum x_i)^2}} \tag{6}$$

where s is the standard error, n is the number of points used in the regression, x^* is the x value at which the estimate of y (y^*) is made, and $\bar{x}$ is the mean value of x over the range of the regression. A 95% confidence interval on the estimate of y is used to estimate the dilution error contribution due to standards curve preparation, and is given by:

$$S(D)_{stds}/D = (t_{0.25,n-2} \cdot s_{y^*})/y^* \tag{7}$$

where t is the t-distribution tabulated in most statistics textbooks.

Error estimates based on (6) and (7) above for a standards curve prepared from wastewater obtained from the Detroit collection system are presented in Figure 3. The accuracy of the estimate is a function of the location on the curve, with the tightest bound on accuracy typically between 60% and 80% of the range of fitted data. Other similar standards curves prepared for the 0-100 ppb range have generally shown estimation errors on the order of 0.5 - 2.0% for the upper 50% of the curve. Based on these results, standards curves prepared for analysis of dye test data are set up so that the majority of collected data falls in the region of minimal estimation error.

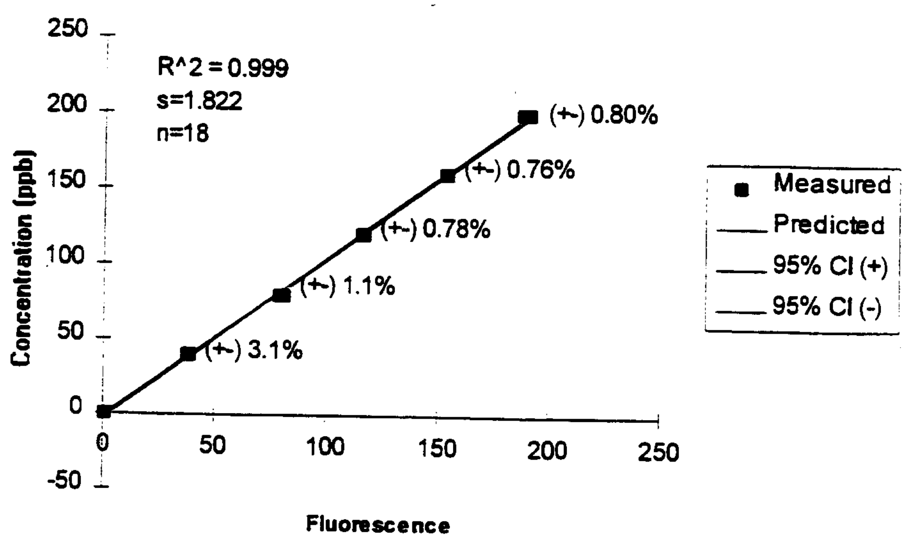

Figure 3: Standards curve with 95% CI on estimate of concentration

Temperature Compensation

It is known that measured fluorescence varies with temperature according to an exponential function of the form:

$$F_r = F_s e^{k(T_s - T_r)} \tag{8}$$

where T_r is the reference temperature, T_s is the sample temperature, F_s is the observed fluorescence of the sample, F_r is the fluorescence, adjusted to the reference temperature, and *k* is the dye batch specific temperature coefficient. Plotting fluorescence vs. temperature data on a semi-log plot (ln(*F*) vs. *T*) should give a straight line with slope equal to -*k*. Linear regression of temperature/fluorescence data is used to estimate the magnitude and 95% confidence interval of the temperature coefficient for each batch (30-gallon drum) of the Cole-Parmer line of rhodamine WT. Data is obtained by continuously pumping a standard solution through the flow-through cell of the fluorometer, and either chilling or warming the reservoir containing the standard. In order to examine the utility of the relationship over the range of dye concentrations expected, standards of 50 ppb and 10 ppb are used. Sample results of such a linear regression is presented in Figure 4. Repeat trials of temperature correction coefficient calculations show highly consistent results within each batch of dye. However, the coefficients can vary by as much as 10% from batch to batch, potentially introducing a major source of error in dye test flow rate estimates if batch-specific values are not determined and used.

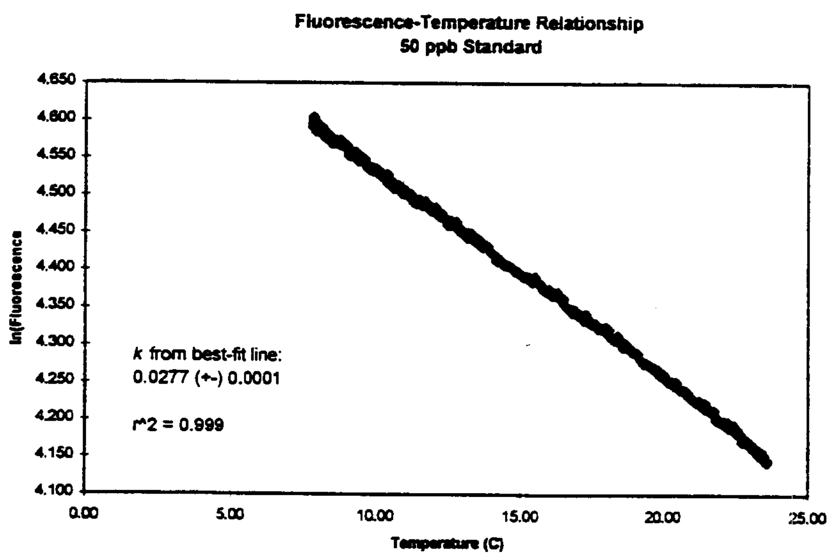

Figure 4: Regression of temperature-fluorescence data for calculation of temperature coefficient

Suspended Solids

The presence of suspended solids in the sewage stream attenuates the amount of fluorescence exhibited by a sample, due to absorbance of the light used to analyze for dye concentration. The fluorometric method used to estimate the concentrations described above implicitly corrects for the presence of suspended solids through the use of sewage to prepare the standards curve dilutions. However, fluctuation in the degree of turbidity can contribute to uncertainty in the measured dye concentrations. Numerous field tests have indicated that the quantity of suspended solids in the sewage stream can fluctuate significantly over the course of a test. Since these fluctuations can occur rapidly, a method is needed to continuously screen for suspended solids changes.

In order to quantify the degree of interference caused by different amounts of suspended solids, a spectrophotometric method was developed. The fluorometric analysis technique used to analyze for rhodamine WT involves bombarding a sample with light at a wavelength of 550 nm, and measuring the emittance of light at the fluorescent wavelength of rhodamine WT of 580 nm. Accordingly, a spectrophotometer was used to measure light transmittance at the two wavelengths of interest in a set of standards prepared at different rhodamine concentrations and with sewage samples from different locations.

Figure 5 shows a fluorescence/absorbance relationship for a standard prepared with sewage obtained from a 36" sewer located in the Clinton-Oakland County Sewerage District. Standards were prepared at concentrations of 20 and 100 ppb rhodamine WT. Fluorescence and absorbance (550 nm) were measured for the standards under well-mixed (high suspended solids) conditions, and after successive amounts of suspended solids had been removed by settling and centrifugation methods. Fluorescence values were then normalized by dividing by the predicted fluorescence in the middle of the range of measured absorbances (Abs = 0.35) in order to make results for the 20 and 100 ppb standards directly comparable.

The results are plotted vs. relative absorbance (measured absorbance minus the reference absorbance of 0.35). As expected, removal of suspended solids has the effect of decreasing light absorbance and correspondingly increasing the measured value of fluorescence. The line fit appears to be equally appropriate for the 100 ppb standard data (triangles) and the 20 ppb data (squares), indicating that this type of relationship is relatively insensitive to the measured concentration.

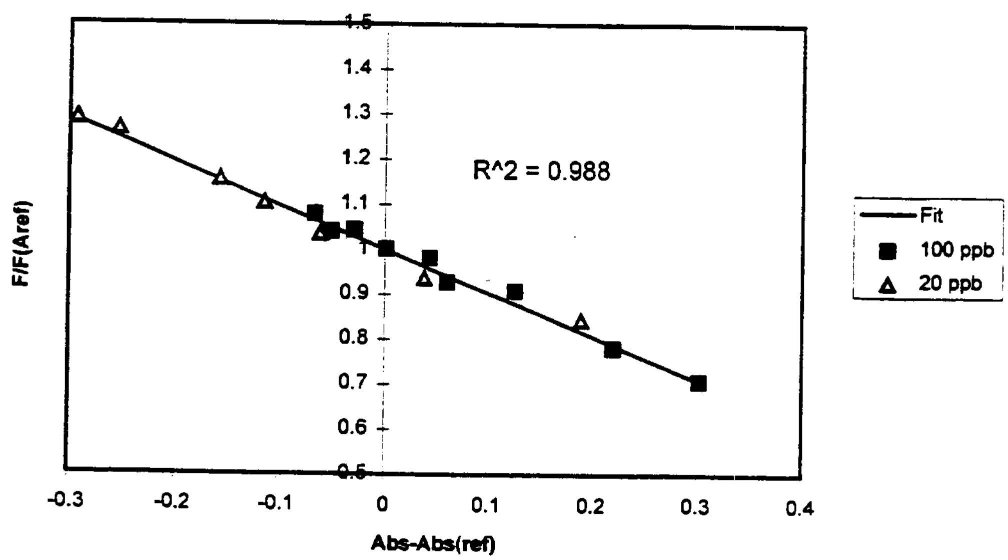

Figure 5: Fluorescence/absorbance relationship for sewage obtained at W. Utica and Dequindre

Initial attempts to use a relationship of the form shown in Figure 5 to correct measured fluorescence values were unsuccessful, as such relationships were found to be highly site- and time-specific. In order to account for the potential influence of light absorbance, the field testing protocol includes collecting upstream (blank) wastewater samples on a fifteen-minute interval, and preparing standards curves from them for time points throughout each test. While absorbance monitoring is not used as a corrective measure, the method is crucial for screening for periods of excessively high absorbance or for rapid changes in absorbance that cannot be accounted for with 15-minute interval standards curves. After performing approximately 100 dye tests, our experience has shown that sudden variation in absorbance is the rule rather than the exception, and screening for absorbance changes is a necessity for estimating both flow rate and the error bound associated with estimated rates. Sample test fluorescence and absorbance traces are shown in Figure 6, showing a clear relationship between measured absorbance and the Rhodamine analytical technique.

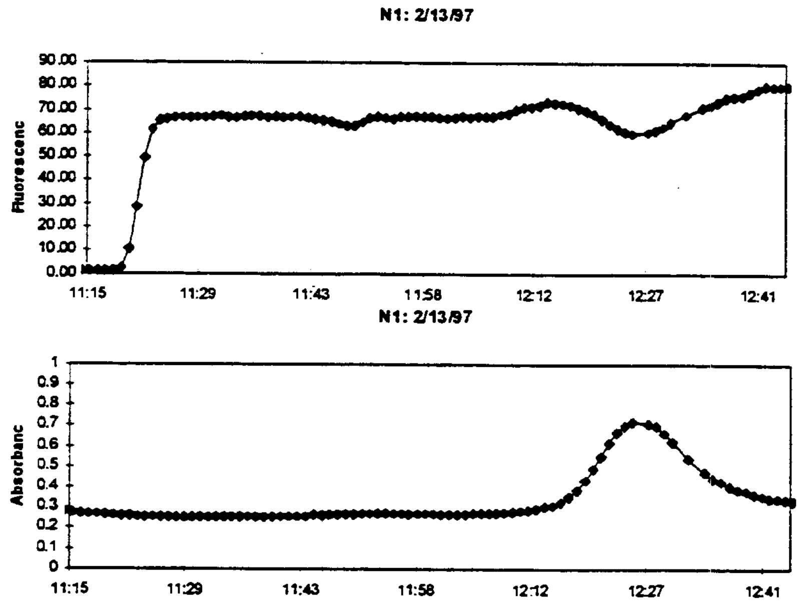

Figure 6: Sample test fluorescence and absorbance traces

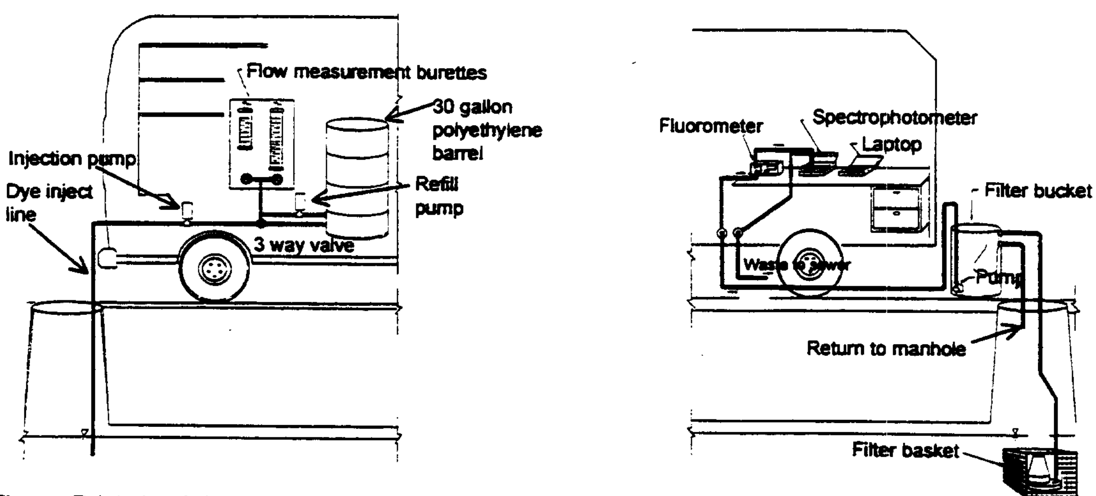

Figure 7 (a) dye inject van; (b) sampling trailer

FIELD IMPLEMENTATION

The dye testing method was implemented in the field by constructing a van-based dye injection system and a trailer used for sample collection and data analysis. Schematics of the van and trailer setups are shown in Figure 7a and b. A fluid metering pump is used to deliver dye into the sewer at a constant rate

(7a), with periodic flow rate checks made by timing the duration required for drawdown of a 250 mL or 500 mL burette. Measurement of the dilution of the dye at the downstream sampling location is performed in the sampling trailer (7b), which utilizes a system of submersible pumps to deliver a sample stream to a fluorometer and spectrophotometer in series. Both the fluorometer and spectrophotometer are linked to a laptop PC for continuous collection and plotting of fluorescence, absorbance and temperature data.

RESULTS

In order to check for bias in the testing method, dye testing results were compared with high quality magmeter flow estimates and with drawdown testing performed at the Greenfield pump station, located in Dearborn, Michigan. Testing was performed by abruptly closing the wet well influent gate and recording well depths while dye testing and magmeter recording was underway downstream. Flows were calculated by determining the cross-sectional area of the wet well at the depths recorded during the test, and multiplying by the change in depth for each time interval recorded. Results of the drawdown testing are presented in Figure 8, showing a consistent drawdown rate over the five minute run of the test and an average flow over the test of 21.3 cfs. The dye test/meter comparison is given in Figure 9, showing agreement between dye test and meter values at the three comparison points (standards curve prep times). An overall summary is found in Table 1, indicating a good three-way comparison between the dye test, drawdown and meter flow rate results (dye test/meter multiplication factor = 0.99 ± 0.05, meter/drawdown comparison 20.4/21.3 cfs at 12:40). These results are highly consistent with similar testing performed in March of 1997.

DISCUSSION AND CONCLUSIONS

While space considerations limit us to a brief discussion of our development of a rigorous dye testing method, the complete error analysis performed to support this study identified a number of key requirements for accurate and reliable dye testing. While not detailed in this paper, these requirements are listed below:

- Continuous monitoring of dye injection rate
- Verification of dye consistency throughout
- Accounting for time-of-travel
- High quality standards curve preparation from representative sewage samples
- Frequent standards curve preparation
- Continuous monitoring of suspended solids
- Comprehensive error analysis

Peformance of a comprehensive error analysis includes accounting for the contribution of each one of these factors to the overall uncertainty of the flow rate estimate. In general, the majority of error introduced in a typical dye test is related to preparation of standards curves and variation in suspended solids and background fluorescence. In general, a thorough understanding of the theory and potential sources of error in dye testing makes it possible to minimize the key sources of error and perform highly accurate flow rate estimates.

The testing methods described in this paper have been used to perform well over 100 dye tests at metering sites throughout the greater Detroit area. The method has been used to measure flows from 3 to 350 cfs, and has been shown to give highly accurate and consistent results throughout the range of measured flow rates. As part of a system-wide evaluation of meter accuracy in the GDRSS, dye testing has been invaluable in identifying problems with existing meter installations and building confidence in the operation of many of the meters in the system. Dye testing has also been a valuable tool for verifying the accuracy of new meters and debugging problems with installations.

Based on our experience with a wide range of metering technologies, including point- and transit-time ultrasonic meters, magmeters, and flumes and weirs, our general observation has been that problems with meters tend to be related to specific installations, rather than to any particular technology or manufacturer. Given this observation, it is our recommendation that calibration or verification of meter accuracy should be performed for virtually any installation, regardless of manufacturer's claims to the contrary. Our experience has shown dye testing to be a valuable tool for achieving this goal.

IS COMPREHENSIVE REHABILITATION FOR I/I REMOVAL COST EFFECTIVE IN HOUSTON?

ABSTRACT

The City of Houston was under mandates from the U.S. Environmental Protection Agency (EPA) and the Texas Natural Resource Conservation Commission (TNRCC) to control wet-weather overflows caused by excessive infiltration/inflow (I/I) during rainfall events by December 31, 1997. The City of Houston complied with these regulatory orders by completing the largest Sanitary Sewer Overflow (SSO) correction program in the country, notwithstanding extremely tight schedule constraints and a massive $1.17 billion capital improvement program. The Wastewater Program (Program) was created in 1992 to manage the work toward mandated compliance.

One of the alternatives analyzed for achieving compliance with the administrative orders was sewer system rehabilitation to reduce I/I. The analysis made the assumption that comprehensive rehabilitation is required to achieve significant I/I reduction. Rehabilitation that addresses all components of the system (mainlines, laterals, and services) is termed "comprehensive rehabilitation". The analysis determined that this type of rehabilitation was not cost effective on a system wide basis for Houston. It is speculated that this is due in part to Houston's unique climatology and collection system characteristics. It should be noted that this analysis studied only comprehensive rehabilitation. Other kinds of rehabilitation may prove to be cost-effective even in Houston.

A rehabilitation demonstration project was undertaken to determine the costs and effectiveness of two levels of rehabilitation in reducing rainfall dependent I/I (RDI/I). The extent of rehabilitation under both levels was less than that of comprehensive rehabilitation. Both approaches were less effective at reducing RDI/I than the method for comprehensive rehabilitation assumed in the Houston analyses. In a subsequent analysis in one of the demonstration basins, the incremental cost to complete the rehabilitation effort on private property (i.e. expand the rehabilitation effort to comprehensive) was shown to be more expensive than providing relief sewers in that basin to alleviate potential overflow conditions.

KEYWORDS

RDI/I, rehabilitation, cost effective, comprehensive rehabilitation

INTRODUCTION

The analysis of the cost-effectiveness of sewer system rehabilitation used in the City of Houston Cost-Effectiveness Analysis (CEA) has been based on the assumption that significant reductions in RDI/I can only be achieved in a given area of the system when every sewer line up to 30.5 cm (12 inches) in diameter is rehabilitated. This includes all main lines in the public right-of-way and in easements, and all laterals and private services. The rationale behind this assumption is that water migrates. If only the detected leak defects in a sewer reach are fixed, the water will migrate to other nearby undetected defects or the next sewer reach, which may not have been previously leaking. In 1980, EPA analyzed 18 municipal sewer systems that had completed EPA Step 3 Construction Grant projects on sewer line rehabilitation (Conklin, 1980). They found that realized RDI/I reduction fell short of predicted reduction. One of the contributors was a migration of water from repaired joints to joints that had not been repaired. Since then, rehabilitation projects throughout the country have reported wide ranges in RDI/I reductions,

R0025141

demonstrating the complexity and difficulty in predicting the I/I reduction benefits from sewer system rehabilitation.

For the Houston CEA, assumptions were made on the effectiveness or efficiency of removal of RDI/I by comprehensive rehabilitation. For other methods of rehabilitation which did not address all mainlines, laterals and private services, it was assumed that the effectiveness of RDI/I removal could not be conclusively established theoretically but only through demonstration projects.

METHODOLOGY

Houston's large sanitary sewer collection system encompasses 9,656,000 km (6,000 miles) of mainline pipe in 51 wastewater treatment plant service areas. It was divided into three groups, called Rounds in the administrative orders, for analysis purposes. The Round 1 service areas encompass approximately 26 percent of the City by area, and the Round 2 service areas encompass approximately 53 percent of the City. Due to schedule considerations, the Round 1 CEA had to be completed in the first 90 days of the Program. This necessitated that simplifying assumptions be made to accelerate the analysis.

Round 1 Analysis

The comprehensive rehabilitation assumption was applied to each hydrograph basin, the smallest unit of flow input to the Program's SWMM EXTRAN model. A hydrograph basin typically consists of several upstream temporary flow monitor subbasins, each comprised of 1,500 to 6,000 m (5,000 to 20,000 linear feet) of main line sewers. Therefore, a typical hydrograph basin might include 6,000 to 30,000 m (20,000 to 100,000 linear feet) of main line sewers.

Comprehensive rehabilitation was assumed to achieve a 70 percent reduction in RDI/I (both volume and peak) within the area rehabilitated. It was assumed that roughly 80 percent of the RDI/I was contributed by the worst 50 percent of the basin. Therefore, comprehensive rehabilitation within the subbasins comprising the worst 50 percent of the basin would reduce the total basin RDI/I by about 50 percent (70 percent reduction of 80 percent of the RDI/I equals 56 percent reduction, which was rounded down to 50 percent).

The total potential cost savings in relief, treatment, and wet weather facilities resulting from comprehensive rehabilitation was estimated for each service area and allocated to each hydrograph basin in proportion to its RDI/I contribution. The total service area overflow correction cost (sum of relief, treatment, and wet weather facilities plus comprehensive rehabilitation) was plotted as a function of increasing RDI/I removed, and the lowest total cost was determined from this curve. The curve was developed by making broad assumptions about the relationship between flow reduction in the upstream basins and the resultant sizes of downstream relief projects. For each service area, model runs were made for the 0 percent and 100 percent rehabilitation scenarios (equivalent to 0 and 50 percent RDI/I reduction, respectively) plus two intermediate points, and the curve was interpolated between these points. The resultant cost-effectiveness curve for the FWSD No. 23 Service Area in Houston is shown in Figure 1.

Based on these assumptions for the Round 1 service areas, it was determined that comprehensive rehabilitation was not cost-effective. Rather, the most cost-effective overflow control alternative was found to be a combination of relief and treatment, and wet weather facilities in some service areas.

Round 2 Analysis

The comprehensive rehabilitation assumptions were modified for the Round 2 service areas for several reasons. The schedule allowed more time to do a more detailed analysis, and there was genuine interest in giving comprehensive rehabilitation every chance to succeed. The Round 1 rehabilitation assumptions were modified for the Round 2 analysis, as follows:

The unit of analysis for comprehensive rehabilitation was the smaller subbasin rather than the larger hydrograph basin.

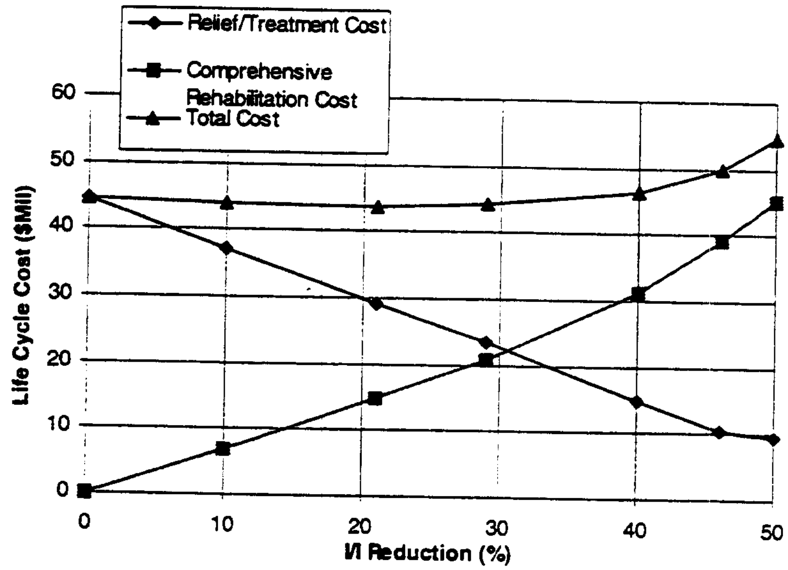

Figure 1. Typical Cost-Effectiveness Analysis Curve

It was reasoned that if every main line, lateral, and service within a subbasin were rehabilitated, then the resulting RDI/I rate should reasonably be similar to that of a newly constructed sewer system, regardless of the existing RDI/I rate. The 2-year design storm peak RDI/I rate used in the CEA for areas of future development is 23.4 m^3/ha/day (2,500 gpad). The RDI/I rate, or "cap", for a newly rehabilitated subbasin was set at twice this amount, or 46.8 m^3/ha/day (5,000 gpad). This cap was assumed to be the same whether the existing RDI/I rate for a subbasin was relatively low (e.g., 93.5 m^3/ha/day; 10,000 gpad) or very high (e.g., 1,870 m^3/ha/day; 200,000 gpad). This more aggressive approach in RDI/I reduction was intended to target the leakiest basins in the City. Figure 2 shows the range of projected design flow rates for one of the Round 2 service areas. One hundred percent rehabilitation in a subbasin was assumed to be required to achieve an RDI/I rate of 46.8 m^3/ha/day (5,000 gpad).

In the Round 1 cost-effectiveness analyses, the specific subbasins that formed the 50 percent of the basin which was rehabilitated were not identified, nor were the specific downstream projects affected by comprehensive rehabilitation in each basin identified. The Round 1 analysis simply assumed that downstream projects in general would diminish in direct proportion to the reduction in flow attributed to comprehensive rehabilitation of the upstream subbasins. For the Round 2 analysis, a direct relationship was established between the reduction in RDI/I due to the rehabilitation in a particular subbasin or group of subbasins and the resultant change in the required downstream projects. The cost savings realized through the elimination or downsizing of a downstream project was distributed to each upstream subbasin that contributed to the savings. Distribution was on the basis of peak flow reduction in the case of relief and treatment facilities and flow volume in the case of wet weather facilities.

CE ratios. The cost effectiveness of comprehensive rehabilitation was determined by comparison of the cost to rehabilitate a subbasin to the cost saved by the reduction of downstream projects. A cost-effectiveness (CE) ratio was calculated for each subbasin. The CE ratio is defined as the ratio between the cost savings realized in the downstream project reductions due directly to the comprehensive rehabilitation of an upstream subbasin and the cost to rehabilitate the subbasin. Needed structural rehabilitation in a subbasin was also considered in the analysis. This was accomplished by reducing the estimated cost for comprehensive rehabilitation by the cost of either incurred or planned structural rehabilitation. For subbasins in which structural rehabilitation plans have not been developed, structural rehabilitation costs were estimated based on the structural rehabilitation costs in adjacent subbasins. This adjustment was made to ensure that deterioration of the existing pipe system was accounted for in the analysis.

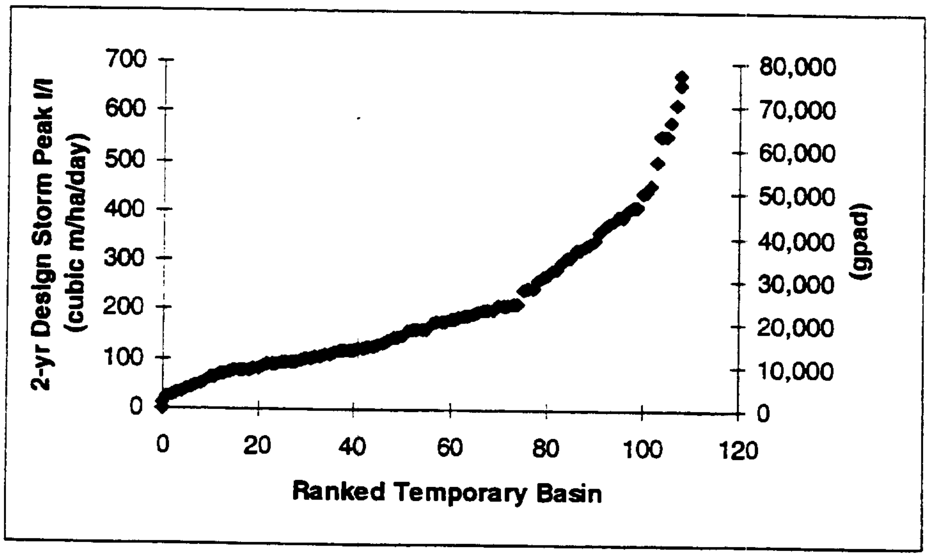

Figure 2. Variation of Design RDI/I Rate for Typical Service Area

Subbasins with CE ratios greater than 1.0 were assumed to be cost effective to rehabilitate. Preliminary CE ratios were determined first by an initial model run assuming comprehensive rehabilitation and a resulting reduction in existing RDI/I flow for all subbasins in the service area. Then, a second run was made in which existing RDI/I flows were reduced only for those subbasins with initial CE ratios greater than 1.0. In this run, fewer projects were eliminated and project reductions were smaller than in the initial run because the overall flow reduction was less. The revised CE ratios calculated based on the second run were generally smaller than the initial values, and fewer CE ratios were found to be greater than 1.0.

The effectiveness of comprehensive rehabilitation in reducing flows and eliminating or reducing downstream projects is illustrated in the computation of the CE ratios for the subbasins in a service area. The Northside Phase II and Almeda Sims service areas were the only Round 2 service areas that had any subbasins with initial CE ratios greater than 1.0. (A few subbasins in other service areas had initial CE ratios between 1.0 and 1.1, but these were considered too marginal for further consideration.) When subsequent computer runs were completed in which subbasin flow reductions were assumed only in those subbasins with initial CE ratios greater than 1.0, the overall flows in the system increased. Fewer downstream projects were eliminated or reduced causing a reduction in the cost benefit of the upstream rehabilitation. This was generally sufficient to lower the CE ratios below 1.0.

Results. Of the 650 Round 2 subbasins analyzed, only two had a final CE ratio greater than 1.0. Both subbasins, however, are on the list of subbasins targeted for review and flow re-monitoring because their high flow projections are not supported by the field investigations summarized in the Physical Inspection Reports. Flow re-monitoring has the potential to both reduce projected design flows and eliminate or reduce the need for downstream projects, which would likely reduce the CE ratios to below 1.0.

In addition, the final CE ratios are based only on life cycle capital costs. There are other costs associated with implementation of a private services rehabilitation program including such things as inspection, testing, and legal fees. If the City were responsible for all or a portion of these additional costs, the rehabilitation alternative becomes more expensive and less attractive; the CE ratios decrease. For these reasons, it was concluded that comprehensive rehabilitation was not cost-effective in the Round 2 service areas. Comprehensive rehabilitation analysis was not undertaken in the remaining service areas. It was reasoned that Rounds 1 and 2 encompass approximately 80 percent of the City, and the chance that comprehensive rehabilitation would be found cost effective elsewhere in Houston was too small to expend the effort in analysis.

There are several factors which are believed to contribute these results. Houston/Gulf Coast climatology is characterized by two types of storm events. Frontal storm events usually are of longer duration and have lower intensities. These storms do not tend to be the ones that cause the overflow problems. Summer thunder storms with short durations, high intensities cause flows with wet-weather peaks typically 20 times the dry weather flow. These storms are the ones likely to cause overflow problems. However, while these storms cause high peak flows, they are low volume events. The isolated facilities in the system, trunk sewers and lift stations, that do not have sufficient capacity to convey the peak flow cause the flow to back up in the system and overflow. When these bottle necks are relieved, the overflows are eliminated. It is generally much cheaper to relieve these bottle necks than to rehabilitate all of the pipes in an area to keep the flow out in the first place.

Cedar Bayou Service Area

Whereas the Round 2 comprehensive rehabilitation analysis was more detailed and aggressive than the Round 1 analysis, it also made some simplifying assumptions with regards to the number of private service in a service area, the manner and magnitude of future growth, and the cost of relief facilities. An analysis was prepared for the Cedar Bayou Service Area in which these quantities were refined further.

Based on the CEA for the Cedar Bayou Service Area, a relief, transport and treat alternative was identified as the cost-effective solution. The recommended facilities were progressed through preliminary and final design resulting in the following estimated capital costs shown in Table 1.

Table 1
Total Overflow Control Costs Without Rehabilitation
Cedar Bayou Service Area

WWTP LS and Stormwater Clarifier	$2,971,000
WCID No. 73 LS, 40.6 cm (16 in) FM, 76.2 cm (30 in) Sewer	$5,359,000
Sunny Glen LS and 30.5 cm (12 in) FM	$1,526,000
Glengyle LS and Relief	$347,000
TOTAL	$10,203,000

It was decided to revisit the rehabilitation analysis beginning with the design flows. There are a total of 675 served and 377 unserved dwelling units in Cedar Bayou for an estimated population of 3,156 (1,052 units X 3.0 people/unit). A population projection was prepared based on current census tract growth rates tempered by the availability of infrastructure improvements to encourage growth. The projected population for the year 2030 (the planning horizon) is 4,960. Future flow estimates were based on this number.

assuming reductions of RDI/I as high as 95 percent for comprehensive rehabilitation. Even in these cases, comprehensive rehabilitation was not cost effective. The conclusion is that comprehensive rehabilitation is not cost effective in Houston. It is cheaper to relieve Houston's collection system bottle necks for the short duration, high intensity thunder storms of the Gulf Coast region.

In addition to comprehensive rehabilitation, a rehabilitation demonstration construction project with pre- and post-rehabilitation flow monitoring studied two other methods of rehabilitation less extensive than comprehensive rehabilitation. These two methods were found to be effective at reducing RDI/I, but were less effective at reducing RDI/I than the method for comprehensive rehabilitation assumed in the Houston analyses.

It should be noted, however, that many types of rehabilitation with varying levels of rehabilitation were not tested and could prove to be cost effective. In addition, the methods of rehabilitation tested could prove to be cost effective for more limited, localized problems in other portions of the City's system. Finally, soil characteristics and climatology vary from region to region as well as sewer system conditions and available system capacity, and the conclusions found for Houston may not be applicable in other parts of the country.

ACKNOWLEDGMENTS

This project was funded by the City of Houston, Department of Public Works and Engineering under the auspices of Wendell L. Barnes, P.E., Deputy Director and Program Director of the Wastewater Program.

ABSTRACT

This paper discusses a method of evaluating and optimizing effectiveness of sewer rehabilitation. It proposes standard methods for reporting and evaluating sewer rehabilitation projects that will allow readers to understand the project and compare it to others.

KEY WORDS

I/I Reduction, Sewer Rehabilitation, Effectiveness, SSO Elimination

INTRODUCTION

Thousands of communities and municipalities, nationwide have rehabilitated portions of their collection systems, yet very few know whether or not they have been successful. With its current focus on SSO's, EPA expects communities to spend more than $20 billion on sewer rehabilitation in an effort to eliminate SSO's. The big problem is that no one can forecast how effective the rehabilitation will be. EPA doesn't know; the communities don't know and the engineers don't know. That amounts to a $20 billion program whose outcome is extremely uncertain. It might make sense to find out more about the actual effectiveness of rehab before committing the entire county to a $20 billion project.

This paper proposes using small test basins or pilot projects in each community to find out what really works before committing the community to a large-scale sewer rehabilitation program. On a small basin, a community and its engineer can afford to experiment without breaking the bank. Try to eliminate direct connections and see how much I/I that removes. If that doesn't remove enough I/I, try rehabilitating the sewer mains and see how much more I/I that eliminates. And if that doesn't work out very well, try rehabilitating the building laterals. If none of the rehab strategies work, then the municipality may need to abandon rehab altogether and just build bigger sewers, bigger plants and perhaps off-line storage for wet weather flows. In the end each community should be able to settle on a strategy that works the best for its own sewer system.

The large majority of North American engineers and regulators, with a few notable exceptions, take a pessimistic view of sewer rehabilitation. Very few believe that rehab can remove any more than 30% or 35% of the I/I from a sewer system. In Ohio, its even institutionalized; Ohio EPA will not issue loan money to communities that forecast I/I reductions that exceed 35%. They don't believe a community can achieve better than 35% reduction. So how successful can rehabilitation really be?

Extensive research through published literature and engineering reports has yielded some interesting information about sewer system rehabilitation:

1. I/I reduction information is available from at least 91 sewersheds worldwide
2. The average reported reduction is 49% of peak I/I rate
3. The standard deviation is 25%, meaning that about two-thirds of the reported projects fall between 25% reduction and 75% reduction
4. Twelve projects exceeded 75% reduction

References for most of the sewersheds cited above are included at the end of this paper. Table 1, shown below, shows the I/I reductions as reported in the literature. References are cited in the rightmost column.

REPORTING STANDARDS

The large number of question marks and blanks in Table 1 above suggest the need for consistent reporting standards. If the industry is to learn what works and what doesn't, then authors should report their results more completely. In effect, authors should report enough information to complete Table 1 above.

First the rehabilitated sewer system should be fully inventoried and described. Describe sizes and lengths of mainline sewer as well as pipe materials, joints, type of backfill and type of trenches, (i.e. common trench versus separate trench, see Figure 1). Describe manhole construction and materials including frames and covers. Discuss the condition of the joint between the frames and the top section of manhole. Don't forget building laterals. Report the number of buildings, the sizes and types of pipe used both inside and outside the right-of-way. Discuss ownership of the laterals and describe the location and configuration of cleanouts, if any.

Report the percentage of mainline sewers, the percentage of manholes and the percentage of laterals actually rehabilitated.

To estimate actual I/I reduction, compare rainfall derived I/I (RDII) versus rainfall for many storms both before and after rehabilitation. Report the number of wet weather events used – both before and after. Calculate both the mean percentage of I/I removed and the standard deviation. Finally, report the same statistics for the control basin to adjust for seasonal or antecedent differences between the pre-rehab RDII and the post-rehab RDII.

One reason that most agencies and professionals remain skeptical of rehabilitation is that the information published in Table-1, above, has not been well publicized. Compiling the list has involved researching every reference listed at the end of every manuscript on I/I reduction that the author has ever read. In addition, it has involved questioning engineers, over the last 10 years about measurable I/I reduction projects in which they had been involved. A second reason that many professionals remain skeptical is that thousands of their own

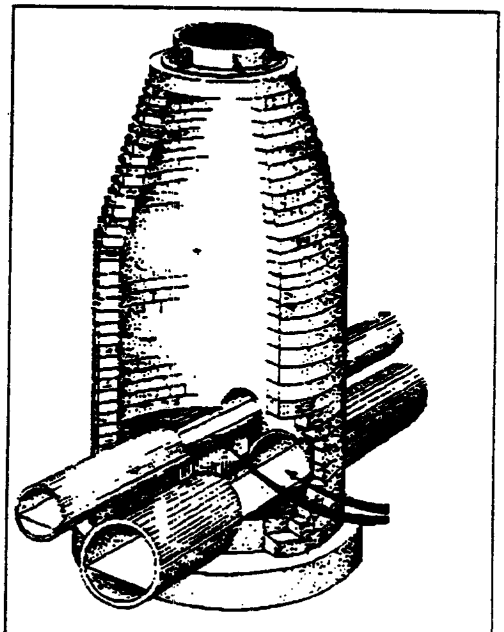

Figure 1 – Common Trench Sewer with Single Manhole

communities have had negative experiences with sewer rehabilitation. That is, many communities have spent lots of money on sewer rehabilitation with no discernible, tangible or measurable results.[24]

Even though a list of 91 projects may seem impressive, it represents less than 1% of all sewer rehabilitation projects ever conducted. Why are successful sewer rehabilitation projects so rare? Why does rehabilitation apparently fail to remove significant portions of I/I so often? How many rehabilitation projects may have actually been successful with no way of knowing?

These are important questions since one of the central strategies in SSO elimination is I/I reduction. To the extent that I/I reduction is successful, all the other strategies become less expensive. For instance, if a community can eliminate 70% of its I/I then it may not have to enlarge any sewers or treatment works saving an immense amount of money. Conversely, if that same community fails to remove any more than 30% of its I/I, then it may need to invest millions more dollars in sewer system enlargement to eliminate SSO's.

After more than a quarter of a century of sewer rehabilitation experience the collection systems community still can not predict, with reasonable confidence, how much I/I a community could expect to eliminate. We don't have enough data and it's our own fault. EPA hasn't demanded it; consultants haven't requested it, and municipalities haven't required it. So were still operating in the dark on a $20 billion question.

METHODOLOGY

One way to capture the needed data is to set up a network of small test basins. If each community contemplating significant sewer rehabilitation would set up a small test basin, say 5,000 to 15,000 linear feet of mainline sewer, and also set up a control basin of similar size, then we could start collecting the needed data quickly. If WEF or EPA would agree to be the clearinghouse for sharing experiences and results through their Web pages, then the information could be disseminated quickly. It is important to publish not only successes, but also failures, because the profession can learn as much from mistakes as it can from successes.

Each test basin needs to have a long-term monitor installed at the downstream end and a rain gauge situated within it; the same for the control basin. The concept is to gather rainfall and flow data from dozens of storms prior to rehabilitation, dozens of storms during rehab and dozens after rehab so that we can create a statistically meaningful relationship between rainfall and I/I before and after rehab, see Figure 2

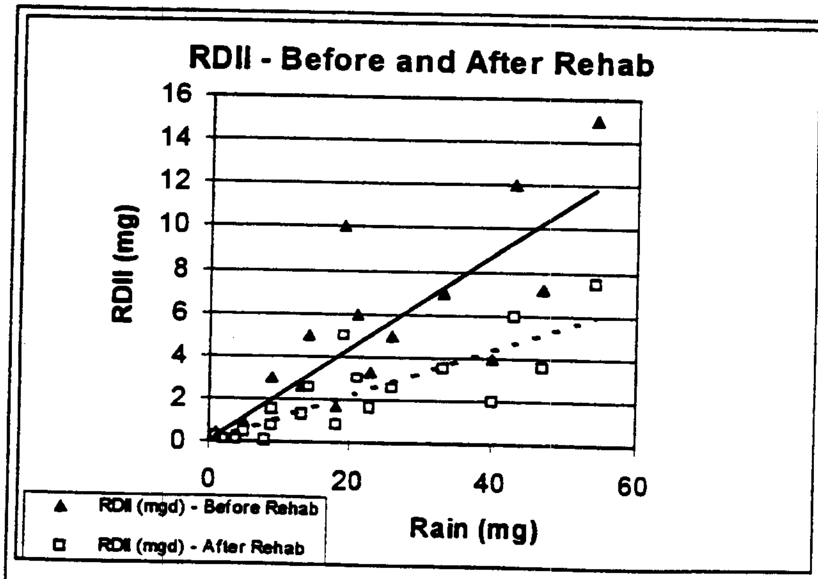

Figure 2

In this case rainfall and RDII data were taken from 20 storms before rehab shown by the dark triangles and also from 20 storms after rehab shown by the boxes. Both sets of data show a lot of scatter and they overlap. The solid trend line shows a linear regression estimate of RDII before rehab. The dashed line shows a linear regression estimate of RDII after rehab.

A control basin should also be set aside as a scientific control for the experiment. It serves the same function as a laboratory blank does in chemistry. The control basin should be left alone with no rehabilitation. The control basin helps account for the differences between a wet pre-rehab period and a dry post-rehab period or vice versa.[5]

By keeping the test basins relatively small, a community can limit its "experimental" expenditure on I/I reduction. If the rehab strategy works, then the strategy can be expanded to other parts of the collection system. If it doesn't then another rehab strategy can be tried without risking too much capital. Since each collection system is different, there is no assurance that what worked so well in Lower Paxton Township[4] in 1997, will work in Columbus. Small test basins also make the inevitable work on private property more politically palatable, since their are fewer building lateral owners to deal with. Finally, smaller basins allow engineers and municipalities to practice dealing with I/I migration issues on a small scale before trying to extend a possibly incomplete strategy to the rest of the collection system.

The downstream long-term monitor serves three other important functions. First, the people hired to find all the sources of I/I (sewer system evaluation survey) know that they need to look a little harder because they're being watched by the monitor. Second, the engineer hired to design the rehab project knows that he or she had better recommend effective rehab because they're being watched by the monitor too. And finally the contractors performing the rehab know that they better do the job just right, because they're also being watched. A little accountability goes a long way and this industry needs it.

Engineers who have tried to compare before and after rainfall and flow data from sewer rehabilitation projects know the difficulties and frustrations associated with trying to reach a simple conclusion. Many factors affect the rainfall-to-runoff relationship in a sanitary sewer, so there is inevitably a wide scatter in the data, again see Figure 2 above. Factors most affecting the rainfall to runoff relationship within a basin include: 1) rainfall intensity, 2) antecedent moisture, 3) season, 4) storm duration, 5) surface water coverage, and 6) new construction or rehabilitation. In fact, the scatter caused by these 6 variables is often so wide that a simple comparison of a month's worth of I/I before rehab to a month's worth of I/I after rehab is highly unlikely to capture the true effectiveness of rehabilitation. The solution is to collect data from many, many storms before, during and after rehab. Test basin monitors, therefore, should stay in the ground for 1 to 4 years or more. Since the monitors and rain gauges need to operate for such a long period of time, they should be connected to phone lines. Collecting data for 25¢ per phone call is much less expensive than sending $70 per hour crews into the field to collect data.

The key units to measure are: 1) rainfall intensity, 2) rainfall duration, 3) rainfall derived I/I (RDII) rate, and 4) RDII volume. Figure 3 shows a graphical definition of RDII rate and volume. The key relationships to calculate are 1) peak rainfall intensity to peak instantaneous flow rate, and 2) rainfall volume to I/I volume. See Figure 3.

Engineers can use some interesting units of measurement for the above comparison. Peak rainfall intensity commonly measured in millimeters per hour or inches per hour can be converted to liters per second of rain or millions of gallons per day of rain (mgd). Converting rainfall rates into common wastewater flow units provides an unusual perspective on the immense amount of rain that comes out of the sky. It also makes direct comparisons quite easy.

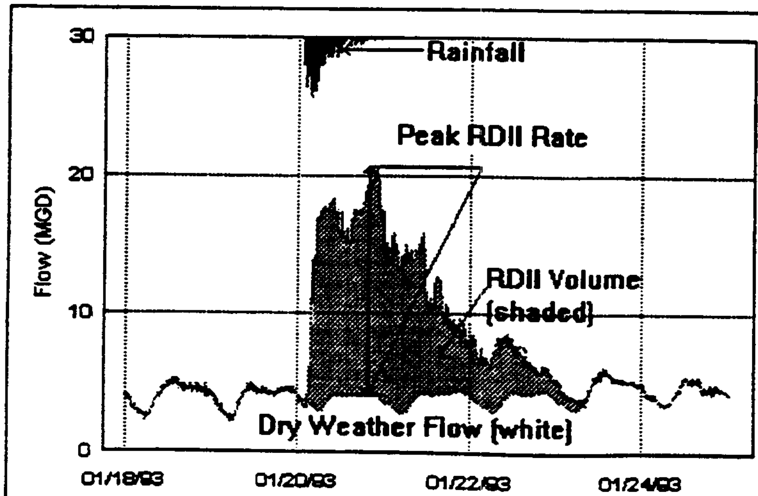

Figure 3

RESULTS

Two test basins have already been set up in Ohio: one in the Point Place neighborhood of Toledo and

R0025152

one in Erie County near the center of Huron. Both communities also have control basins. Each test basin and each control basin have a telemetered flow monitor and a telemetered rain gauge installed. Both sets of test basins in were set up in 1996 as part of the I/I monitoring.

Toledo performed Sewer System Evaluation Survey work in Point Place in 1996 and early 1997. Scott Weasel, P.E. and Jim Breznai, P.E. from Peterman and Associates out of Findlay, Ohio were the Engineers. ADS Environmental Services performed the fieldwork under subcontract to Peterman. Based on the results of the SSES, Peterman recommended replacing the storm sewer in the test basin because it was structurally deteriorated and its outlet to Maumee Bay was plugged. Fieldwork also indicated that the storm sewer surcharged and leaked indirectly and profusely into the sanitary sewer mains and laterals during rainstorms. The storm sewer was replaced and 6 of the 54 building laterals were also replaced, within the right-of-way, in October and November 1997.

Pre-rehab analysis of 25 storms dating from December 1996 through October 1997, shows that RDII rates averaged 22.6% of the rain falling on the ground. The standard deviation was 17% indicating a wide scatter in the data. Post-rehab analysis of 6 storms between November 13, 1997 and January 4, 1998 yielded an RDII rate of 10.4% with a standard deviation of 4%. This means that rehabilitation removed an average of 54% of the RDII in the test basin. The preliminary certification letter from Peterman and Associates conservatively claimed only a 50% reduction in I/I.

This is the first time that sewer rehabilitation in the state of Ohio has achieved documented success of 50% or more. These results give the City of Toledo confidence that sewer rehabilitation can successfully remove large amounts of I/I from their collection system.

Four more test basins and control basins are scheduled to be installed in Ohio in 1998, 2 in Columbus and 2 in Clermont County. Hopefully all four municipalities will be able to share their experiences, both positive and negative, through a WEF Web site or an EPA Web site.

CONCLUSIONS

1. I/I reduction is more effective than most people think. The average reduction reported from 91 basins worldwide is 49%. Twelve basins exceeded 75% reduction.
2. Test basins should be used to check out sewer rehabilitation strategies on a small scale before committing a community to a large-scale program that may be incomplete and ineffective.
3. Before-rehabilitation results should be reported many, many storms of varying intensities. Likewise, after-rehabilitation results should be reported from a similar number of storms. Control basins should be used to account for differences in antecedent moisture between the before-rehabilitation data set and the after-rehabilitation data set.
4. Reports on rehabilitation results should include enough standard information about the project for other communities to learn about the scope needed for effective rehabilitation. Reports could benefit the most people by being posted on a World Wide Web site set up for sewer rehabilitation.
5. Based on the results of the test basin, the City of Toledo knows that it is possible to reduce RDII in a neighborhood by over 50%. Stated differently, the City knows that plugged storm sewers can create enormous amounts of indirect I/I into the sanitary sewer system. Replacing the storm sewer and also replacing some of the sanitary laterals beneath the storm sewer can reduce the RDII rate by 50% or more.

FOOTNOTE

Test basins are not a new idea. USEPA in "*Facilities Planning 1981*" Section 5.4.4, states: "*For projects where large ... scale work is proposed the recommended approach is rehabilitating first a selected sample of sewers or a small subsystem. Analyze the results of the pilot rehabilitation to be sure the benefits are attained before conducting a full scale rehabilitation.*" USEPA thought of this idea 16 years ago, but its value is just now becoming apparent.

THE INSPECTION OF SURCHARGED SEWERS USING SONAR TECHNOLOGY

Gerald T. Preau, P.E.
Principal Civil Engineer, Sewerage & Water Board of New Orleans

Sal A. Ahmad
Senior Engineer, Montgomery Watson Inc.

Alan McCloskey
Vice President, Amtec Surveying Limited

ABSTRACT

In recent years, sewer rehabilitation efforts adopted by many municipalities throughout the United States, especially in older cities where wastewater collection systems are approaching their life expectancy, are based on similar assessment techniques. The ability to inspect aging sewer lines in a manner that would provide useful information to engineers and professionals is a major challenge. In addition to the typical smoke testing, dye flooding, and closed circuit television (CCTV) methods used to assess the condition of the gravity sewer systems, sonar inspection (a new emerging technology) is beginning to get recognition in the United States. Used in Europe for over 10 years, this new method of inspection, survey, and evaluation is providing valuable information to engineers on sewer lines that are fully or partially submerged and unable to be inspected by other methods. For example, estimating the amount of silt accumulation in any segment of a sewer line has always been desired in order to prioritize cleaning operations, but considered impossible. The new sonar technology can not only provide estimations of silt accumulation but can actually measure it. In this paper, the authors introduce this exciting new inspection technology, provide a historical background on its development, and explain the makeup of its components. The paper also demonstrates how high-resolution sonar gives an internal cross-section profile of a sewer, so that a pipeline can be surveyed and fully assessed, including measuring the magnitude of defects. An inspection project in the City of New Orleans that successfully utilized the use of sonar technology combined with typical CCTV is presented and discussed as a case study. Videotape that shows the findings of Totally Integrated Sonar and CCTV Inspection Technique (TISCIT) will be available as background material. Sonar and TISCIT, with their ability to assess the condition of partially submerged sewers (CCTV system being positioned above the waterline and the sonar below resulting in a 360-degree survey of the pipeline), are new approaches to sewer inspection.

BACKGROUND

The advent of surveying sewer pipelines with Closed Circuit Television (CCTV) in 1965 became a great boon to pipeline engineers as they could, at last, plan system maintenance in advance of pipelines collapsing. They could also help in improving the longevity of the pipelines by rehabilitating damaged pipelines based on the defects found and the environment in which the pipelines exist (i.e., its strategic importance). This development created an immediate market in rehabilitation and renovation techniques of which now there are solutions for almost any situation found in the pipeline.

Because pipeline engineers could plan renovation and remedial measures, the need for more information about the pipelines increased, which caused a dramatic increase in the number of CCTV surveying companies offering their services. With the accumulation of so much data and the desire to capture more, it soon became apparent that the CCTV survey techniques available at the time were limited. The restrictions were generally related to the inability of the CCTV camera to survey pipes greater than 60 inches in diameter, the inability of the CCTV camera to "see" under the water line (in case of sewers that are difficult to de-water), and the inability of the CCTV camera to accurately measure the degree of pipe deformation. These restrictions were addressed by a number of companies as follows:

a. With the use of charged-coupled device chips instead of the tube inside the CCTV camera, the sensitivity greatly increased over the years as technology advanced. This advancement meant that CCTV cameras could now survey pipes in excess of 120 inches in diameter. The development of the "Pan and Tilt" type cameras increased this ability even further.

b. In 1988, the United Kingdom's Water Research Center (WRc), Amtec Surveying Inc. (Amtec), and MEL Inc. (a British offshore sonar company) developed a short range, high resolution, sonar system giving continuous survey information on the condition of pipelines below the water line. The sonar can be used alone for fully surcharged pipelines, or in conjunction with a CCTV camera for semi- surcharged pipelines (CCTV above the water line and sonar below resulting in a 360-degree survey of the pipeline). This method is called the Totally Integrated Survey and CCTV Inspection Technique (TISCIT).

c. LightLine, a method developed by Amtec, enables the shape of the pipe to be accurately profiled and measured. LightLine enables "pinch points" to be measured along the pipeline where more accurate dimensions are required. It is a particularly effective method for surveying plastic pipes (or any other flexible material pipe) where measuring deformation by CCTV is ineffective.

SEWER SYSTEM EVALUATION AND REHABILITATION PROGRAM

The Sewerage and Water Board of New Orleans (S&WB) is implementing a multi-year Sewer System Evaluation and Rehabilitation Program (SSERP). The purpose of this program is to eliminate sewer system overflows by fixing the major structural defects in the collection system. The SSERP will also address the collection and transmission system bottlenecks by upgrading pipeline carrying capacity utilizing a system-wide hydraulic model.

Several Collection System Evaluation Studies (CSES) are planned to provide physical assessments of the gravity sewer conditions. These CSESs include the typical techniques of sewer inspection and survey such as smoke testing, dye flooding, flow monitoring, night flow isolation and CCTV. However, due to the age of the New Orleans sewer system (over 100 years old) and to the fact that some large diameter sewer lines were impossible to de-water for normal CCTV, new techniques were researched and evaluated which led to the use of sonar technology as a pilot project.

PILOT PROJECT

The S&WB's Clara Street sewer is one of the key gravity lines in the New Orleans collection and transmission system. This sewer line carries the flow of multiple interceptors that collect wastewater from the Carrollton, Uptown and Central Business District (CBD) service area basins. The Clara Street sewer line is constructed of mostly brick and is more than ninety (90) years old. This sewer is approximately 22,000 feet of 36-inch diameter to 84-inch diameter pipeline that terminates at the regional sewer pump station ("A") . The objective of this pilot project was to internally inspect, survey and evaluate the Clara Street sewer using the Sonar and TISCIT systems. Another objective was to establish the ability to document and determine the interior condition of pipes in varying material, shape, and size from the data generated by this technique.

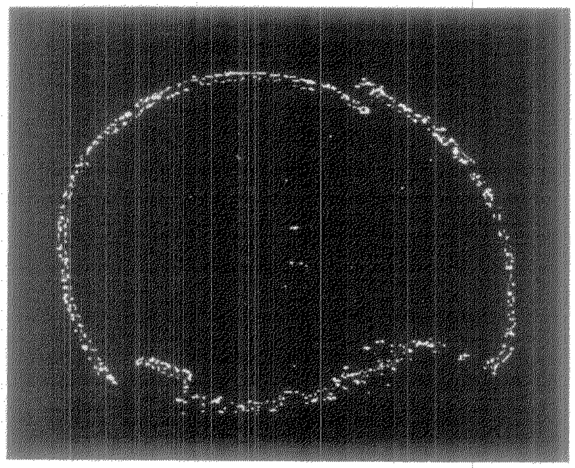
TECHNOLOGY USED

Sonar System

The Sonar System used in this project was specifically designed for the survey of submerged pipelines in that it uses high resolution/short range sonar. High-resolution sonar gives an internal cross sectional profile of a sewer, so that the pipeline can be surveyed and fully assessed, including measuring the magnitude of defects. The system itself is capable of surveying pipelines that vary in size from eight inches to in excess of 18 feet in diameter.

R0025158

The head of the sonar, its transducer, looks sideways (at right angles) to the direction of the motion through the pipe, resulting in one cross-sectional view of the pipe every second in "real time". The image below shows a 36-inch pipe with a break resulting in deformation of approximately 15 percent of the original pipe diameter. The image also shows heavy and compacted silt in the invert denoted on the sonar screen by the coloring (in cases where silt accumulation is less compacted, the coloring in the invert would be blue).



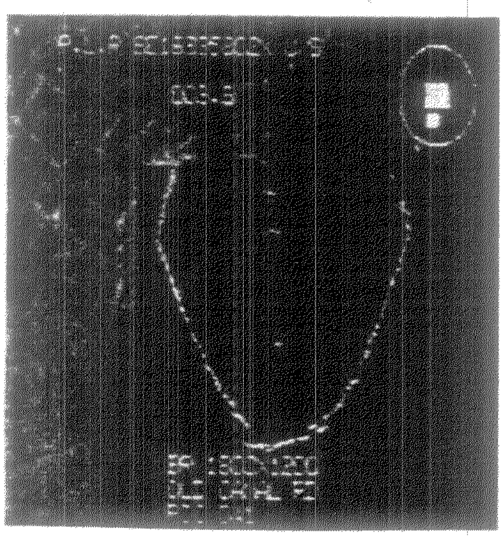
- The image on the left shows a 36-inch pipe with a break at 1 o' clock, resulting in deformation of approximately 15 percent.
- There is heavy compacted silt in the invert denoted by the coloring (if the siltation was less compact then the coloring in the invert would be blue).

TISCIT

This system is the combined technology of CCTV and high-resolution sonar that provides composite views of partially submerged sewers. TISCIT is an acronym for:

Totally **I**ntegrated **S**onar and **C**CTV **I**nspection **T**echnique

The CCTV system is positioned above the water line and the sonar below the water line resulting in a 360-degree survey of the circumference pipeline. The sonar image is superimposed onto the CCTV picture using a "mixer" which enables the rig manager to see both above and below the water line on one monitor. The image below shows a typical result from a TISCIT survey with the invert of the pipeline superimposed in the middle of the CCTV picture.



- A typical result from a TISCIT survey with the invert of the pipeline superimposed in the middle of the CCTV picture.
- Once a defect or feature is noted in the invert, the sonar image can be captured to disk to be subsequently viewed and measured in the office.
- The sonar image is removed periodically so that the line of the pipe can be seen.

This system can only be applied to pipes sized greater than 24 inches in diameter and would then be subject to the water level. As the speed of inspection is critical for the longitudinal resolution, the general guideline for the speed of survey is approximately four inches per second.

The sonar uses a color display to indicate the type of surface the sonar is sweeping, denoted by red for a hard surface and blue for a softer surface.
As with the CCTV system, the method of propulsion for the Pilot Project was either self- propelled or floated depending upon known circumstances in the pipeline, or the pipe size as follows:

- If heavy silt is expected, then pipelines above 24 inches would be surveyed by the sonar being floated along the crown of the pipe.

- If the pipeline is less than 24 inches, then either the self-propelled or winch- assisted self-propelled method would be used.

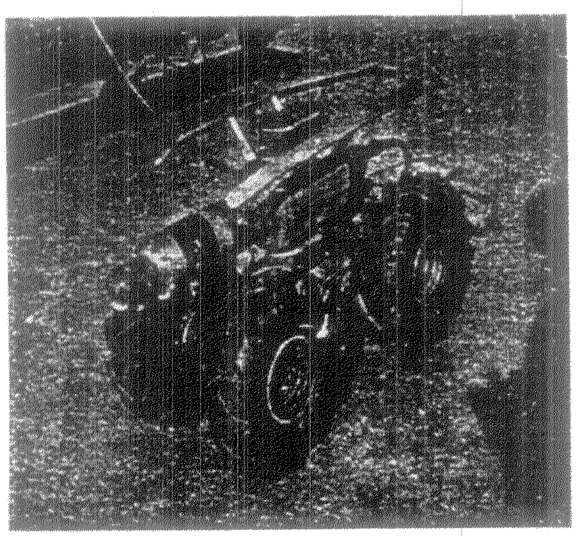
OVERVIEW OF EQUIPMENT

An experienced field team consisting of four individuals (a team leader, rig manager and two rig operators) was assembled to carry out the inspection for the Pilot Project. This team used a survey rig, generally referred to as the "Special Rig" to survey pipelines which range from "dry" all the way through to fully surcharged. This rig has the following survey propulsion methods:

- Self-Propelled
- Winched on Skids
- Floated (CCTV and Sonar or Sonar only)
- Winch-assisted Self-Propelled

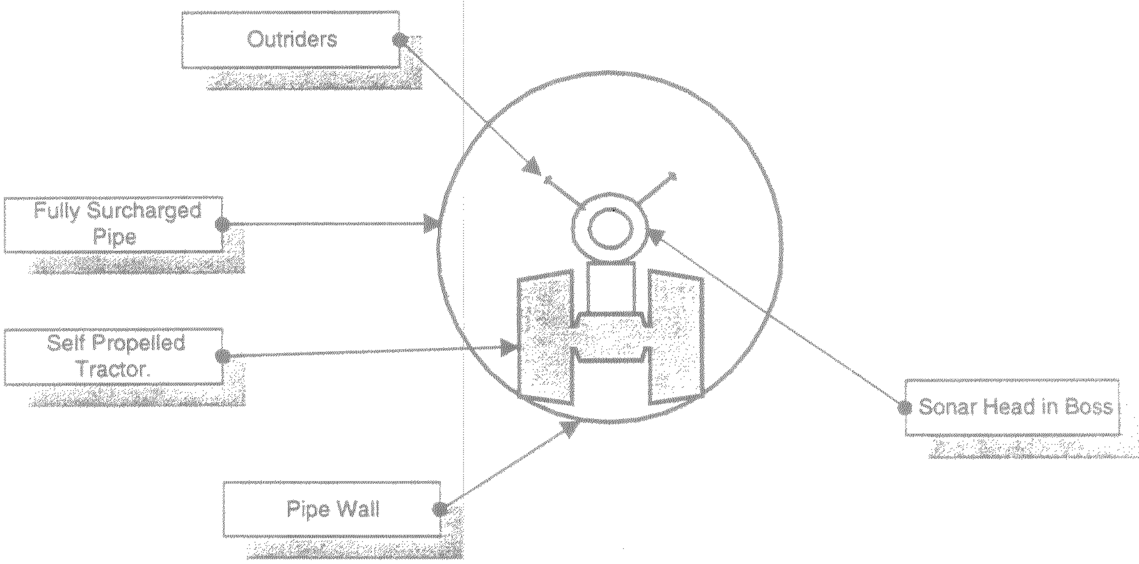
The following survey methods were used in the inspection of Clara Street sewer line:

1. Sonar only, self-propelled system; applied to fully surcharged pipelines

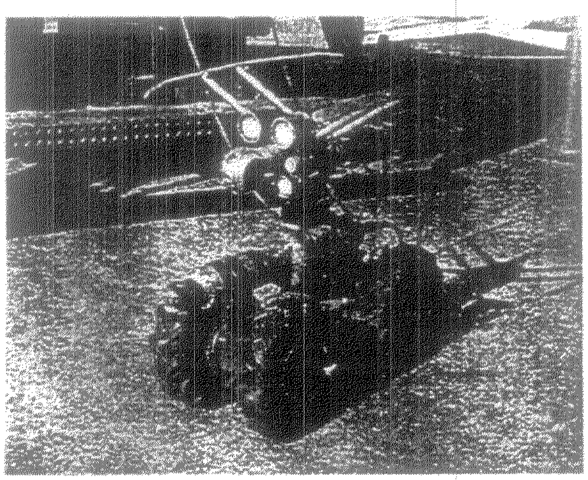


- This method was applied to the pipelines 36 inches in diameter or greater.
- Note the size of wheels which assists in the negotiation of siltation and the "outriders" which ensures the equipment's stability should it "fall" to one side.
- The block between the outriders is where the CCTV camera would be attached to should the need for TISCIT arise.

Set up for Sonar Only. Fully Surcharged. Self Propelled method.

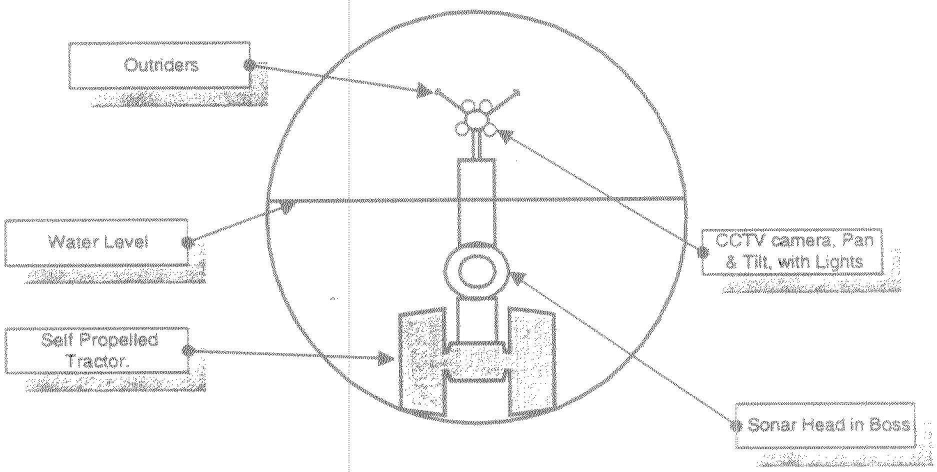


2. **TISCIT, self-propelled system. Applied to semi surcharged pipelines.**

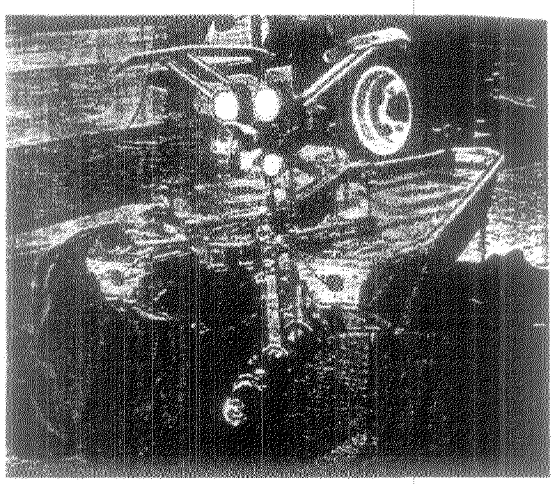


- This method was applied to the pipelines 36 inches in diameter or greater.
- Note the size of wheels which assists in the negotiation of siltation and the "outriders" which ensures the equipment's stability should it "fall" to one side.
- Building Blocks can be added between the camera and the sonar depending on the water level and pipe size.

Set up for CCTV/Sonar Combined. TISCIT. Self Propelled method.



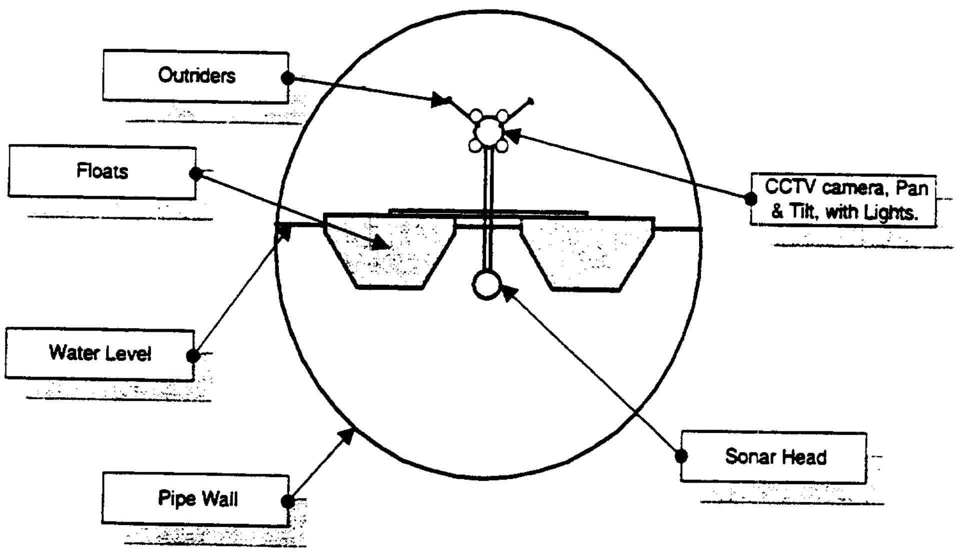
1. **TISCIT, float and winched system; applied to semi-surcharged pipelines that are greater than 36 inches in diameter.**



- This method was applied to pipelines greater than 36 inches.
- The distance between the floats can be changed to suit the size of pipe as can the distance between the sonar and the camera by using "spacer bars".
- A single float can be used where the pipe size allows such a set up.
- This method is not hampered by silt deposits.

R0025162

Set up for CCTV/Sonar Combined. TISCIT Floating Method. 360 degree coverage.



Larger Sizes set up. Two floats.

COLLECTION OF DATA

In order to collect the data and analyse it in an organized, uniform way, a coding system that is based on the Manual of Sewer Condition Classification (prepared by the United Kingdom Industry Engineering and Operations Committee) was adapted and utilized for this project. This coding system rates each defect feature based on defect magnitude (or severity). Table 1 lists some of these sewer condition codes.

For the Pilot Project, the rig manager complete a report sheet (field sheet), per survey, on site which was subsequently imported into a data handling software. The software had a very high level of validation that resulted in more accurate data. The collected data was then imported into a data interrogation software (Examiner, by Amtec) for subsequent analysis.

TABLE 1. **Sewer Condition Codes**

CODES	DEFINITIONS
BCL(J)	Crack longitudinal at ... o'clock (at joint)
CC(J)	Crack circumferential from ... to ... o'clock (at joint)
CM(J)	Cracks multiple from ... to ... o'clock (at joint)
FL(J)	Fracture longitudinal at ... o'clock (at joint)
FC(J)	Fracture circumferential from ... to ... o'clock (at joint)
FM(J)	Fractures multiple from ... to ... o'clock (at joint)
B(J)	Broken pipe at ... (OR from ... to ...) o'clock (at joint)
H	Hole in sewer at ... (OR from ... to ...) o'clock
D	Deformed sewer ... %
DH	Deformed sewer ... % loss of horizontal dimension
DV	Deformed sewer ... % loss of vertical dimension
X	Sewer collapsed ... % cross-sectional area loss
JDS	Joint displaced slight
JDM	Joint displaced medium
JDL	Joint displaced large
OJS	Open joint slight
OJM	Open joint medium
OJL	Open joint large
SSS	Surface damage, spalling slight at ... (OR from ... to ...) o'clock
SSM	Surface damage, spalling medium at ... (OR from ... to ...) o'clock
SSL	Surface damage, spalling large at ... (OR from ... to ...) o'clock
SWS	Surface damage, wear slight at ... (OR from ... to ...) o'clock
SWM	Surface damage, wear medium at ... (OR from ... to ...) o'clock
SWL	Surface damage, wear large at ... (OR from ... to ...) o'clock
MS	Mortar missing surface at ... (OR from ... to ...) o'clock
MM	Mortar missing medium at ... (OR from ... to ...) o'clock
MT	Mortar missing total at ... (OR from ... to ...) o'clock
DB	Displaced bricks at ... (OR from ... to ...) o'clock
MB	Missing bricks at ... (OR from ... to ...) o'clock
DI	Dropped invert, gap ... mm
RF(J)	Roots fine (at joint)
RT(J)	Roots tap (at joint)
RM(J)	Roots mass ... % cross-sectional area of loss (at joint)
IS(J)	Infiltration seeper at ... (OR from ... to ...) o'clock (at joint)
ID(J)	Infiltration dripper at ... (OR from ... to ...) o'clock (at joint)
IR(J)	Infiltration runner at ... (OR from ... to ...) o'clock (at joint)
IG(J)	Infiltration gusher at ... (OR) from ... to ...) o'clock (at joint)
EL(J)	Encrustation light from ... to ... o'clock (at joint)
EM(J)	Encrustation medium from ... to ... o'clock ... % cross-sectional area loss (at joint)
EH(J)	Encrustation heavy from ... to ... o'clock ... % cross-sectional area loss (at joint)
ESL	Scale light from ... to ... o'clock
ESM	Scale medium from ... to ... o'clock
ESH	Scale heavy from ... to ... o'clock
DE(J)	Debris (non-silt/grease) ... % cross-sectional area loss (at joint)
DES(J)	Debris silt ... % cross-sectional area loss (at joint)
DEG(J)	Debris grease from ... to ... o'clock ... % cross-sectional area loss (at joint)
OB(J)	Obstruction ... % height/diameter loss (at joint)
WL	Water level ... % height/diameter loss
LL	Line of sewer deviates left
LR	Line of sewer deviates right
LU	Line of sewer deviates up
LD	Line of sewer deviates down

DESCRIPTION OF DEFECTS

Eighty-seven (87) surveys were attempted throughout the Clara Street sewer line. Seven-five (75) surveys were successfully completed and twelve (12) survey attempts were abandoned due to debris and excessive silt accumulation. The following describe and summarize some of the defects found during Sonar/TISCIT inspections.

Structural Defects

Structural performance refers to the structural integrity of the system. Structural defects may ultimately worsen, resulting in failure by sewer collapse. Some structural defects are defined below as:

- Cracks and Fractures

Cracks can be identified as lines visible on the sewer wall, with the pieces of the wall still in place. A crack may be either longitudinal (i.e., following the longitudinal axis, or length, of the sewer), or circumferential (i.e., around the periphery of the sewer). Cracks are not serious defects, but are indicative of the initial stages of sewer deterioration. Multiple cracks are a combination of both longitudinal and circumferential cracks.

Fractures may be identified where the wall of the sewer is visibly open along the length and/or circumference of the sewer, with the pieces of the sewer wall in place. As with cracks, a fracture may be longitudinal or circumferential. The sewer may be seen to suffer from some distortion. The defect is indicative of the secondary stage of sewer deterioration and constitutes a more serious problem than a crack. Multiple fractures are a combination of both longitudinal and circumferential fractures.

- Broken Pipes

When broken pipes are encountered, pieces of the sewer conduit are noticeably displaced, differentially, and some pieces could be missing. Thus, a hole in the fabric of the sewer is also classified as broken. A broken sewer is the most structurally serious defect. A chipped sewer wall is not considered broken, but should be noted and kept under observation for possible further development into a break.

- Deformed or Collapsed Pipes

Deformation of a pipe is a measure of the vertical and horizontal reduction or change in the cross-section of a sewer as a result of self-weight or external forces. Three levels of deformation are normally observed:

<u>0-5 percent deformation</u> is acceptable, may not need structural upgrading, and normally requires monitoring.
<u>5-10 percent deformation</u> requires some form of structural enhancement, possibly a lining; and
<u>10 percent deformation</u> is a collapse condition and the sewer should be replaced.

- Displaced or Open Joint

A displaced joint is one in which adjacent conduit sections are not concentric. An open joint is one in which adjacent conduit sections are open. Displacements are observed as a fraction of the wall thickness (t) of the conduit as follows:

<u>Slight</u>	$< t$
<u>Medium</u>	$< 1.5\ t$
<u>Large</u>	$> 1.5\ t$

- Corrosion

A sewer conduit may be damaged in various ways, including spalling, wear, erosion, or by any deleterious mechanism.

Service Defects

Service performance relates to the ability of the system to perform its intended function, i.e., convey wastewater. Problems that impair service performance include severe root intrusion, debris accumulation, sags in pipes, etc. These types of problems are typically not considered structural defects, but nonetheless can result in operational failures of the system due to blockages and resultant flow backups and overflows.

- Infiltration

Groundwater that enters the wastewater collection system through defective pipes, pipe joints and manhole walls is classified as groundwater infiltration. The magnitude of groundwater infiltration depends on the condition of the collection system components, the depth of the groundwater table with respect to the defects, and the percentage of the collection system that is submerged. Variation in groundwater levels and subsequent groundwater infiltration is normally seasonal. Groundwater infiltration will be a relatively constant volume throughout individual seasons. Groundwater infiltration will be greater in the rainy seasons when the water table is high and less in the dry seasons when the water table is low. Where sewers are constructed in year round swampy areas, or in proximity to and below the level of major creeks or other water bodies, groundwater infiltration will be relatively constant during all seasons.

The various levels of ground water infiltration may be identified as follows:

Seeper - The slow ingress of infiltration through sewer or manhole structure, identified by a glistening effect of the water under the influence of a survey lighting apparatus;
Dripper - Infiltration characteristically dripping into the wastewater system through sewer or manhole structural defects;
Runner - Infiltration running into the wastewater system through sewer or manhole structural defects;
Infiltration - Infiltration entering the wastewater system under hydrostatic pressure via structural defects.

- Roots

Root intrusion may occur through defects of sewer conduits, laterals, or manholes, and can be described as fine, mass, or tap roots depending on severity.

Fine roots - are slender or fibrous roots that result in a partial reduction in hydraulic capacity;
Mass roots - are a formed congealed density of roots that restrict flow; and
Tap roots - are individual root strands over 12.5 mm thick.

- Debris

Debris includes grease, rocks, sand, and silt in a sewer line, excluding items mechanically attached to the line (e.g., intruding service connections or intruding pipe and joint materials). Debris can cause turbulence in the sewer conduit and a reduction in hydraulic capacity.

Debris is normally identified by the following characteristics:

General (e.g., rocks, grease)
Mechanical
Structural

R0025166

Strata (e.g., sand, silt)

The estimated amount of silt accumulation identified in the Clara Street Sewer Pilot Project is shown in Table 2 below:

Table 2. **Silt Accumulation in Clara Street Sewer**

Amount of Silt	**Approximate Distance Affected**
Less than 3 inches	11,000 feet
Between 3 inches and 5 inches	6,000 feet
From 5 inches to 12 inches	5,000 feet

Construction Defects

Construction defects include those defects relating to junctions, connections, and manholes. They sometimes fall under the category of service defects, since they can impair the service performance of the system.

- Connection

Have become damaged during or after construction,
Are incorrectly positioned,
Are of poor workmanship, or
Obstruct the flow, causing a reduction in hydraulic capacity and efficiency.

- Intruding Connection

An intruding connection is one in which the connection intrudes into the sewer and has become damaged during or after construction, causing a reduction in hydraulic capacity and efficiency. Most intruding connections are defective.

DEFECTS SUMMARY

Table 3 provides a listing of some major defects identified from the Clara Street Inspection along with the number of their occurrences.

Table 3. **Major Defects**

Defects	Number of Occurrences
A – Structural	
Breaks	1
Crack – Circumferential	9
Crack – Longitudinal	7
Deformed	2
Displaced Brick(s)	65
Fracture – Circumferential	10
Fracture – Longitudinal	4
Hydro Sulphide Attack Heavy	1
Hydro Sulphide Attack Medium	3
Joint Displaced Large	1
Joint Displaced Medium	1
Missing Brick(s)	24
Mortar Missing Medium	8
Open Joint Medium	2
Surface Wear	48
B – Service	
Debris	501
Infiltration Running	1
Obstruction	20
C – Construction	
Connection Intruding	2

CONCLUSION

The Sonar/TISCIT technology has enabled inspection of the surcharged Clara Street sewer line for the first time since its original installation more than 90 years ago.

The locations of defects varying from broken segments of the pipelines, longitudinal and circumferential cracks, displaced and missing bricks, longitudinal and circumferential fractures, displaced joints, corrosion, intruding connections, debris, infiltration, and obstructions were identified and recorded using Sonar/TISCIT. This inspection technology also assisted in better estimating the amount of silt accumulation in various parts of the sewer line.

Superimposing a captured sonar image of a particular line segment onto a CCTV picture allowed the engineers to see both above and below the water line resulting in a 360–degree survey of the sewer. Determining the severity of deformation for an existing pipe is another valuable feature this technology provides. This was accomplished by utilizing tools that plot the exact cross-sectional figure of the pipe (based on its original diameter) and then comparing it with a sonar image of the existing sewer. The same tool measures the depth of silt accumulated in the bottom of the sewer providing more accurate debris quantification.

The Sonar/TISCIT technology has proven to be a valuable method for surcharged sewer inspection. This technology's ability to detect, identify, and locate defects in sewer lines that are partially or fully submerged is both effective and efficient. The ability to quantify the amount of silt accumulated in various sections of sewer lines utilizing Sonar/TISCIT helps prioritize sewer cleaning efforts. It has been recommended that the Sewerage and Water Board of New Orleans adopt these technologies for all future surcharged sewer line inspections, rehabilitation and cleaning tasks.

BASEMENT FLOODING- SALEM, OREGON'S EXPERIENCE

ABSTRACT

In recent years, a significant number of residents in the City of Salem, Oregon have had the unpleasant experience of finding raw sewage backed up in their basements. The City of Salem has an aging sanitary sewer collection system which experiences extensive surcharging during rainfall events.

It is estimated that as many as 500 homes within the City are experiencing basement flooding due to sanitary sewer backups. During the winter of 1996-97, the City initiated an investigation of eight selected neighborhoods and identified alternatives for reducing or eliminating basement flooding. The investigation consisted of surveying customers, inspecting sewer lines, smoke testing, and flow monitoring. City staff worked closely with the neighborhoods in finding a solution.

As a result of the investigation four alternatives were identified which would reduce or eliminate basement flooding from sanitary sewage. These alternatives include:

A. Rehabilitation/Replacement (R/R) of significant portions of the sewer collection system in selected neighborhoods including replacement of sewer laterals.
B. Infiltration/Inflow reduction program using grouting, sliplining, spot repairs, etc.
C. Modify the interior plumbing of the home and install a backwater valve.
D. Modify the interior plumbing of the home and install a new service and ejector pump.

Alternatives C and D were selected since they provide the highest level of protection at the least cost. These alternatives allow sewer mains to surcharge without flooding area basements and bring older homes up to current plumbing code standards.

As a result of the investigation, the City of Salem implemented the Positive Protection Program. This program provides technical assistance to the homeowner and zero interest loans for making needed improvements which protect the basement from future storm events.

Approximately 100 home owners are currently signed up for the program. The City has budgeted $790,000 for the initial year of a multi-year program. Total cost is estimated at $4.0 to $5.0 million.

KEYWORDS

Sewer backup, infiltration, basement flooding, rehabilitation, backwater valves, ejector pumps, Positive Protection Program.

INTRODUCTION

The City of Salem, Oregon is located in the heart of the Willamette Valley. The City operates a regional wastewater treatment facility which provides service to approximately 183,000 people including the City of Keizer and several unincorporated areas. The wastewater collection system consists of approximately 1,094 km (680 miles) of sewer mains and 30 pump stations. Main lines consists primarily of concrete pipe 15.2 cm (6 inches) to 1.9 meters (75 inches) in size. Portions of the collection system date back to the late 1800s.

The City has a rehabilitation and replacement (R/R) program which concentrates on replacing undersized or structurally deficient portions of the collection system. Follow up studies on some of the City's earlier R/R projects indicated only a minimum amount of success in reducing groundwater infiltration when sewer service laterals were not upgraded along with the sewer mains. Since 1990, the City has included as an integral part of all R/R projects, replacement of the sewer service laterals from the main to the house, at public expense.

Salem residents are accustom to wet winter weather since the area receives nearly 102 cm (40 in.) of annual precipitation. However, 1996 was a record year with approximately 152 cm (60 in.) of rainfall. This included a February storm event which lasted for over a week and included four consecutive days with over 6.0 cm (2.4 in.) of rainfall. Statistically this is equivalent to an 80 to 100 year storm event. The City experienced extensive surface flooding in addition to many flooded basements and was forced to shut down the treatment plant for a short period of time. Salem hasn't experienced a storm of this magnitude in over 30 years.

While still recovering from the February storm event, the City experienced another large storm in November 1996. During this storm event, 11.5 cm (4.52 in.) of rain fell over a two day period. This amount of rainfall is in excess of a 50 year storm event. In addition to these two large storms, six other smaller but major storms helped make 1996 the wettest year on record. Meteorologists are predicting that the next 20 years will be wetter than normal.

In recent years basement flooding from sanitary sewer backups has resulted in a great deal of frustration on the part of the property owners as well as Public Works staff who maintain and operate the sewer collection system. In November 1996, a large group of citizens went before the City Council requesting that a solution be found regarding basement flooding and the City made a commitment that this problem would be resolved.

Sewage backing up into a basement could be caused by grease, roots, or other types of blockages in a sewer main. Effective maintenance programs have contributed to the relatively rare occurrence of this type of problem which can normally be corrected in a short amount of time.

A more common and difficult cause of basement flooding results from an excessive flow in sewer lines during periods of heavy rainfall. This results in the carrying capacity of the sewer line being exceeded, backing up the flow in the sewer mains and eventually ending up in basement storage and living areas. The excessive flow results primarily from infiltration of groundwater which enters the sewer lines through cracks, holes, and joints in the pipes. Older homes may also have their footing drains attached to the sewer service lateral resulting in a large source of infiltration. Inflow may also contribute to sewer surcharging, but is not believed to be the primary source of excessive water within the Salem collection system. Inflow results from direct connections with surface water, such as roof drains, catch basins, open cleanouts, etc.

A typical plumbing system for an older home in Salem with a basement is illustrated in Figure 1. Plumbing from the upper floor of the home is typically tied into the basement plumbing resulting in a common service line which runs under the basement floor and continues to the sewer main located in the alley or street. As illustrated in Figure 1, in many homes the basement floor is often less than a meter above the top of the sewer main. In this situation, only a relatively minor surcharging event can result in significant basement flooding. Even a few centimeters of water within a basement living area may cause extensive damage. Many homeowners have indicated to the City that any incidence of basement flooding from sanitary sewer backups is unacceptable.

METHODOLOGY

During the November 1996 storm event, 160 residents throughout the City reported to Public Works that their basements were flooded from a sanitary sewer backup. Many more residents are believed to have experienced basement flooding but chose not to report it to the City. It is estimated that as many as 500 homes within the City could be experiencing basement flooding from sanitary sewage. Many of these homes have experienced flooding on a frequent basis even for relatively small storm events.

Typical plumbing system for an older home with a basement.

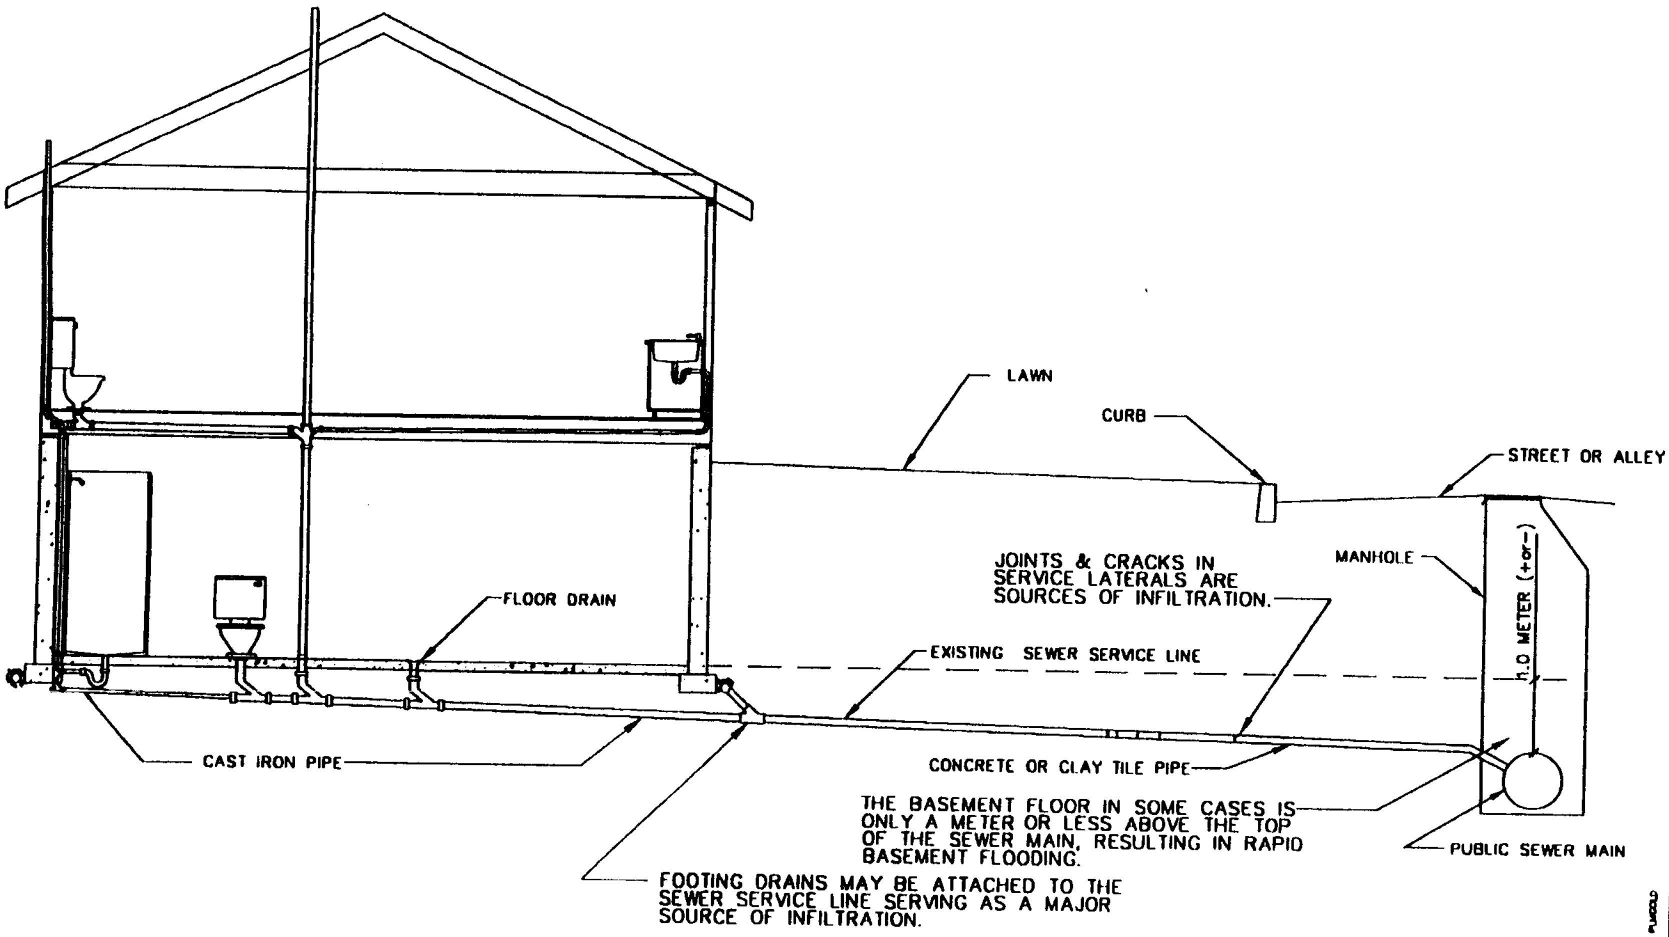

Figure 1

In December 1996, the City of Salem Public Works Department established an investigative team to identify alternatives for reducing or eliminating basement flooding resulting from sewer backups. A total of eight neighborhoods were included in the field investigation. Study areas were prioritized based on the number of incidences of basement flooding reported to the City. The investigative team consisted of engineers and technicians in both the Engineering and Operations Divisions of Public Works.

The investigative process for each study area included:

- Surveying the neighborhood with questionnaires to determine the scope of the problem.
- Assessing the condition of the sewer lines via video inspection records.
- Monitoring sewer flows within the study area.
- Reviewing existing smoke testing records where available.

With this information, the investigation team was able to assess the overall condition of the sewer collection system and determine where basement flooding was taking place. Informational meetings were held with the affected neighborhoods to report the findings and recommendations.

Questionnaire/customer survey

Questionnaires were sent to all residences in each selected neighborhood. The purpose of the survey was to determine which homes had a basement and of those homes which ones were experiencing basement flooding caused by sanitary sewer backups. The survey also gathered information about the number and type of fixtures in the basement and whether a backwater valve had previously been installed.

Results from the questionnaires were supplemented with a "windshield survey" in order to quantify the number of homes having a basement within the study area. Survey information was used to estimate the total number and location of homes within each neighborhood which were experiencing basement flooding. Results of the each survey was visually displayed on a map using the City's Geographical Information System (GIS).

TV investigation

A video inspection of all sewer mains was performed within each study area. This investigation was used to determine the overall condition of the lines and determine if there were any restrictions which could have contributed to the basement flooding.

Much of the TV inspection was conducted during the winter months while groundwater levels were high. Clear water was noted to be flowing from many of the sewer service laterals in basement flooding areas. Many of these services are 60 to 80 years old and installed at the time the home was constructed. Estimated flows from the services ranged from 0.06 to 0.32 liters/ sec (1.0 - 5.0 gpm).

As a result of the TV inspection each sewer main received a rating of good, fair, poor, or bad. Ratings were based on the overall structural condition of the pipe. Typically 20 - 25 percent of the sewer mains within the study areas were rated as poor or bad. Those lines considered to be in bad condition are structurally deficient to the point where rehabilitation of the line segment is warranted. Line segments in this category would typically have erosion along the inside of the pipe, holes, wide joints, large cracks and pieces of missing pipe. Typically the sewer service lines connected to these line segments are also in poor condition and a major source of groundwater infiltration.

Flow monitoring

Flow monitoring was used to determine the response of the sewer collection system to a rainfall event.

The City of Salem has a number of portable flow monitors which can be placed in a sewer mainline and provide a continuous measurement of flow at a particular site. Flow information can then be compared with the quantity of rainfall measured at one of the ten rainfall gauging stations located throughout the City.

The system response to a storm event is dependant on the time of the year. Heavy rainstorms in the fall will elicit a much different response then the same storm occurring during the winter months. Once the groundwater rises within the vicinity of the sewer line, the collection system appears to respond very quickly to a rainfall event increasing the possibility of basement flooding.

The flow monitoring results indicate that areas experiencing basement flooding typically have high peaking factors. The peaking factor is determined by dividing the peak wet weather flow by the peak dry weather flow. Peaking factors in the range of four to seven were not uncommon in basement flooding neighborhoods, depending on the magnitude and duration of the storm event.

Smoke testing results

The entire sewer collection system within the City of Salem was smoke tested twice during the 1970s and early 1980s. Numerous sources of inflow were removed during that time period.

Smoke testing results from 1994 where available for approximately half of the study areas. The results typically indicated that these areas did not have a high number of inflow sources (roof drains, catch basins, open cleanouts). However, smoke test results did indicate a high number of failing sewer service laterals and other sources of infiltration.

RESULTS

The following conclusions were reached as a result of the field investigation:

1. Basement flooding is most pervasive in the City of Salem within older neighborhoods located in areas with relatively flat topography.

2. A significant portion (20 - 25%) of the sewer collection system within the basement flooding areas is structurally deficient and needs to be replaced. However, the majority of the sewer mains within the problem neighborhoods are rated in good condition.

3. A large amount of rain induced infiltration appears to be widespread throughout the study areas. This conclusion was reached on the basis of the field investigation, the number and location of flooded basements within each study area, and flow monitoring results.

4. A significant portion of the infiltration is believed to be coming from the sewer service laterals. This conclusion is based on observations made during the TV inspection of the sewer mains. As a result of follow up improvement projects, it was also learned that many older homes with basements have footing drains attached to the sewer service laterals.

5. In some locations there appears to be little elevation difference between many of the basements and the sewer main. Therefore, only a relatively minor amount of surcharging (one meter), or backup in the system can result in the basement flooding.

DISCUSSION

The alternatives evaluated for reducing basement flooding can generally be divided into two groups. The first group involves alternatives which would reduce the surcharging or backup within the trunk sewer system. These alternatives either provide additional trunk sewer capacity or reduce the amount of groundwater infiltration. By increasing capacity or reducing flow, these alternatives decrease or eliminate surcharging of the system, reducing the potential for system backups which causes the basement flooding the basement area from the remaining portion of the house. Backwater valves have been installed for a number of years, are fairly reliable, and require some annual maintenance.

The cost for Alternative C as illustrated in Figure 2 will vary depending on the amount of existing finish work in the basement. Those homes which have a fully finished living area in the basement are more expensive to retrofit with this type of system. A cost of $6,000 per dwelling, including $3,000 for a new service lateral, was used for estimating purposes.

Alternative D--Modify the interior plumbing of the home and install a new service and ejector pump.

This alternative includes the installation of a new sewer service line from the sewer main to the house. It also includes the installation of a new ejector pump system within the basement floor which pumps sewage from the basement area into the new sewer service line. This system allows the basement to be used under any surcharge conditions which are taking place within the trunk sewer line and is illustrated in Figure 3. This alternative may be more appropriate for those homes that have a bathroom in the basement living area or plan on constructing one in the near future.

Alternative D provides a lower risk of failure however, as with Alternative C, some maintenance is required. Ejector pump systems have been used in thousands of installations and have proven reliability.

This alternative results in major costs to retrofit the existing house plumbing, install new equipment, and provide a new sewer service lateral. Costs will vary depending on the amount of existing finish work in the basement and the location and length of the new sewer service lateral. More excavation and labor will be required for this installation than for Alternative C. Costs for Alternative D average about $10,000 per home in Salem including the cost of the new sewer service lateral.

Evaluation of alternatives

In order to evaluate and compare alternatives, the following criteria were used:

- Effectiveness- How effective is the alternative in keeping the basement from flooding from sewer backups?
- Timeliness- How fast can the alternative be implemented? It is likely that further basement flooding will occur in Salem during future rainy seasons which extend from October to April.
- Cost effectiveness- Do the benefits outweigh the costs for the selected alternative?
- Implementation- Is the alternative implementable? How easy is it to install and make operational?

Using this set of criteria, an evaluation matrix was used to rank the alternatives. Based on the selected criteria, Alternatives C and D ranked higher than Alternatives A and B. Alternatives A and B could reduce the amount of basement flooding which is occurring in the affected neighborhoods. However, it is unlikely that Alternatives A or B would ever eliminate basement flooding from occurring under severe conditions.

Alternatives C and D provide positive and relatively reliable protection against basement flooding caused by sewer surcharging even during severe conditions. Even if alternatives A or B were selected, some property owners would find it advisable or necessary to install backwater protection devices recommended under Alternatives C and D.

The modifications undertaken as a part of Alternatives C and D are relatively easy to implement and use proven technology. Most area plumbers have the experience and skill to install these facilities.

CITY OF Salem AT YOUR SERVICE

Alternative D: Modify the interior plumbing of the home and install a new service and ejector pump.

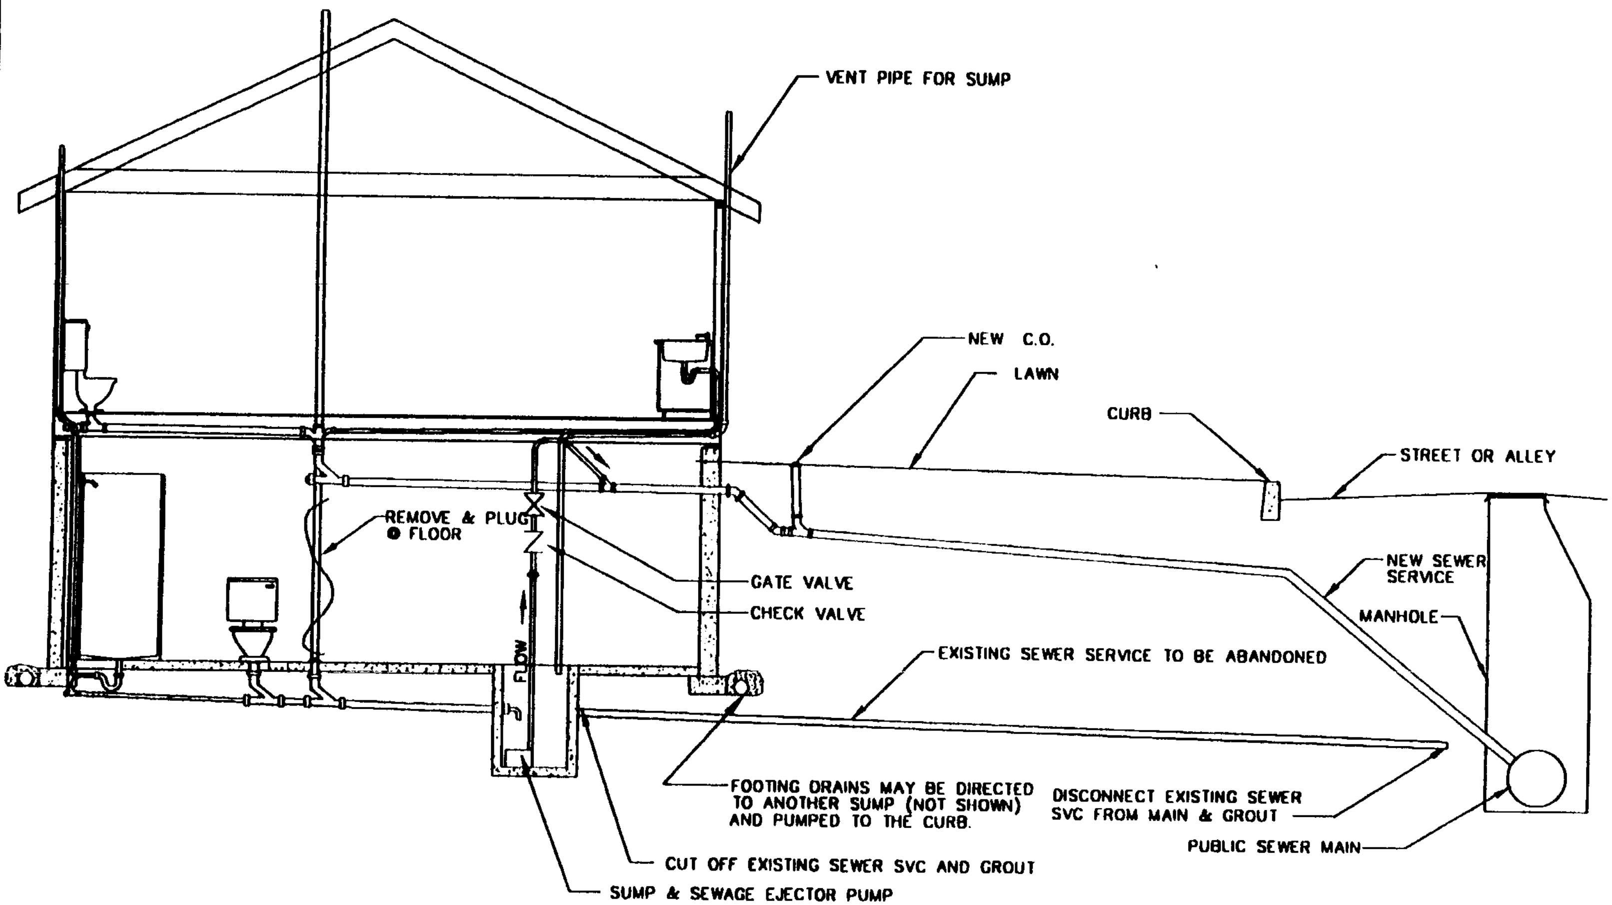

Figure 3

Positive Protection Program

In July 1997, the City Council adopted the Positive Protection Program (PPP) as a strategy for partnering with homeowners to eliminate basement flooding. Some of the features of this program include:

- The home must be located within a study area, have a basement, and experienced flooding due to sanitary sewer backups.
- The City provides technical assistance to the homeowner and a zero interest deferred payment loan (DPL) to fund improvements similar to Alternatives C or D.
- There are no income requirements to be eligible for a deferred payment loan.
- The homeowner is encouraged to receive bids from at least two contractors to do the work. The owner is not required to accept the lowest bid, however the selected bid is reviewed by City staff and must be reasonable.
- Repayment of the deferred payment loan is not required until the property is transferred.
- To be consistent with the City's existing R/R program, the cost of a new sewer service lateral for the home, if required, is funded at public expense.
- Footing drains, when encountered, are diverted to a separate sump and pumped to the curb. Cost for this portion of the project are included in the DPL.

CONCLUSIONS

Over 100 homeowners are currently participating in the City's Positive Protection Program. To date 39 improvement projects have been successfully completed at a total cost of approximately $405,000. Alternative D has been selected the most often by area residents. This may be due to the fact that the majority of the participants in the program consider their basements as a portion of the home's living area and not simply for storage.

The alternatives developed as a result of the City's investigation are believed to be a successful means of eliminating basement flooding in older homes caused by sanitary sewer backups. The program has also been successful in partnering with the community in finding a solution to an ongoing problem.

The Salem City Council is currently reviewing the Positive Protection Program. It is anticipated that some changes in funding for the program may occur in future years.

ABSTRACT

Compared to other cities, New York City (NYC) is abundantly endowed with parklands and open spaces, many of which can be utilized to treat and dissipate stormwater runoff flows, in conjunction with the preservation, restoration and creation of ecological systems. Such use of available parklands and open spaces has the benefit of decreasing costs for stormwater treatment and conveyance, while at the same time enhancing the natural biological systems. Through the combined efforts of the NYC Department of Environmental Protection (NYCDEP), which is responsible for stormwater control, and the NYC Department of Parks and Recreation (NYCDPR), which is responsible for preserving and restoring the ecological systems of parklands and open spaces, URS Greiner, Inc. (URSG) developed a project to provide for the treatment of stormwater and the attenuation of peak stormwater flows through restoration and creation of wetlands within Oakland Ravine (located in the densely populated northeastern section of the Borough of Queens, NYC). The proposed Oakland Ravine Stormwater Treatment System Project was developed in conjunction with the East River Combined Sewer Overflow (CSO) Abatement Project, which is part of the NYC comprehensive program to reduce CSO discharges into receiving waters. Discharges into Alley Creek through Outfall TI-7, an outfall located about one-half mile northeast of the ravine which has been designated for CSO abatement, will be reduced as a result of the proposed stormwater treatment system project. The principal objectives of the project are to reduce discharges into Alley Creek, address stresses and disturbances identified within Oakland Ravine and Oakland Lake (located at the north end of the ravine) with regard to erosion and lack of vegetation on the slopes of the ravine and deterioration of the water quality in the lake, reduce/eliminate sewer system flooding in areas adjacent to the ravine and lake, and create a natural park setting in an urbanized area. These project objectives will be met by re-routing stormwater from adjacent sewer systems into the upper (south) end of the ravine and providing primary and secondary treatment of the stormwater within sediment pools and created/restored wetlands, prior to the water being discharged into Oakland Lake, and ultimately into Alley Creek. The project will also include stabilization and planting of the slopes of the ravine with vegetation and trees native to the area, and construction of access trails through the ravine, including bridges over the wetlands, for use by persons walking and riding bicycles.

KEYWORDS

stormwater, wetlands, treatment, ravine, lake

INTRODUCTION

Oakland Ravine, which is part of a City-owned park, is situated in the densely populated northeastern section of the Borough of Queens, NYC. The park also includes Oakland Lake, located immediately north of the

R0025177

ravine. Figure 1 shows the location of Oakland Ravine and Lake within the Borough of Queens. The park, which is surrounded by residential development and educational facilities, serves as an important open space for local residents to engage in such recreational activities as walking, fishing and interacting with the waterfowl which frequent the lake. The ravine is undeveloped and generally consists of trees, scrub plants and wetlands. The slopes of the ravine are steep (ranging from 30 to 60%) and heavily eroded in several areas due to overland stormwater runoff flow from the Queensborough Community College campus which borders the ravine to the east, and from Springfield Boulevard located along the ravine's western boundary as shown on Figure 2. In addition, the portion of the ravine located in proximity to 56th Avenue, which extends along its southern boundary, contains fill material and some debris.

As a result of past studies and investigations relating to the effects of CSO discharges into Alley Creek and to the general degradation of Oakland Ravine and Lake, problems have been identified that need to be addressed to allow the area to be environmentally rehabilitated. In a draft report entitled "Stormwater Treatment and Environmental Quality in Oakland Ravine," prepared in 1993, The Gaia Institute indicated that Oakland Ravine and Lake are ecological systems with impaired functions. Specifically, the report identified a number of stresses and disturbances within Oakland Ravine and Lake, which have resulted in a reduction in biological diversity and loss of native ecological communities capable of purifying incoming water and modulating temperatures. These stresses and disturbances could be reversed by re-routing stormwater from the existing stormwater sewer systems into the ravine. The principal problems identified that need to be addressed from an environmental perspective are as follows:

- Reduced water quality in Oakland Lake and Alley Creek, which have resulted in seasonal anoxic events in the lake.
- High CSO peak flows into Alley Creek through Outfall TI-7.
- Sewer system flooding along 56th Avenue and Springfield Boulevard.
- Erosion and lack of vegetative growth on the ravine slopes.
- Reduction in the amount of water available within the ravine to support native ecosystems as a result of alteration of the surrounding area due to development.
- Sediment buildup in Oakland Lake.

Through the combined efforts of the NYCDEP, NYCDPR and URSG, a project was developed to address the above-listed problems through the re-routing of stormwater into the ravine, and the restoration and creation of wetlands within the ravine to treat the stormwater. The proposed project, referred to as the Oakland Ravine Stormwater Treatment System Project, was developed in conjunction with the East River CSO Abatement Project which includes abatement of CSO discharges into Alley Creek through Outfall TI-7 as shown on Figures 1 and 2.

The principal objectives of the proposed stormwater treatment system project are to address the six (6) problems identified above. An additional objective of the project is to provide enhancements to a City-owned park located in an urbanized area for the use and enjoyment of the local residents and visitors.

EXISTING SEWER SYSTEM

Re-routing of stormwater into Oakland Ravine from the existing sewer systems is a critical feature necessary to meet the objectives of this proposed stormwater treatment system project. As indicated by the existing sewer system schematic presented on Figure 2, the sewers located in proximity to Oakland Ravine and Lake consist of those that convey strictly stormwater (storm sewer) as well as sewers that convey a combination of sanitary sewage and stormwater (combined sewer). During storm events, the combined sewage is conveyed through the combined sewers and discharged into Alley Creek through Outfall TI-7 at peak flow rates as high as 499,620 cubic meters per day (m^3/d) (132 million gallons per day [mgd]). In addition to the sewage from the tributary sewers, the overflow from Oakland Lake is discharged into Alley Creek through Outfall TI-7 as shown on Figure 2 for the purpose of maintaining an ecological balance within the creek.

R0025178

PRINCIPAL WATER SOURCES

The sources of stormwater identified for re-routing into Oakland Ravine to supply the water necessary for implementation of the project consist of the following:

- Flow from the storm sewer located in 56th Avenue.
- Runoff from the Queensborough Community College campus.
- Runoff from the areas in the vicinity of Springfield Boulevard.

The storm sewer located in 56th Avenue, which varies in diameter from 530 to 1,500 millimeters (21 to 60 inches), extends westerly from Cloverdale Boulevard to Springfield Boulevard. The drainage area served by this storm sewer consists of approximately 24.7 hectares (61 acres) of which about one-third is located within the boundaries of the Queensborough Community College campus, and the remaining two-thirds encompasses the predominantly high density residential area located south of 56th Avenue. The area of the college campus, which is not included in the drainage area of the storm sewer located in 56th Avenue, consists of about 6.1 hectares (15 acres). Therefore, the total drainage area available for generating stormwater runoff for re-routing into Oakland Ravine from the storm sewer located in 56th Avenue and the Queensborough Community College campus is approximately 30.8 hectares (76 acres).

A large combined sewer located in Springfield Boulevard along the west side of Oakland Ravine conveys sanitary sewage and stormwater from predominantly residential areas south of 56th Avenue and west of Springfield Boulevard. This sewer discharges into the combined sewer located in 46th Avenue. The stormwater runoff generated within this drainage area is the third principal source of stormwater for re-routing into Oakland Ravine.

The projections of the flow volumes and pollutant loadings anticipated to be discharged into the proposed stormwater treatment system from the storm sewer in 56th Avenue and the storm sewer system located on the Queensborough Community College campus were determined. A combination of manual drainage calculations and modeling of the storm sewer systems utilizing the RUNOFF Block of the United States Environmental Protection Agency Stormwater Management Model were used to develop the projections. Rainfall quantities measured in the local area, and measurements of flows and pollutant concentrations within the storm sewer in 56th Avenue during six (6) storm events (three in 1997 and one each in 1990, 1992 and 1993) were used to develop the model. The projections of the annual flow volume and quantities of pollutants anticipated to be discharged into Oakland Ravine through re-routing of the stormwater from the storm sewer in 56th Avenue and the Queensborough Community College campus for a year with an average rainfall of approximately 1,092 millimeters (43 inches) (based on measured rainfall at LaGuardia Airport for the period of 1948 through 1995) are presented below in Table 1:

Table 1: Average Annual Projections of Flow and Pollutant Loadings

Flow Volume: 189,270 cubic meters (50 million gallons)

Pollutant Loadings: kilograms (kg)

- Biochemical Oxygen Demand (BOD_5): 1,565 kg (3,450 pounds)
- Ammonia (NH_3): 45 kg (100 pounds)
- Nitrate (NO_3): 132 kg (290 pounds)
- Total Kjeldahl Nitrogen (TKN): 36 kg (80 pounds)
- Total Phosphorous (TP): 54 kg (120 pounds)
- Total Suspended Solids (TSS): 2,885 kg (6,360 pounds)

The projected annual pollutant loadings presented in Table 1 are relatively low. Therefore, such results provide confidence that the wastewater being conveyed within the storm sewer in 56th Avenue and from the college's stormwater collection system consists predominantly of stormwater. The investigation to determine similar flow and loading projections for the stormwater runoff from the areas adjacent to Springfield Boulevard are still underway.

EXISTING HABITAT CHARACTERISTICS

A major consideration in development of the proposed Oakland Ravine Stormwater Treatment System was to maintain and enhance the native characteristics (tree species, plant and animal habitats, lake water quality, etc.) of the ravine and lake to the greatest extent possible. Extensive evaluations and assessments of the ravine and lake were conducted to establish and identify the native characteristics for use in development of the proposed stormwater treatment system. Following is a summary of the principal results of these evaluations and assessments:

- Approximately 300 trees with trunks larger than 150 millimeters (6 inches) in diameter as measured at about 1.4 meters (4.5 feet) above the ground were identified as to species and their locations were documented; the ravine slopes are generally dominated by large oaks with occasional large hickories, beeches and tulip trees, and with smaller hickories, black cherries, birches and maples located in the understory.
- A total of twenty-two different species of birds were observed within the ravine and lake, and healthy populations of sunfish, bluegill, white crappie, bass, large carp and goldfish were observed in the lake.
- Anoxic conditions were observed in most areas of the lake near the bottom with anoxic/hypoxic conditions extending to within 4 feet of the water surface.
- Nutrients in the lake water were relatively low; phosphate levels were below 0.05 milligrams per liter (mg/l) at all times, and nitrate levels were below 0.25 mg/l during warm weather and rose to slightly more than 1.0 mg/l in colder weather.
- Macrophyte coverage of the lake was observed to be extensive with *Potamogeton crispum* being predominant in early summer and by mid-summer being replaced by *Cabomba caroliniese*.
- One (1) wetland area was identified in the ravine encompassing an area of 0.57 hectare (1.4 acres) consisting primarily of palustrine persistent emergent.
- No rare, threatened or endangered species were identified.

DESCRIPTION OF STORMWATER TREATMENT SYSTEM

Based on the information and data obtained from evaluations and assessments of the ravine and lake, investigations of the sewer systems in the vicinity of the ravine and lake, discussions with individuals who possess specific knowledge of the local area, and literature searches, a conceptual plan for the proposed Oakland Ravine Stormwater Treatment System was developed. This conceptual plan was developed to meet the project objectives, thereby addressing the identified problems, as previously discussed, with stormwater being re-routed into the ravine from the three (3) principal sources. The conceptual plan of the proposed stormwater treatment system is presented on Figure 3 and illustrative sections of the plan are presented on Figure 4.

The major components which make up the proposed stormwater treatment system are as follows:

- Re-routing of stormwater from the storm sewer in 56th Avenue, the Queensborough Community College campus and areas adjacent to Springfield Boulevard into the ravine.
- Plunge pools with rock cascades for energy dissipation.
- Rock check dams with naturalized rock channels for velocity reduction and habitat enhancement.
- Pools for collection of sediment, floatables and debris.
- Restoration/creation of wetlands to treat stormwater.
- Stabilization and planting of ravine slopes.
- Trails and signage throughout the ravine with bridges extending over wetlands to create a park setting.

The measures included in the conceptual plan of the proposed stormwater treatment system for re-routing the stormwater into the ravine from the storm sewer in 56th Avenue and the Queensborough Community College campus are shown on Figures 3 and 4. Stormwater from the storm sewer in 56th Avenue will be re-routed into the ravine by disconnecting the 1,500-millimeter (60-inch) diameter storm sewer from the combined sewer located in Springfield Boulevard, constructing a diversion chamber within 56th Avenue at a location approximately 115 meters (380 feet) east of Springfield Boulevard, and extending a 1,500-millimeter (60-inch) diameter storm sewer in a northerly direction from the diversion chamber into the ravine where the stormwater flow will be freely discharged into the upper plunge pool. Stormwater runoff from the Queensborough Community College campus stormwater collection system will be re-routed to a stormwater collection system constructed along the tops of the eastern slopes of the ravine as shown on Figures 3 and 4. This proposed stormwater collection system consists of an underground 1,500-millimeter (60-inch) diameter collection/detention pipe with holes through the walls to allow the water to percolate into the eastern slopes of the ravine in a controlled manner. The collection/detention pipe will be installed in a rock-filled trench to enhance the percolation of the water into the soil and to provide increased storage volume. Percolation of the water into the slopes of the ravine is important to sustain vegetative growth. Although re-routing of stormwater runoff from areas adjacent to Springfield Boulevard is a component of the proposed stormwater treatment system, the method of how this re-routing of flows will be accomplished, is still under investigation, and as such, the facilities required to re-route these flows are not shown on Figures 3 and 4. However, it appears that a stormwater collection system installed along the tops of the western slopes of the ravine, similar to that proposed for the eastern slopes, to allow a controlled percolation of water into the slopes may be the preferred method.

As shown on Figure 3, the proposed stormwater treatment system is separated into four (4) zones; identified as Upland Cascades, Rock Riffles, Wetland Forebay and Emergent Marsh. The principal features and benefits pertaining to each of these zones are summarized as follows:

- Upland Cascades
    - 1,500-millimeter (60-inch) diameter pipe discharging stormwater from the storm sewer in 56th Avenue.
    - Series of three (3) plunge pools with gabion mattresses or natural rock bottoms and rock cascades to dissipate energy for a 6.1-meter (20-foot) drop.
    - Aeration of stormwater by rock cascades.
    - Access trail from 56th Avenue.
    - Stabilization and re-vegetation of area.
- Rock Riffles
    - Series of four (4) rock check dams with rock channels to further dissipate velocity.
    - Aeration of stormwater with rock cascade having a vertical drop of about 2.4 meters (8-feet).
    - Access trail.
    - Stabilization and re-vegetation of slopes.
- Wetland Forebay
    - Further dissipation of velocity.
    - Retention and collection of floatables, oil, grease, debris and settleable solids in pools.
    - Primary treatment of stormwater within pools and wetland fringe having a combined area of about 0.53 hectare (1.3 acres).
    - Earth berm with control structure and discharge conduit designed to discharge stormwater into the Emergent Marsh Zone while preventing the passage of floatables, oil, grease, solids and debris.
    - Emergency rock channel spillway to pass high flows caused by large storms (greater than the 25-year storm).
    - Access trails with bridges.
    - Stabilization and re-vegetation of slopes.
- Emergent Marsh
    - Secondary treatment of stormwater within an emergent wetland having an area of about 0.49 hectare (1.2 acres) through pollutant breakdown by bacterial action and nutrient uptake by plants.
    - Hydraulic connection to lake.
    - Access trails with bridge.
    - Stabilization and re-vegetation of slopes.

The proposed Oakland Ravine Stormwater Treatment System provides both physical and biological processes for pollutant removal from the stormwater. Physical treatment processes include flow moderation, settling of solids, filtration and adsorption. Biological treatment processes include pollutant breakdown by bacterial action and nutrient uptake by plants. The Wetland Forebay Zone will be designed to efficiently trap floatables, oil, grease, debris and settleable solids to protect the downstream Emergent Marsh Zone. Within the Emergent Marsh Zone, pollutant removal will take place as a result of the biological processes. A circuitous flow path will be provided through the Emergent Marsh Zone to increase contact time between the water and the plants to enhance the biological treatment.

Based on the performance results of wetlands being used to treat stormwater, it is anticipated that the proposed Oakland Ravine Stormwater Treatment System will reduce the levels of total suspended solids in the stormwater by about 50 to 75%, total phosphorous by 45%, total nitrogen by 25% and organic carbon by 15% with some reduction in metals. These reductions in the pollutant levels will have a significant impact on the quality of water in Oakland Lake with a lesser impact on the water quality in Alley Creek. However, the proposed stormwater treatment system will have a significant impact on Alley Creek by attenuating the CSO peak flow discharges through re-routing of stormwater through the ravine and lake.

The estimated cost to construct the proposed stormwater treatment system, excluding facilities to re-route stormwater into the ravine from areas adjacent to Springfield Boulevard, is approximately $5,000,000. Construction of the project is anticipated to be completed in the year 2001.

CONCLUSIONS

In conjunction with the NYC East River CSO Abatement Project, a project has been developed to provide for the treatment of stormwater in Oakland Ravine, located within the densely populated northeastern section of the Borough of Queens, NYC. Stormwater, which will be re-routed into the ravine from adjacent sewer systems, will receive primary and secondary treatment within a naturalized treatment system consisting of water pools, rock cascades and created/restored wetlands. The project will address the following identified problems pertaining to the environmental quality of the area:

- Reduced water quality in Oakland Lake and Alley Creek.
- High CSO peak flows into Alley Creek through Outfall TI-7.
- Sewer system flooding along 56th Avenue and Springfield Boulevard.
- Erosion and lack of vegetative growth on the ravine slopes.
- Reduction in the amount of water available within the ravine to support native ecosystems.
- Sediment buildup in the lake.

In addition to providing solutions for the identified problems, the project will provide enhancements to a City-owned park located in an urbanized area.

ACKNOWLEDGMENT

The authors wish to thank the many representatives of the NYCDEP and NYCDPR as well as other interested private citizens and groups, who provided valuable input and assistance in the development of the Oakland Ravine Stormwater Treatment System Project.

ABSTRACT

An Administrative Order issued by Region VI of the U.S. EPA and a Consent Order entered into with the Oklahoma Department of Environmental Quality require the Tulsa Metropolitan Utility Authority (TMUA) to report overflows and complete projects to eliminate overflows and bypasses on a specified schedule. This paper describes data collection and computer modeling to identify and correct deficiencies in a group of sub-basins tributary to one treatment plant. The project required evaluation of over 300 km of 150 mm through 1,500 mm gravity sewer, approximately 5,300 manhole structures, several inverted siphon crossings of area drainage courses, and a dual barrel crossing of the Arkansas River to the plant influent pump station. A computer model of the major (typically 250 mm and larger) gravity lines was used to evaluate the system's ability to pass the design storm flow.

TMUA operates several long-term flow meters, six of which provided flow data for this project. 27 additional area velocity temporary flow meters and 6 rain gauges were installed to subdivide drainage basins into reasonable tributary areas. Dry and wet weather flow data were collected and analyzed to establish flow patterns and calibrate the model. Data from four of the six long-term sites were determined to be usable, but inconsistencies in data from the other two sites prevented their use.

Flow data confirmed that no capacity problems exist under normal conditions, but capacity is frequently exceeded during wet weather. Peak dry weather flows ranged from a low of 5.7% to a high of 64.5% of nominal capacity while peak wet weather flows ranged from a low of 20.9% to a high of 272.3%. Evaluation of data established that the predominant problem is inflow, with some 63% originating in six tributary basins outside of the study area. Four sub-basins contribute in excess of 50% of the inflow attributable to sources within the study area. Computer modeling of the system further defined the extent of capacity problems within the project area and confirmed necessary corrective actions to eliminate overflows.

Approximately 97% of the manholes were inspected for inflow contributing defects. The remaining 3% were inaccessible. All lines were smoke tested and CCTV inspection in conjunction with dye testing of suspected inflow sources was completed for selected line segments. A dynamic computer model, capable of accurately modeling open channel, surcharged and restricted flow, was used to simulate existing system response and project response following rehabilitation.

KEYWORDS

Inspection, monitoring, modeling, rehabilitation, SSO, testing.

INTRODUCTION

The sanitary sewer collection system tributary to Tulsa's Southside Wastewater Treatment Plant is subject to large increases in flow during rainfall and snowmelt events. The entry of extraneous wet weather flow into the system has frequently resulted in overflows from surcharged manholes, backups in low-lying structures, and bypasses into the Arkansas River and its tributary creeks which pass through the metropolitan area. The TMUA has been addressing the extraneous flow problems in its entire wastewater system for the past several years through a number of flow monitoring studies, sewer system evaluations, relief sewer construction programs, and rehabilitation of existing lines and manholes. Both the United States Environmental Protection Agency (USEPA) and the Oklahoma Department of Environmental Quality (DEQ) have issued enforcement orders to reduce the frequency and duration of overflows and bypasses from the sewer system.

The sewer subsystem described in this paper collects wastewater from the most downstream basins tributary to the Southside Wastewater Treatment Plant and conveys flow originating in upstream basins to the plant. The subsystem includes over 300 km of gravity sewers ranging in size from 150 mm to 1,500 mm in diameter, a crossing of the Arkansas River by twin 900 mm lines, several multiple barrel siphon crossings of area creeks and drainage courses, and approximately 5,300 manholes and lampholes. The specific purpose of the study described in this paper was to determine the extent of the infiltration/inflow (I/I) problem, locate and quantify specific sources of I/I, and establish a cost-effective rehabilitation program to reduce flow in the collector and interceptor sewers so that no bypasses or overflows would occur during any wet weather event up to and including the five (5) year design storm.

Significant lengths of sewer line in the project area have been in service for more than 50 years and display the typical signs of aging expected in sewers of that vintage. Vitrified clay pipe (VCP) and concrete pipe (RCP) are the predominant materials of construction for these sewers. Cast iron pipe (CIP) or ductile iron pipe (DIP) have been used to a limited extent, primarily where the lines cross beneath small creeks and other surface drainage features.

METHODOLOGY

A total of 27 temporary flow meters would be installed for a period of 45 days at the beginning of the study to measure flow within the system at key points. Data collected would be supplemented with data from six (6) TMUA-owned long term meters installed in several of the major interceptors. Six (6) automatic tipping bucket rain gauges would be installed at selected locations across the study area to provide rainfall data for correlation with the flow data. Analysis of the flow and rain data would permit identification of specific areas where wet weather appears to most heavily impact the system under study. The data also would be used to calibrate the computer model and confirm that it represented the sewer system and its response to wet weather events with reasonable accuracy.

A visual inspection of the sewer system would be conducted to determine the condition of the manholes and segments of connecting pipe visible from the manholes. Smoke testing would be conducted on the entire system (with minor exceptions) to locate defects such as suspected cross connections between the storm and sanitary sewers, area drain connections, defective manhole frames, covers and seals, and pipe defects which could admit ground water into the system. Following the visual inspection and smoke testing, suspect areas would be inspected by use of closed circuit television cameras in conjunction with dyed water flooding of suspected sources of extraneous flow, to confirm the type, location and severity of the suspected defects. In addition to location of defects, the inspection methods would be used to confirm manhole and line sizes, depths, and connectivity to permit accurate system modeling and updating of existing collection system maps. Field surveys would be conducted to provide correct elevations at manholes where data were not available from record drawings or previous modeling activities.

Data collected through the various inspection methods would be analyzed to categorize defects by priority and anticipated method of rehabilitation. In addition to defects contributing to I/I, defects potentially affecting the structural integrity of the sewer system would be evaluated and their correction prioritized. Defects posing an immediate hazard would be reported to TMUA staff for prompt attention. Likewise, any defects noted on private property would be reported to TMUA staff for resolution with the property owner(s). Data would be collected and entered into a database for ease of manipulation and analysis. Photographic documentation of defects would be digitally recorded for ease of reference and recovery.

The major interceptor lines, and smaller collector lines in which temporary flow monitors were installed, would be defined in a computer model which would be calibrated from the monitored flow data and tributary area land use and population. The calibrated model would then be used to determine the expected effectiveness in eliminating overflows and bypasses from completion of the recommended rehabilitation measures. The modeling results would indicate to what extent correction of defects within the study area,

DISCUSSION

The Southside Plant Influent Sewer System Evaluation Survey is but one of a number of investigations undertaken by the TMUA in response to wet weather conveyance problems in TMUA's service area. The overall correction program has been underway for a number of years, and has involved the efforts of many consultants as well as Tulsa Department of Public Works (DPW) staff. The City of Tulsa recently celebrated its 100th anniversary, and some of the sewer lines serving the city are approaching their centennial anniversary as well. Tulsa's decision to address problems on a system-wide basis provides a consistent, integrated approach which should yield the most cost-effective long term solutions, while still providing for a quick response to high priority problems.

Flow monitoring

A network of long term flow monitors installed by TMUA, supplemented with temporary flow monitors placed at key locations during each separate area study, permitted prioritization of problem areas for further analysis. In addition to helping identify significant problem areas, the long term monitors provide a means to measure the general effectiveness of rehabilitation work accomplished over the life of the program by providing comparative data throughout its duration. Two separate flow paths exist at two locations within the collection system described in this paper, as can be seen on the flow schematic in **Figure 1**. The use of two additional temporary flow monitors to determine how flow is split between the separate flow paths at each of these locations would have increased the accuracy of the flow analysis for the system. However, since a significant difference in invert elevations exists between the two flow paths at each location, the absence of the additional flow monitors had no effect on dry weather flow measurement. Assumptions were necessary regarding the percentages of flow carried in each line during the wet weather flow analysis.

Flow monitoring data indicated that the monitored sites experienced neither depths of flow greater than 0.7 times pipe diameter nor peak flows in excess of 80% of the nominal full pipe capacity during any of the monitored dry weather periods. Likewise, data indicated that 15 of the monitored sites surcharged (depth of flow exceeded pipe diameter) and 9 sites experienced flow rates in excess of nominal full pipe capacity during at least one wet weather event. Four of the sites that surcharged did not experience flows in excess of full pipe capacity, indicating they were experiencing backwater conditions. **Figure 4** shows a typical wet weather response observed at the temporary monitoring sites, indicating that inflow sources represent a larger SSO problem than do infiltration sources. Inflow is indicated by the immediate response to the heavy rainfall the night of October 20th, followed by a rapid return to slightly elevated flow levels. Infiltration into the system is represented by the more gradual return to pre-storm flow levels following the longer duration but lower intensity rainfall on October 22nd.

Manhole inspections

Approximately 97% of the manholes and lampholes were physically inspected for defects and to confirm depths to pipe inverts and connectivity of the sewer system for modeling purposes. Since a significant portion of the system being investigated was constructed in easements rather than in dedicated public rights-of-way, a limited number of the structures could not be accessed for inspection. Typical reasons included construction of obstructions (fences, decks, outbuildings, etc.) over the recorded location of the structures. It is suspected that a number of structures were buried by subsequent fill or paving operations. The inspections completed were extensive enough to be representative of the entire study area and the absence of smoke escaping from suspected buried manhole locations indicated that I/I admitting defects were unlikely to exist at those uninspected sites.

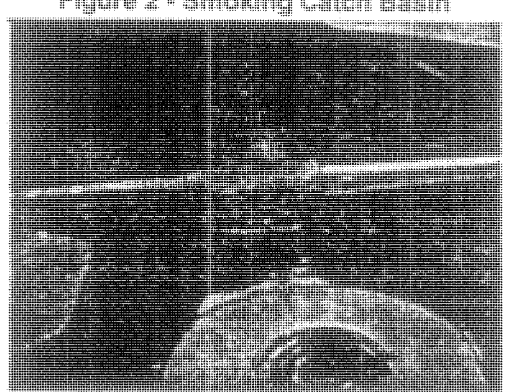
All identified manhole defects were assigned a rehabilitation priority based upon the severity of the defect (or combination of defects in a single manhole). Severities were determined from both personnel safety and I/I volume estimates associated with the defects. A majority of the defects identified were significant enough to warrant either immediate or very near term corrective actions being taken. Significant inflow removal is expected to result from replacement of the large number of vented manhole covers identified by the inspection program and by installation of flexible seals between the frames and the manhole chimneys.

Smoke testing

Over 300 km of main line sewer, and the connecting private service lines, were smoke tested to locate cross connections with the storm sewers in the area, identify I/I entry points in manholes not detectable by visual manhole inspection, locate buried openings in mainlines through which groundwater could enter, and document sources of I/I from defects or illegal connections on private property. Defects indicated by visible smoke were photographically recorded in addition to being noted on inspection forms and graphically depicted in sketches. All smoke testing results were transferred into the inspection database. Photographs were scanned into the recording system to provide a permanent and easily accessible record of the smoke testing results. Prints of the photographs depicting private property defects were provided to the TMUA for follow-up action with the property owners. Suspected cross connections with storm sewer lines were evidenced by smoke escaping from a significant number of catch basins. See **Figure 2** for an example. Little evidence was found of roof drains being connected to the sanitary sewer system.

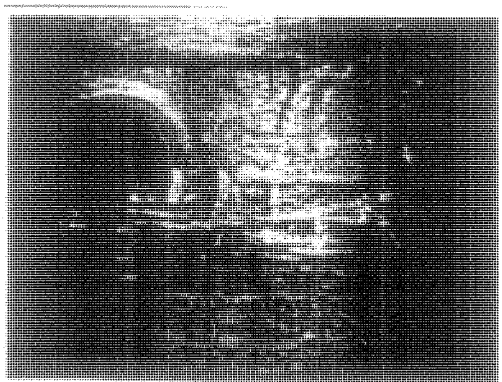
CCTV inspection

Figure 2 - Smoking Catch Basin



All pipe defects identified by smoke testing or during manhole inspections were assigned priority ratings from 1 through 3, with 1 being the highest. All priority 1 pipeline defects were scheduled for inspection by closed circuit television (CCTV) methods. Representative priority 2 defects were also included in the CCTV inspection program. Dyed water flooding of suspected inflow sources was conducted concurrently with the CCTV inspection to confirm that the suspected source was an actual source and to estimate the rate of inflow from the confirmed source. Although a number of catch basins had shown evidence of cross connections to the sanitary sewer during the smoke testing phase, the CCTV inspection was unable to confirm a single direct cross connection. However, a number of indirect cross connections, some with significantly high estimated rates of inflow, were detected. Major problems identified during this phase of the study included sewer lines which appeared to have suffered heavy damage by construction or settlement of other utility lines crossing above the sanitary sewer. **Figure 3** is an example of such damage. In this photograph taken from the recorded video tape, we see a storm sewer line has been constructed across the top of a sanitary sewer line. An entire section of sanitary sewer pipe has been broken out, a void surrounds the remaining portion of the sewer line, and the storm sewer is actively leaking into the sanitary sewer through a defective joint in the storm sewer. Due to the possibility of a surface collapse at this defect, it was reported to TMUA immediately upon discovery for correction.

Figure 3 - Storm/Sanitary Cross Connection



Computer modeling

Close calibration between modeled flows and both dry and wet weather monitored flows was attained. This successful calibration of the model provided confidence in the ability of the model to accurately identify specific problem areas and project the impact of proposed rehabilitation measures. Modeling also permitted evaluation of varying input rates from the multiple influent sources to the Southside Wastewater Treatment Plant during critical flow periods and the impact of the planned diversion of one pumping station flow from the Southside Wastewater Treatment Plant to another treatment facility. It also confirmed that significant efforts must be made to correct I/I source defects on private property for TMUA's program to eliminate overflows and bypasses in the study area to be successful.

including those on private property which would be the responsibility of individual property owners, would result in attaining the required reductions in overflows and bypasses. It would also indicate the extent to which reductions in wet weather flows from upstream basins may be necessary should sufficient reductions not be attainable within the study area basins alone.

RESULTS

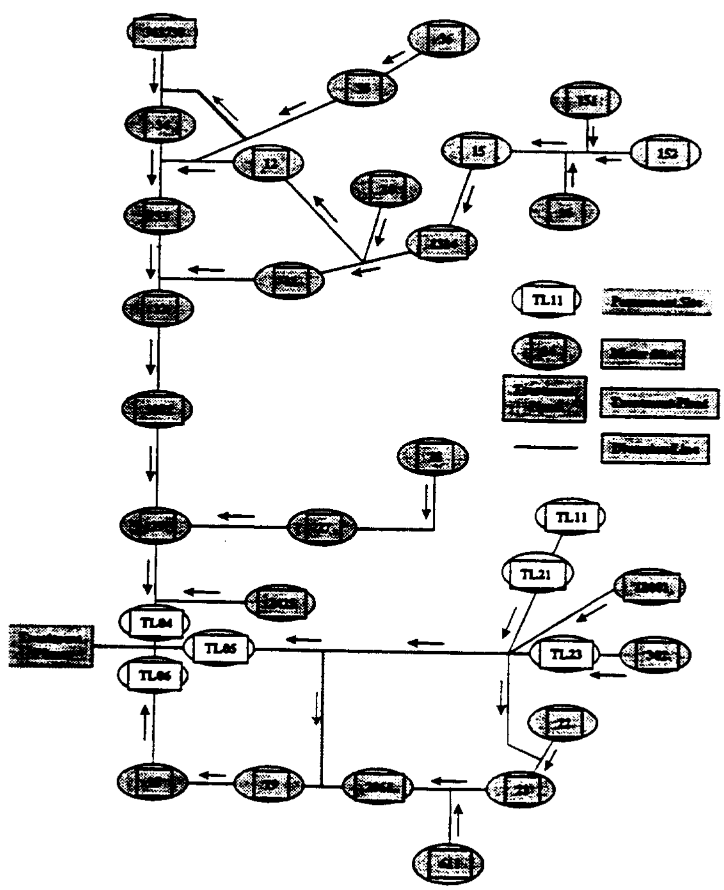
Flow monitoring

Of the 33 meters used during the 45 day flow monitoring period, 31 produced results which could be used in analyzing dry and wet weather flow at key points in the sewer system. Two of the long term meters produced data of questionable accuracy during this period. One site experienced erratic velocity readings during the period and the flow data supplied was based upon Manning's equation. The depth at this site was also suspect since the recorded level increased significantly during each rainfall event and, unlike other sites, failed to return to normal values after conclusion of the rain event. The second questionable site recorded levels an average of 2.5 to 10 cm lower than upstream meter sites. Physical examination of this site following receipt and review of the questionable data showed levels approximately 7.5 to 10 cm higher than reported under similar conditions during the monitoring period. **Figure 1** is a flow schematic indicating the relationship between each of the flow monitors in the collection system monitored for this study. Flow monitoring confirmed that no problems with system capacity exist under normal dry weather conditions, but conveyance capacity was exceeded at several monitoring locations during the 45 day monitoring period.

Manhole inspections

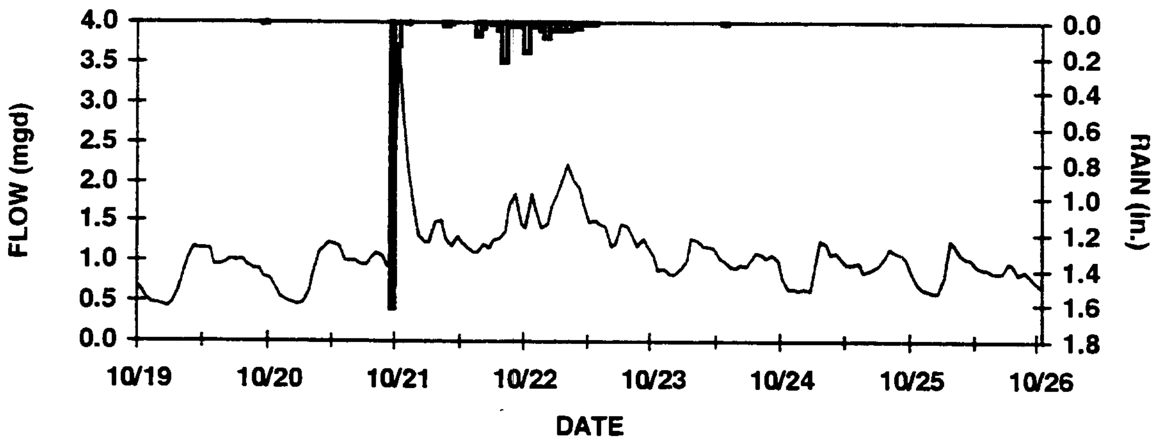
5,174 manholes and lampholes were physically inspected for defects which could admit extraneous flow or affect the integrity of the structure. An additional 151 which could not be located in the field, were buried, or were otherwise inaccessible, were not inspected. Included in the 5,174 total were a number of manholes and corresponding line segments which did not appear in TMUA records but were discovered and added to the records during the inspection process. Each manhole that could be opened was inspected, regardless of its condition, and inspection observations were recorded on standard manhole inspection forms for transfer into the appropriate database records. Manhole inspections identified in excess of 5,000 individual defects which warranted attention, either immediately or within the next five (5) years. The most common defect contributing to significant inflow problems within the area studied was vented manhole covers located in areas subject to surface runoff ponding or sheet flow. Manhole inspections also identified potentially significant defects in a number of the sewer lines where they entered the manhole, or within the first few pipe segments visible from the manhole.

Figure 1 - Flow Schematic



R0025191

Figure 4 - Typical Wet Weather Response



All manhole inspection data were entered on standard manhole inspection forms for subsequent scanning into the manhole database. Standard entry codes were used to minimize errors in input and scanning or misinterpretation of entries during subsequent analysis of the data. Provisions were made at the outset to identify new structures which were not included in the original TMUA database or did not appear on the sewer atlas sheets. Standard numbering of manholes and consistent references were maintained throughout the inspection and analysis activities.

Standard forms and codes were also used for entering pipe inspection data conducted concurrently with the manhole inspections. Adhering to the standardized numbering system for identification of line segments minimized errors in assigning inspection results to the correct line segments. Standardization also provided consistency in reporting among the different crews used to perform the inspections.

Smoke testing

Smoke testing was conducted throughout the study area, with the exception of the sewer lines immediately adjacent to a large hospital and its corresponding medical complex. All of the facilities connected to the lines near the hospital which were not smoke tested were included in the building inspection program for detection of significant I/I sources. Smoke testing located a large number of defects on private property, including major I/I sources such as area drains. Roof drain connections to the sanitary sewer system do not appear to be a significant source of inflow within the study area.

Data from smoke testing were also recorded using standard defect codes on standard forms for scanning into the database. In addition to photographic documentation of defects evidenced by smoke escaping from the lines under test, sketches showing the location of each defect relative to known features were made. Photographs and sketches were converted into computer files with links to the specific defects. Electronic recording of the data and supporting documentation will permit easy access for review and follow-up by TMUA personnel as the program progresses. Smoke testing results became a primary source for selection of specific lines to be inspected by CCTV.

CCTV inspection

Approximately 5% of the total length of sewer lines were selected for CCTV inspection to confirm suspected defects identified by pipe inspections or smoke testing. Highest priority was given to investigating possible cross connections to the storm sewer system due to the potential for extremely high inflow rates through

R0025192

such connections. Although smoke was seen to escape from a number of storm sewer inlets, only one direct cross connection was detected through CCTV inspection. In this particular instance, what appears to be a short relief line was constructed between the storm and sanitary sewer systems in such a manner that it could operate as a relief line in either direction, depending upon the flow level in the respective sewers. Other cross connections appear to be of the indirect type, where the two systems either cross or are within close proximity to each other, and both systems have defects which permit exchange of flow.

All CCTV inspections were conducted with color cameras equipped with movable heads to permit examination of service connections to the main line and the first few sections of pipe in the service lines themselves. Dyed water flooding was performed in conjunction with CCTV inspection of many suspect line segments. Positive detection of dyed water entering the sewer system was recorded for over 90% of the suspected sources tested in this manner. Although some sources showed I/I rates that were barely more than slow seepage, rates exceeding several liters per minute were estimated at a significant number of the positive locations. Some major I/I sources confirmed by this method were heavy leakage from flooded storm sewers through significant defects in the sanitary sewer lines (broken or shattered pipe, open or broken joints, holes in the pipe, etc.) and defective service connections in the vicinity of sink holes visible on the surface. Several significant structural defects were noted (collapsed pipe sections, shattered pipe sections, circular and longitudinal cracks, etc.) which did not demonstrate active I/I at the time of the CCTV inspection and were not adjacent to dyed water tested segments, but may well serve as I/I entry points.

A large number of the VCP lines showed evidence of root penetration through nearly every pipe joint. This problem was not unexpected considering the age of the lines and the extensive usage of side and rear yard easements for construction of the sewer lines. A number of the smaller diameter concrete lines displayed evidence of deterioration from corrosion. CIP and DIP segments displayed varying degrees of deterioration, with none representing structural problems at this time. However, some of the older iron pipe segments have developed interior tuburculation sufficient to create hydraulic restrictions.

Computer modeling

Computer modeling of the study area was intended to serve a number of purposes. First and foremost was to determine whether or not removal of identified I/I sources within the study area would eliminate bypasses from an overflow structure (**Figure 5**) on the east bank of the Arkansas River at the upstream end of the dual pipe river crossing to the South Side Wastewater Treatment Plant. An additional purpose was to identify problem areas which could result in backups or overflows at other locations in the sewer system and the extent of I/I reduction necessary to prevent this from happening. Since a number of the projects completed or underway in sewer basins upstream from the area of this study included provision of relief sewers to alleviate backup and overflow problems, the modeling would also have to project the impact of receiving upstream flows at a faster rate than has previously occurred. TMUA is also planning to divert flow from one pumping station which currently discharges into the Southside Plant system into another of their treatment facilities. The modeling addresses the effect of this flow reversal on the collection system in the study area and upon the treatment plant flow.

Figure 5- Overflow Gate

Modeling of the collection system, the river crossing, and the Southside Plant influent pump station confirms that adequate dry weather capacity is available to convey all tributary flows without bypassing or overflowing from the system unless an unexpected blockage occurs. It also confirms that correction of I/I sources, both public and private, identified in the study area are necessary to prevent regular overflows during extreme wet weather conditions.

CONCLUSIONS

One major conclusion can be drawn from the results of the study reported in this paper. The TMUA can effectively reduce the frequency and volume of bypasses from the Southside Plant Influent Sanitary Sewer System by continuing the program of evaluation and rehabilitation they initiated several years ago. The investigations conducted and recommendations resulting from this study, when completed, will reduce wet weather peak flow rates to within the capacity of the sewer system and the treatment plant. Implementing the recommendations will not be inexpensive, but phasing of the work in accordance with the priorities established will address the most serious concerns first and provide the most cost effective approach to correcting the overall problem.

COMBINED VERSUS SEPARATE SEWERS FOR FUTURE DEVELOPMENTS : A CASE STUDY IN MONTREAL

* Asseau-BPR, 5100 Sherbrooke Est, Suite 400, Montreal, Quebec, H1V 3R9

ABSTRACT

Under provincial regulation, the City of Montreal is required to separate wastewater and stormwater for all new developments. This even applies to small areas enclosed into an existing urban watershed drained by a combined sewer network. In some cases, this situation can generate significant costs because of the need to prolong the stormwater pipe to an appropriate outfall.

Based on environmental analysis and on investment comparison, we demonstrated for one watershed situated in the City of Montreal, that pursuing the development of the combined sewer network for new urbanized areas, associated with in-line retention and real-time control, is cheaper and it reduces the impact to the environment. The demonstration was obtained through the development of a sewer model, calibrated on rainfall and overflow recordings.

KEYWORDS : combined sewer overflow, urban wet weather pollution, global planning, selection of sewer type, real time control modeling.

INTRODUCTION

New developments in the City of Montreal are restricted to a few urban watersheds, and about 90% of the existing sewer networks are combined. For more than twenty years, provincial regulations demand the implementation of separate sewer systems for all new urban development and give priority to the separation of the tributary collection system. Until recently, special authorization could be obtained to continue combined sewer construction in predominantly urbanized watershed already served by a combined sewer network. For the last two years, the authorities are uncompromising in their regulation's application. Their recent acknowledgement of the impacts of combined sewer overflow (CSO) seems to be the main cause.

In view of this, the City of Montreal has chosen to perform a detailed analysis on one case study in order to compare the benefits of combined versus separate sewers for new small development areas enclosed in a combined sewershed. The case study concerns ZONE 01, a residential development project, which forms part of the Marc-Aurèle Fortin watershed. This watershed is already more than 82% urbanized and ZONE 01 only represents 11% of the total area. Table 1 shows the zoning and the corresponding surface area, and figure 1 presents a simplified map of the watershed.

The main collector of the Marc-Aurèle Fortin (MAF) watershed is linked to the North Interceptor of the Montreal Urban Community (MUC). It is a combined sewer and has the capacity to accept flows from ZONE 01. ZONE 01 is located 1480 meters away from the downstream regulation and interception chambers. The interception system consists of a 30 kilometer long tunnel ranging in size from 3.35 to 4.88 meters in diameter. Its capacity is 45 m^3/s and it runs along the North border of the Island of Montreal. Twenty (20) derivation/regulation chambers control the flows from the combined collectors to the interceptor. The interceptor drains a total of 12 000 ha of urbanized area. Automated gates regulate the inflows to the North Interceptor, and local dynamic control is applied at each regulation chamber. The system is designed to maximize inflow from each site. The MAF watershed is located 9 km upstream from the end of the North Interceptor that is, at the wastewater treatment plant. Figure 2 shows a diagram of the MUC interceptor system.

Table 1 : Zoning and corresponding surface areas of the Marc-Aurèle Fortin watershed

Zoning	Surface area (ha)	Surface area (%)	Impermeability effective (%)
Residential	63.6	36	43.3
Commercial, institutional and industrial	68.1	38	74.8
Green spaces	7.4	4	1.7
Undeveloped land			
Zone 01	20.4	11	31.0
Others	11.6	7	0.0
Highways	7.8	4	43.0
Actual Total	178.8	100	45.8
Total after Zone 01's development	178.8	100	49.6

METHODOLOGY

The methodology to compare options to either develop ZONE 01 in combined or separate sewer network focused mainly on environmental assessment and cost analysis.

Stormwater runoff transports a significant pollutant load leaching from urban areas. It represents a high proportion of pollutants present in combined sewer overflows. The same pollutants are present in stormwater pipe discharge, albeit with different concentrations (Chocat, 1994; OTV, 1994). Hence, in both cases, the environmental analysis has to consider the impact of either stormwater or combined sewer overflow, although usually impact analysis are only prescribed for CSOs.

The analysis used the following tools:

- A detailed representation of the hydrology and hydraulics of the MAF watershed with the RUNOFF and EXTRAN blocks of XP-SWMM. The model was calibrated against data obtained from an extensive monitoring campaign;

- A modeled representation of the real time control (RTC) system of the MUC interceptor. This was needed because some events and configurations on ZONE 01 affected CSOs not only on the MAF watershed, but also downstream along the interceptor, because of the presence of the RTC system. The MUC model was custom designed twenty years ago. It includes runoff representation of tributary sewershed and collectors, a time-lag routing method for the interceptor hydraulics, and local dynamic control at each regulation site;

- All simulations for rainfall events from an average year (May 1st to October 31st) to evaluate impacts generated by common and frequent events.

- An evaluation of CSO discharge to the Des Prairies River (the receiving water body), in terms of flow and suspended solids, BOD, and COD loading;

- Cost estimation for each alternative.

SEWER DEVELOPMENT ALTERNATIVES

Three distinct options have been retained for the Zone 01's development:

1. Combined sewer, option A : Implementation of local combined sewer linked to the existing main collector;

2. Combined sewer, option B : Implementation of local combined sewer linked to the existing main collector. Use of the in-line capacity of an existing 2400 mm Ø main sewer, by adding a control gate, instrumentation and control. The retention capacity is designed to create no more overflows than at present;

3. Separate sewer option : Implementation of local separate sewers. Installation of a new storm sewer and a new sanitary sewer from ZONE 01 to the derivation/regulation chamber of the existing combined collector. The sanitary sewer would be directly linked to the interceptor, without regulation, while the storm collector would be connected to the CSO outfall pipe.

RESULTS

Calibration of the model was performed against 1995 data. Five rainfall stations were used for the entire MUC territory, and flow data and RTC data were available for all 6 CSO events recorded at the MAF watershed. Table 2 shows the comparison between measured and simulated overflows. The MUC model provides a good estimate of the CSO volume and duration, despite the scale of the territory versus the number of rainfall stations, the number of inflows to the interceptor, and the operating conditions.

Table 2 : Measured and simulated overflow comparison for real development

Rainfall			Measured	Simulated	
No	Depth (mm)	Duration (h)	Duration (min)	Volume (m^3)	Duration (min)
5	22.1	7.25	140	11 250	155
9-10	25.7	10.42	555	15 525	300
22	35.3	9.92	275	21 150	240
23	19.6	2.92	100	2 775	80
27	11.9	3.25	95	4 050	120
39	17.8	7.08	140	10 050	155
Total			1 305	64 800	1 050
Average			218	10 800	175

Charts 3 and 4 present CSO volumes at the Marc-Aurèle Fortin site, and at 5 other sites downstream in the interceptor. These evaluations were made under existing conditions but including the development of ZONE 01. First, we notice that Zone 01's development generates no new CSO events. Second, results show a total overflow increase of 613 m^3/s due to Zone 01's development, of which most of it, 575 m^3/s, is generated at the MAF site.

Table 3 : Annual CSO at the MAF overflow site

	Real development	Zone 01 with overflow	Increase	
	Volume (m^3)	Volume (m^3)	Volume (m^3)	Volume (%)
Total	64 800	68 250	3 450	5%
Average	10 800	11 375	575	5%

Table 4 : Annual CSO at the MAF overflow site and at 5 other downstream overflow sites

	Real development	Zone 01 with overflow	Increase	
	Volume (m^3)	Volume (m^3)	Volume (m^3)	Volume (%)
Total	385 725	389 400	3 675	1%
Average	64 287	64 900	613	1%

From these results, we can proceed to compare CSO according to the different development options.

The pollutant loadings are evaluated with the use of average concentrations during wet weather. We estimated there was no need to use a model to represent the variability of pollutant concentrations, since the purpose of this exercise is to compare options. The average concentrations are based on results from past studies and our monitoring experience in numerous cities. Their range in value also correspond to those presented in different publications.

Table 5 : Average concentrations during wet weather according to network types

Parameters	CSO	Stormwater
Suspended Solids (mg/l)	175	85
BOD5 (mg/l)	100	15
COD (mg/l)	270	85

Table 6 shows the resulting flow and pollution loads of the different development options.

Table 6 : Wet weather discharge and costs estimates for each development option

	Current	Combined option A	Combined option B	Separate option
Number of discharge events	6	6	6	32
Volume (m^3)	64 800	68 475	64 350	79 450
Suspended solids (t.m.)	11.3	12.0	11.3	12.6
BOD5 (t.m.)	6.5	6.8	6.4	6.7
COD (t.m.)	17.5	18.5	17.4	18.7
Costs estimate (US $)		$2 800 000	$3 200 000	$6 200 000

DISCUSSION

Table 6 results clearly show that developing a combined sewer network under option A on Zone 01 is the most economical option. Option B, that is option A with added in-line retention, is slightly more costly, although it does not include management, operation and maintenance annual costs. Building a separate sewer system is much more costly than the two combined sewer options.

From a technical point of view, developing a separate sewer system demands the implementation of two parallel sewer networks connected to the interceptor chamber and the overflows interceptor on 1480 m of land and roads already cluttered with underground infrastructures. The costs are important and it is commonly believed to be justified because of the benefits to the environment. The present case demonstrates the opposite. This is due to two principal factors: the discharge evaluation includes both CSO and stormwater discharge into the Des Prairies River; the interceptor system with RTC has a significant residual capacity to intercept most wet weather flows.

The combined sewer, option B with in-line retention, presents comparable discharge to current conditions, while the combined sewer, option A, presents higher pollutant discharge. Option B represents the context where combined sewer system extensions would be allowed if CSO would not increase. Results show the retention need would equal 613 m^3 to ensure an annual CSO equal to present conditions. The added benefit of adding flow regulation to profit from in-line retention seems marginal: there are no changes in the annual number of CSO events, and CSO volumes and loading are reduced by 6%.

The MUC interception system has significant residual capacity for wet weather flow control thus allowing a limited overflow frequency. This is particularly true for the downstream CSO sites along the North Interceptor. Our evaluation shows that an important proportion of flows generated by the ZONE 01 development can be intercepted. As a result, there is little increase in CSO volume and it is limited to only a few events each year.

The interdependence between upstream and downstream sections of a network leads to evaluate the effects of new developments not only individually, but globally (Valiron and Tabuchi, 1992). Taking such a global perspective could lead to more pertinent solutions to improve the quality of the environment, such as for example seeking lower CSO frequency from the North Interceptor. The average number of CSOs from 1994 to 1996 varies from 1.3 to 12.3 annually and from site to site. A study performed by the MUC in 1995 indicates that investments in the order of 55 M$ US would be needed to significantly reduce the number of CSO events to 4 times per year. To attain this goal, an additional 87 000 m^3 retention capacity would be required. This represents a concrete objective showing the intervention level needed to adequately protect the environment.

CONCLUSION

An environmental and cost analysis was performed to compare how a new development project included in a combined sewershed should be better sewered: with separate or combined sewers. The case study is taken from the Marc-Aurèle Fortin watershed in the City of Montreal.

It is demonstrated through an extensive analysis that for this case study, building a separate sewer system on the new development project, ZONE 01, enclosed in a combined sewershed, would be much more costly and discharge more pollution to the Des Prairies River than if developed as a combined sewer network, including equipment to benefit from in-line retention capacity in an existing collector. As a result, we find that applying generic regulations may be detrimental when arbitrarily applied. In many cases, this is particularly true when assessing whether to develop a separate or combined sewer for new urbanized areas and overlooking the effect on the receiving water body.

ABSTRACT

King County (Washington) Department of Natural Resources is completing a water quality assessment that compares the Human Health and Aquatic risks from existing combined sewer overflow (CSO) discharges with the risks from other contributing sources (e.g., stormwater, surface run-off, groundwater, etc.).

King County selected the 3-dimensional Environmental Fluid Dynamics Computer Code (EFDC) model to simulate density flow and toxicant transport and fate of the contaminants within the Duwamish Estuary and Elliott Bay. The Duwamish Estuary is located in the heart of Seattle's industrial area. It is a heavily used shipping channel and is a significant habitat area for salmon. The estuary is well stratified (salt-wedge type) and the position of the wedge toe is very dynamic, being controlled by tides and fresh-water flow.

An intensive 26 week field sampling program was performed to collect water and sediment chemical data for the toxicant transport and fate module. Physical data was collected over a ten month period for the hydrodynamic module. Results from the modeling effort are being used in a Human Health and Aquatic Risk Assessment (RA) to compare potential exposure to humans, plants and animals from CSOs and other sources.

This paper focuses on the modeling techniques used and the assumptions and results from the modeling effort. It also presents an overview of the Water Quality Assessment, including the monitoring and sampling program.

KEYWORDS

Water quality modeling, CSO impacts, water quality assessment, toxicant transport

INTRODUCTION

King County owns and maintains the wastewater treatment plants and large conveyance pipes, collecting wastewater from Seattle and most of the smaller cities within the county boundaries. In parts of the conveyance system, the system is connected to both sewage and stormwater lines in what is termed a combined system. During periods of dry weather the conveyance system transports mainly sewage to the treatment plants. When the county experiences a significant rainfall event, the capacity of the conveyance system is exceeded thus forcing combined sewage and stormwater to overflow into the local water bodies surrounding Seattle. These sites are termed combined sewer overflows (CSO). CSOs only discharge when the ability of the conveyance system to transport sewage is exceeded due to the rainfall event. Currently the largest number of CSOs are in the Duwamish Estuary; hence the focus of this study is in the estuary. (See Figure 1)

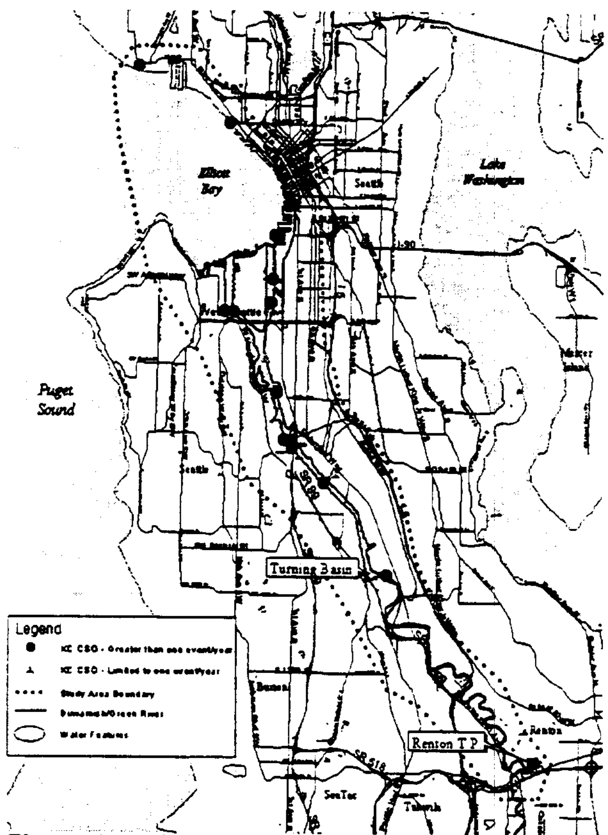

Figure 1. WQA study area

The Department of Ecology (DOE) requires the county to keep records on the number of discharges, volume of overflow, and chemical content of CSOs as part of the National Pollution Discharge Elimination System (NPDES). King County made agreements with DOE to reduce the number of CSO discharges from all sources to one untreated event per year, without a specific deadline for achievement of this standard. Federal standards allow four to six untreated discharges per year.

As part of the county's commitment to maintain or improve water quality, it embarked on the task to determine how significant CSO discharges into the Duwamish Estuary are compared to other contaminant sources that discharge into the estuary as well. The project, called the Water Quality Assessment (WQA), looks at the risk to human health and aquatic life as it exists today and what it would be without CSOs discharging into the estuary. To assess risk, the county is using chemical concentrations in the water, sediments, and aquatic life (primarily fish). Values for the water and sediment chemical concentrations will be obtained from a computer model that has been calibrated against observed field data.

Chemicals of Potential Concern

Eutrophication is not a problem in the Duwamish Estuary and Elliott Bay. Sampling of dissolved oxygen revealed that DO concentrations were always above 7 mg/l, even during CSO events. Flow through the estuary is rapid enough such that no other eutrophication processes pose significant risk to aquatic life. The chemicals that are of potential concern (COPC) in the estuary and bay were selected based on availability of data, water and sediment standards, and those known to impact the health of humans or aquatic life. The COPCs modeled in this risk assessment are,

- Metals
  - Arsenic, Cadmium, Copper, Lead, Nickel, Zinc, Mercury, Tributyltin
- Organic Compounds
  - 1,4 Dichlorobenzene, 4 Methylphenol, Bis(2 ethylhexyl)Phthalate, Fluoranthene, Phenanthrene, Total PCB, Pyrene, Benzo(k)Fluoranthene, Chrysene, Benzo(b)Fluoranthene
- and Fecal Coliforms.

Use of a computer model for the WQA study is twofold: 1) it will be used as a mass balancing tool to estimate chemical contributions from other sources given CSO, ambient, and boundary chemical loads, and 2) it will be used as a surrogate field sampling program. This paper discusses how the model was prepared and applied for the WQA risk assessment.

The Duwamish Estuary

The Duwamish Estuary is located in the heart of Seattle's industrial area southwest of downtown, and flows north into the southern tip of Elliott Bay. It is a heavily used shipping port and is a significant habitat area for salmon and other wildlife. The estuary is defined as the body of water starting from the mouth at Elliott Bay to 18.5 kilometers upstream. Most of the estuary is dredged for shipping with dredging extending approximately 12.5 kilometers upstream from the mouth. The mean river flow is about 42.5 cms (1500 cfs). The estuary is well stratified (salt-wedge type) when fresh-water inflow rates are greater than 28 cms (1,000 cfs); but when flows are less than 28 cms, the lower 5.5 kilometers of the estuary grades into the partly mixed type. Cross-channel distribution is generally uniform for a given location and depth. Salinity migration is controlled by tides and fresh-water flow. The upstream extent of the wedge is dependent upon fresh-water inflow and tide height and can range from 2 to 16 km upstream from the mouth. Dye studies indicate that downward vertical mixing over the length of the salt-wedge is almost non-existent.

Freshwater flow into the estuary comes from the Green River. The river is regulated at the Howard Hanson dam for flood control. However, flow rates do vary considerably day to day because of storm runoff and snow melt. Upstream tidal flow reversal has been observed in the Green River 21 km upstream of the mouth.

Water depth in the dredged sections of the estuary vary from 15 meters at mean lower low water (MLLW) at the mouth to 3.6 meters at 14th Ave bridge (9.5 km). The channel above the turning basin is not dredged and varies in depth from 1 to 2 meters (MLLW). Elliott Bay, at its deepest location, is about 150 meters (MLLW). Tides in the Duwamish have ranged from minus 1.4 to plus 4.5 meters from mean lower low water. Freshwater flow from the Duwamish discharges into Elliott Bay causing a freshwater lens atop the saline waters in the bay.

MODELING OBJECTIVE

The objective of the modeling program was to use the computer model as a mass balancing tool to determine mass loading contributions from sources other than CSOs. The model was then used to assess the differences in resulting water and sediment concentrations due to CSOs and "other sources". These differences could then be used in a Risk Assessment to quantify the risk to humans and aquatic life from CSOs relative to "other sources". Therefore, it was assumed that there are three basic chemical sources in the estuary: boundaries, CSOs, and "other sources". King County had limited financial resources and limited it's scope of work to collecting information on CSO chemical compounds and ambient chemical concentrations. Knowing two of the three sources, the computer model was employed as the third equation to estimate inputs from the other chemical sources.

COMPUTER MODEL DESCRIPTION

King County selected the Environmental Fluids Dynamic Computer Code (EFDC) developed by Dr. John Hamrick for application to the WQA modeling. It was selected over other models because it can simulate highly stratified flows and both nutrients and toxic compounds. It has been applied to many estuarine studies, and it is non-proprietary. The county reviewed 13 different models for application to the Duwamish. They were rated against a set of requirements defined by the county which were based on the needs of the WQA and observed conditions within the estuary. (See Walton, 1998)

EFDC is a curvilinear-orthogonal, three dimensional hydrodynamic-chemical transport and fate model. The hydrodynamic and transport modules are coupled. The vertical dimension is transposed into a stretching coordinate system where cell layers move with the free surface. Hydrodynamics are solved using the depth integrated momentum equation and employs a turbulent intensity and length scale transport equation to solve for turbulent viscosity and diffusion. Transport and fate is solved using the mass transport equation and incorporates a near field model which can be coupled to the mass transport model. For a detailed explanation of the model derivation see Hamrick (1992).

The study area was segmented into 500 cells in the horizontal plane, and ten layers in the vertical for 5,000 cells in total. The EFCD model was modified to simulate near-field CSO effects within the larger model cells, and to simulate chemical fate equations as a function of the physical and chemical state of the estuary and bay.

FIELD MONITORING PROGRAM

Water velocity, elevation, temperature, and salinity were collected during the field monitoring program. Acoustic doppler current meters were used to measure water velocity. Three meters were deployed in the estuary and two in Elliott Bay. The meters measured the horizontal and vertical components of the water velocity. Velocities were measured at half-meter intervals in the estuary and at 4-meter intervals in Elliott Bay. Salinity, temperature, and water elevations were measured at three field stations in the estuary. Two stations had two instruments placed one meter below the surface and one meter above the bottom. The third station had a single instrument placed one meter below the surface.

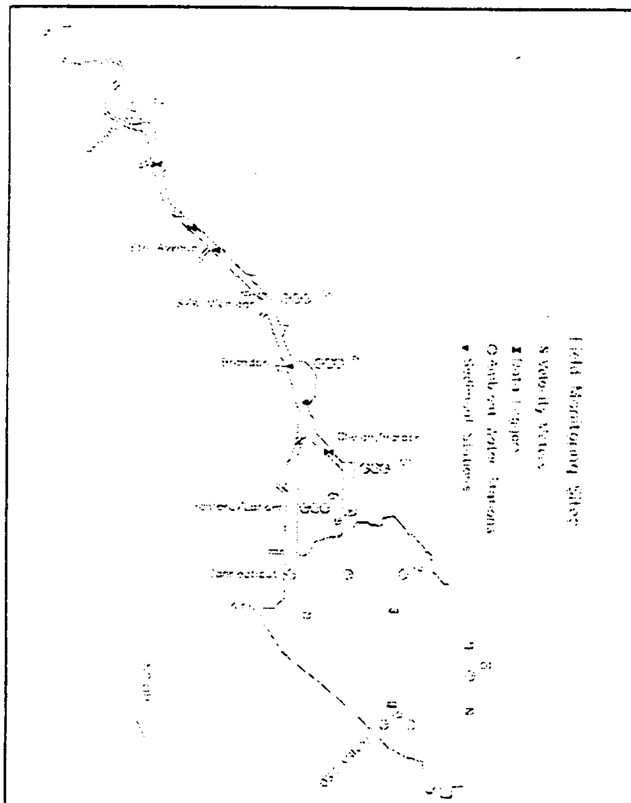

Figure 2. Locations of sampling and field instrument sites.

To determine the feasibility of an intense field sampling program, King County did a pilot study to see if it was possible to collect the number of samples required and if current laboratory analytical techniques were appropriate. The pilot study revealed that most of the organic compounds were non-detects and the saline water of the estuary significantly interfered with measuring metals. The County instigated new laboratory procedures to remove the saline matrix from the water samples, also lowering the detection limit by an order of magnitude. To overcome the inability to measure organic compounds using conventional laboratory procedures, Semi-Permeable Membrane Devices (SPMD) were used. The SPMDs were deployed for two weeks and provide a time averaged estimate of water concentrations over the deployment period. Organics were still sampled using conventional methods approximately once per month and except for Bis(2-ethylhexyl)Phthalate, all other organic COPCs were non-detects.

The field monitoring program was started October 31, 1996 and ended June 4, 1997. Approximately 26 sampling trips where performed during this time period.

Samples were taken either once or three times per week. If the three largest CSOs were not discharging (non-storm event), one sample was collected for that week. If the three CSOs were discharging (storm event), then sampling occurred over three consecutive days. Personnel were put on 24 hr alert, 7 days a week to mobilize for storm sampling. For safety reasons, it was decided that sampling would only occur during daylight hours. Because of this, some storm sampling trips did not commence until the tail end of the storm period when CSOs had slowed considerably.

Sampling locations were selected along the length and width of the estuary, see Figure 2. Samples were taken 1 meter below the surface and one meter above the bottom at most river sites. Samples were

taken 15 to 20 meters below the surface in Elliott Bay. Samples were taken at 3 locations across the river at most of the river sites. The parameters measured are listed in Table 1.

CSO contaminant concentrations were obtained by sampling five of the largest CSOs that discharge along the Duwamish. They were Brandon, Connecticut, King, Hanford, and Chelan Regulators. The sampling program was designed to test whether chemical concentrations changed over the duration of the discharge event (first flush effects), whether they varied between CSO outfalls, or whether they varied across the depth of the CSO pipe. Additionally, previous testing results were available for the Denny Way CSO site regarding chemical analysis, and solids settling, and how metals partition to suspended solids.

Sampling QA/QC

Collection of water samples was started before the County had developed the analytical techniques to remove the saline matrix from the samples. The new technique lowered detection levels an order of magnitude below what was previously achievable. While this was good, it also proved to be a problem. The lower detection limit increased the degree to which sample contamination could be observed. Standard QA/QC revealed significant field blank contamination had occurred in most samples for lead, copper, and zinc. The sample values were subsequently blank corrected using the limited information that was available.

MODEL CONFIGURATION

John Hamrick from TetraTech Inc. configured the model with assistance from King County staff.

Elliott and Duwamish Boundary Conditions

At the model boundaries, Elliott Bay is forced by a phased harmonic tidal series. The Harmonics and phasing where determined from water level time series data taken near Fourmile Rock and Alki Point. The phasing accounts for the time it takes the tidal wave to travel across the boundary length. At the upstream I-405 Green River boundary tidal effects are minor. Conditions at the Green River boundary were driven by fresh water flows obtained from the USGS flow station at Auburn. Daily average flows were used.

Chemical data gathered from the field monitoring program at the Tukwila and Duwamish Head field stations were used at the Green River and Elliott Bay boundaries respectively for model calibration. Boundary conditions for the one-year and ten-year simulations were generated from a simple stochastic model developed from observed data. Correlation analysis of the Tukwila data indicated a significant relation between zinc, lead, and copper, but less so with nickel. No significant correlation existed for arsenic and cadmium. Analysis of the Duwamish Head data at the 20 meter depth indicated a correlation between cadmium, copper, and arsenic. Analysis of all data indicated no significant correlation between river flow, rainfall, or CSOs. Data generation for both boundaries entailed generating a primary constituent with the same statistical properties as the observed field data, and then generating the other constituents from the primary, maintaining the observed correlation.

CSOs

Currently 13 King County CSOs discharge into Elliott Bay and the Duwamish Estuary. Hydrographs used for the calibration are from flow data recorded over the 96-97 year. Hydrographs for the ten-year runs were generated from the county's basin run-off and hydraulic routing models and historical rainfall data from a recent ten year period. The rainfall periods were matched to the historical Green River flow data at the Auburn station.

Analysis of the chemical data from the CSO monitoring program indicated that there were was no significant change in concentrations over the duration of the discharge. Concentrations appeared to vary over the depth of the pipe, and that there were subtle differences in concentrations between a few of the CSOs and a few of the metals of concern. As a result, average concentrations for each of the five CSOs for each of the COPCs were used in the model. For the remaining seven CSOs that were not monitored, concentrations were estimated from one of the five CSOs based on similar basin characteristics, see Appendix A for grouping and concentrations.

Other Sources

The actual number of other sources that discharge into the Duwamish Estuary and Elliott Bay are unknown. However, an estimate of total run-off into the estuary was modeled using the County's basin run-off model. The county currently maintains a basin run-off and conveyance model for the Westpoint and Renton treatment plants to estimate sewer flow through the pipe network. The model is calibrated to observed flows in the sewer conveyance system and includes effects from stormwater inflows generated by rainfall. The portion of the stormwater from impervious areas flow that does not enter the sewer system was considered to drain into the storm system. Run-off flow was routed along basin drainage lines and discharged into the Duwamish and Elliott Bay as an other source. Forty-one discharge hydrographs of stormwater were generated from the run-off model.

Chemical input for the other source loads was obtained from historical stormwater data. Since the intent of the modeling was to estimate chemical loads from other sources, stormwater chemical concentrations were adjusted until model predictions were comparable to observed data. Exact concentrations were not required, only reasonable estimates were needed. Use of the stormwater data does not imply all loads from "other sources" are solely from stormwater drains. The review did not provide stormwater chemical data for some of the COPCs. In these instances, non-sewage-related CSO data was used. Appendix A summarizes initial chemical conditions for other sources.

Sediments and Suspended Solids

Sediment concentrations from Elliott Bay and the Duwamish were obtained from the DOE SedQual database. This data set was supplemented with data collected from the WQA. Sediment particle size for the bay and estuary was obtained from GeoSea Consulting which gathered the data for the Elliott Bay/Duwamish Restoration Program. This data was also supplemented with particle information collected by Science Applications International Corp 1991 for ACOE dredging at the turning basin. Very little sediment chemistry and particle data information is available for the Green River section of the model. A small amount of particle size information was obtained from an in field assessment of percent fines, at four locations, by county technicians. Anecdotal evidence from the USGS was also used. The data was collated to initialize sediment concentrations and particle distribution within all model cells. Multiple points within a single cell were averaged into a single value. Cells with no data points were interpolated from neighboring cells.

Review of all the sediment and CSO sampling data indicated that the sediments could be divided into three general classes, fine sand to course silt, silts, and fine silt to clay. Solids concentrations at the Green River boundary for fine sand/course silt class were generated using the Corps of Engineers Suspended Solids Loading Equation (ACOE 1981). Concentrations for the finer solids were generated from a similar regression equation using TSS field data collected for the WQA and USGS Auburn flow data. The field monitoring program provided suspended solids concentrations for CSOs. Solids concentrations for other sources were obtained from existing stormwater studies.

Chemical Properties

Chemical partition values for the metals As, Cu, Cd, Pb, Ni, and Zn were estimated from field data using the following equation (Thomann 1987),

Equation 1

$$P = \frac{c_T - c_d}{c_d m}$$

Where:
P is the partition coefficient
c_T is total chemical concentration
c_d is dissolved chemical concentration
m is total suspended solids concentration

An average partition coefficient was computed for each sample site and the sample averages were combined to compute a single partition coefficient. A constant partition coefficient was used for all chemicals. However, sample averages indicated that partitioning varied along the length of the estuary. An attempt was made to develop a regression equation to explain the observed relation between salinity and the partition coefficient, but none of the equations proved to be statistically significant. Chemical partitioning for the organic compounds, Tributyltin, and Mercury were obtained from literature references (Hamrick 1998).

Table 2. COPC Chemical Properties

Chemical of Concern	Decay (1/sec)	Partition Coefficient (l/mg)	
		Water	Sediments
Arsenic	None	0.02	0.005
Cadmium	None	0.018	0.004
Copper	None	0.11	0.025
Lead	None	4.4	0.4
Nickel	None	0.042	0.01
Zinc	None	0.082	0.02
Tributyltin	None	1.0e-3	Same
1,4-Dichlorobenzene	None	8.1e-5	Same
4- Methylphenol,	None	2.4e-6	Same
Bis(2-ethylhexyl)Phthalate	3.5e-7	4.8e-3	Same
Fluoranthene	3.1e-6	9.8e-3	Same
Phenanthrene	7.7e-6	8.4e-4	Same
Total PCBs	None	2.2e-3	Same
Pyrene	9.4e-5	3.4e-3	Same
Benzo(k)Fluoranthene	3.9e-7	3.0e-1	Same
Chrysene	1.5e-5	2.1e-2	Same
Benzo(b)Fluoranthene	2.7e-7	1.5e-1	Same
Mercury	None	4.4e-4	Same

Chemical decay rates for the organic compounds were obtained from literature references (Howard et al 1991). Minimum rates were used for both water and sediment columns. A zero decay rate was used for unlisted chemicals. Partition and decay values are summarized in Table 2.

MODEL CALIBRATION

John Hamrick calibrated the hydrodynamic portion of the EFDC computer model and sent the calibrated model to King County staff for the mass calibration of the COPCs.

Sediments

The first constituent to calibrate was the suspended solids. The only parameter adjustment was the suspended solids settling velocity. While the model requires specifying a critical sediment stress at which resuspension occurs, no field measurements were made to estimate a critical stress value. Instead literature references were used as suggested by Hamrick (1.6e-4 $(m/s)^2$ non-cohesive and 1e-4 $(m/s)^2$ cohesive). At first, two sediment types were selected; fine sand and silt. Sediment samples from ACOE (SAIC 1991) pre-dredging studies indicated that most of the solids deposited in the turning basin are fine to medium sands. A third solids class was added with a settling velocity similar to clays and flocculated material due to the fact that too much sediment was settling out. The solids in the CSOs were also divided into silts and clays, with the same settling velocities as those used in the river.

Settling velocities and solids loadings at the Green River boundary were adjusted for all three classes until an optimum fit between observed and predicted solids concentrations was reached. The best fit occurred with a suspended solids distribution at the Green River boundary of 78% fine sands, 15% silts, and 7% clays, and 100% clay at the Elliott Bay boundary. Suspended solids from CSOs and other sources were negligible compared to that from Green River. Final settling velocities for each class was 0.01 m/s for the fine sands, 0.004 m/s for silts, and $1x10^{-6}$ m/s for the clays. The final calibration graph for total suspended solids at the Brandon site are shown in Figures 3 and 4, for the surface and bottom levels.

Metals

Metals were calibrated after the sediment calibration was completed. Calibration entailed adjusting load inputs from "other sources" until simulated metals concentrations were comparable to observed data. Metals loading from CSOs were not adjusted, since it was assumed that inputs from CSOs had been adequately defined in the sampling program.

The model simulated the transport of metals in two phases, dissolved and particulate. Division between the two phases was defined by the partition coefficients given in Table 2 and the suspended solids as given by equation 1. It was assumed that the partition coefficients remained constant in both space and time. Given that the partition coefficient does not vary, and that the suspended solids field has been defined; differences in simulated and observed metals concentrations were ascribed to other source loads. The model simulates chemical loads using a hydrograph and chemical concentration time series. It multiplies the flow rate by the chemical concentration to give a chemical flux into the cell. To adjust the load that discharges into the cell, either the flow rate or the chemical concentrations can be manipulated. For the EFDC model it is easier to manipulate the chemical concentration time series rather than the hydrograph.

Calibration was carried out in a series of steps, each step refined the previous steps. The first steps were to match the general fit of model predictions to field observations. After the general fit was completed the next steps refined model predictions at specific points in the observed time series. This entailed adjusting either the existing hydrographs, chemical time series, or adding a separate hydrograph and chemical time series as needed to match observed field data. Final calibration graphs for zinc at the Brandon site, 1 meter below the surface and 1 M above the bottom, are shown in Figures 5 and 6.

Organic Compounds

The organic compounds were calibrated using sample data from mussels and SPMDs. The concentrations in the mussel tissue were converted to average concentrations in the water column which would approximately result in the sampled tissue concentration. Concentrations in the SPMDs were placed in the water for two weeks. The concentration of contaminants in the SPMDs were converted to average water column concentrations that would result the SPMD values. Data from the model was saved and averaged over the time periods that the mussels and the SPMDs were in the water.

Calibration Results

Final chemical concentrations for other source inputs are listed in Table 3. Final CSO concentrations are shown in Table 4.

Table 3. Final Chemical Concentrations for Other Sources

Metals							Organics	
Other Sources	Eastside Inputs							
Source (mg/l)	Arsenic	Cadmium	Copper	Lead	Nickel	Zinc	TBT	Phenanthrene
Pre-Julian day 400	4.64	0.95	22	22.8	0.0	134	0.0	1.44

Organics								
Source (ug/l)	Chrysene	Fluoranthene	Pyrene	1,4-Dichloro benzene	4-Methyl phenol	Benzo(b) fluoranthene	Benzo(k) fluoranthene	Total PCB
Eastside Inputs	0.06	0.43	3.59	0.15	2.32	0.015	0.0005	0.0
Westside Inputs	0.06	0.43	3.59	0.15	2.32	0.015	0.0005	0.0

RESULTS OF MODELING

The calibrated model was run for one-year and ten-year periods. The one-year period simulation looked at differences between CSOs and other sources in the water column and estimated differences in the sediment column. Chemical concentrations were saved every hour for every model cell. The ten-year period was run to verify or correct the one-year sediment estimates. The ten-year run was necessary because of the generally slow response of sediments to loading changes, and it was not known if current sediment concentrations were in equilibrium with the existing environment.

Table 4. Arithmetic Mean Chemical Concentrations for CSO

Metals (ug/l)								
Arsenic	Cadmium	Copper	Lead	Nickel	Zinc	Mercury (ng/l)		TBT (ug/l)
2.87	0.51	32.78	30.68	8.24	130.17	26.95		0.0
Organic (ug/l)								
Total PCB	Chrysene	luoranthene	henanthrene	Pyrene	,4-Dichloro benzene	-Methyl phenol	Benzo(b) luoranthene	Benzo(k) fluoranthene
0.0	0.242	0.43	0.439	0.363	0.382	5.62	0.239	0.208

Model results for the one-year simulations with and without CSOs have not been evaluated at the time of writing this paper. Therefore, a comparison of the impacts between CSOs and other sources has not been done at this time. However, the calibration process did reveal some information about the models ability to simulate the highly stratified conditions in the estuary, and the relative influence of boundary sources to observed metals concentrations. The model is able to give a reasonable simulation of contaminant transport through the estuary, and the results are being used to perform a Risk Assessment on the impact of CSOs relative to other sources.

SUMMARY

The Duwamish Estuary and Elliott Bay is a highly stratified flow system when CSO and other sources tend to discharge into the system. The EFDC model adequately simulated the stratified flow and transport of metals and organic compounds through the estuary and into the bay, maintaining observed chemical differences between the fresh water lens and the saline wedge. Assessment of the calibration process indicates that the most influential source of arsenic and cadimum is from Puget Sound. The Green River is the primary source for nickel.

ABSTRACT

The U.S. Environmental Protection Agency (EPA) published its final CSO Control Policy in April, 1994. In response to the new national policy, the Massachusetts Department of Environmental Protection (DEP) revised the state's water quality standards to include waterbody classifications that reflect a range of circumstances under which CSOs discharge and issued a new CSO Policy and Guidance Document, incorporating increased flexibility for permittees to demonstrate that CSO discharges are being controlled to the maximum extent feasible. The CSO control plan developed by the Massachusetts Water Resources Authority (MWRA) is the first one to be reviewed and approved under the new state policy and regulations. The planning approach used and documentation provided by the MWRA will serve as the template for other regional wastewater agencies and municipalities seeking approval of CSO control plans from Massachusetts DEP and EPA.

KEY WORDS

CSO policy, water quality standards, percent compliance, designated uses, sensitive use areas, use attainability analysis

INTRODUCTION

Recent changes in EPA and Massachusetts CSO policies now provide more options for regulating CSO discharges. Both policies require that permittees fulfill specific requirements in developing long-term control plans and that certain criteria are met to successfully demonstrate that water quality standards will be achieved and designated uses protected.

National CSO Policy

EPA's policy evolved with extensive input from numerous state, municipal, and environmental stakeholder organizations in an open participatory process. One intention of the policy was to ensure that permittees, regulators, and the public engage in a comprehensive and coordinated planning effort to achieve cost-effective CSO controls that comply with water quality standards and protect designated waterbody uses. It provides for flexibility in developing long-term CSO control plans and allows CSO controls to be tailored to address site-specific impacts of CSOs.

The policy specifically states that development of a long-term CSO control plan should be coordinated with the review and appropriate revision of state water quality standards and implementation procedures for CSO-impacted waters. Further, the policy states that this coordination process provides greater assurance that the long-term plan selected and the limits and requirements included in the NPDES permit will be sufficient to meet water quality standards and comply with the Clean Water Act.

Massachusetts CSO Policy

As a first response to EPA's 1994 national policy, DEP issued a new draft CSO strategy in August, 1995. The agency also revised its water quality standards in 1996 to provide a regulatory framework for additional waterbody classifications that would reflect the range of situations in which CSOs occur. After a dedicated public outreach process, DEP issued its final updated CSO Policy and Guidance Document in August, 1997.

The new state CSO policy and guidance reinforce DEP's original goals for CSO abatement measures:

- Eliminate receiving water impacts from CSOs.
- Where elimination of CSOs is not feasible, minimize CSO impacts to the maximum extent feasible and attain the highest water quality achievable.

In receiving waters where CSOs remain, the identification and protection of sensitive areas that support critical uses is essential. The elimination of CSO discharges through sewer separation, or relocation of CSOs to less sensitive receiving water segments, is required wherever it can be achieved based on economic and technical evaluations. To demonstrate that CSO discharges can not be eliminated, the permittee must show that the cost of sewer separation would cause "substantial and widespread economic and social impact." The DEP CSO guidance document states that the demonstration of severe economic and social impact can be made by showing that the costs of sewer separation (or CSO relocation) are excessive when compared to the benefits to be achieved. When determining the benefits to be achieved, potential interactive and overlapping pollution sources (such as discharges from storm drains after separation) can be taken into account.

The state CSO policy contains a hierarchical "menu" of surface water classifications based on the frequency and impact of overflows to regulate CSO discharges that can not be eliminated. In all cases, permittees are required to implement the nine minimum controls necessary to meet technology-based limitations specified in EPA's national CSO policy.

MWRA CSO Control Plan

The MWRA defined its long-term CSO control plan in its final CSO facilities plan, which was completed in July, 1997. In accordance with EPA's CSO policy, the recommended CSO control plan was developed over a five-year period with continual interaction and direction from DEP, the state agency responsible for enforcing water quality standards. During the MWRA CSO planning process, DEP reviewed its regulations and determined that changes in water quality standards were warranted to better reflect site-specific wet weather impacts of CSOs.

METHODOLOGY

The process leading to approval of MWRA's CSO control plan involved a concurrent, cooperative effort by DEP and MWRA. DEP established new water quality classifications and MWRA demonstrated compliance with them, using a watershed-based approach that considered each receiving water segment on a site-specific basis and that assessed control alternatives using technology-based and water quality-based evaluations.

New DEP Water Quality Classifications

DEP's CSO policy contains a hierarchical listing of surface water classifications to regulate CSO discharges based on the frequency and impact of each overflow. The classifications for CSO-impacted waterbodies are summarized in Table 1. The **Class B or SB** classifications indicate that CSO discharges have been eliminated. If CSOs are not eliminated, the regulatory options include: Class B(CSO) or SB(CSO), indicating minimal CSO impacts whereby Class B standards are met greater than 95 percent of the time; a variance, allowing a short-term modification of standards through the NPDES permitting process to provide time to gather more water quality impact information; a partial use designation, indicating intermittent impairment of water quality goals; and Class C or SC, a downgrade in classification if permanent and sustained impairment of water quality goals is documented. These classifications are discussed below.

Class B(CSO) or SB(CSO). Where elimination of CSO is not feasible and the impacts from remaining CSO discharges will be minor, the segment will be identified as B(CSO). Overflow events may be allowed without a variance or partial use designation, provided that certain conditions are met. DEP's 1996 revisions to the water quality standards regulations formally recognized the B(CSO) water quality category by establishing

TABLE 1. SUMMARY OF WATER QUALITY CLASSIFICATIONS FOR CSO-IMPACTED WATERS

Classification	Requirements
B, SB	CSOs are eliminated
B(CSO), SB(CSO)	CSOs remain but must be compatible with water quality goals
Variance	CSOs remain when allowed under a short-term modification of water quality standards through an NPDES permit
Partial Use Designation	CSOs remain with moderate impacts resulting in intermittent impairment of water quality goals
C, SC	CSOs remain, causing permanent and sustained impairment so that Class B water quality goals can not be met

Note: Class SB and SC denote coastal and marine waters

regulatory significance for the notation "CSO" shown under "Other Restrictions" in the state water quality standards for impacted receiving water segments. The following criteria must be satisfied in order to receive a B(CSO) designation:

a. An approved facilities plan provides justification for the overflows.

b. The DEP finds through a use attainability analysis, and EPA concurs, that achieving a greater level of CSO control is not feasible for one of several reasons.

c. Existing uses and the level of water quality necessary to protect the existing uses shall be maintained and protected.

d. Public notice is provided through procedures for permit issuance and facility planning.

A designation of B(CSO) for a particular receiving water segment will be made only if DEP's facilities planning process and watershed planning efforts show that the allowance of minor CSO discharges is the most environmentally protective and cost-effective option available. B(CSO) does not denote a downgrade of water quality, rather it indicates that Class B or Class SB water quality standards will be met most of the time and that CSO impacts were minimized to a level compatible with water quality goals.

The conditions for showing that a greater level of CSO control is not feasible are the same as those that allow removal of a use that is not an existing use, a partial use designation, or a variance. It must be demonstrated that at least one of six specific conditions exists. In general terms, these conditions include: impacts from naturally occurring pollutant concentrations; natural or low flow conditions; natural physical conditions; hydrologic modifications; human caused conditions, which can not be remedied or would cause more environmental damage to correct; or demonstration of substantial and widespread economic and social impact.

DEP's new policy states that generally eligibility for Class B(CSO) status is limited to discharges which can meet water quality standards more than 95 percent of the time, but the highest level of control must always be achieved for each case as determined in the facilities plan through a cost/benefit analysis. Priority will be given to relocating or eliminating CSOs in sensitive areas such as outstanding resource waters, bathing areas, water supply intakes, endangered species habitat, and shellfish beds. It is DEP's responsibility to prepare a Use Attainability Analysis (UAA), based on the facilities plan, to document that achieving a higher level of CSO control is not feasible or appropriate.

Variance. A variance provision added to the state's water quality standards allows short-term modification of the water quality standards in permits when interim control measures or further studies are appropriate. A variance will be used where long-term attainability of the standard is uncertain, the CSO abatement plan includes phased implementation, and/or DEP believes the standard may ultimately be attained. Unlike a "partial use" designation, a variance would be both discharger and pollutant specific, time-limited, and would not change the currently designated waterbody uses (Class B or Class SB). A variance would allow CSO discharges to be in compliance with "modified" water quality standards in the NPDES permit while additional analyses are conducted and progress is made toward meeting the existing standard.

Variance procedures involve the same substantive requirements that apply to a B(CSO) designation; but since variances maintain the currently designated uses, a formal UAA is not required. DEP intends to use the NPDES permit as the vehicle to grant the variance. Public notice of the permit will clearly state that the variance temporarily modifies the state's water quality standards. Variances will normally be reviewed every three years, and if deemed necessary may be codified in the water quality standards at the required triennial standards review. The regulations allow a variance under the same conditions as a Class B(CSO) classification or a partial use designation, as listed above.

Partial Use Designation. In receiving water segments where DEP is certain that designated uses or standards can not, and will not, be attained on a permanent basis during intermittent storm events, a partial use designation will be granted for specific segments through a regulatory revision, following a UAA. The UAA will assess physical, chemical, biological, and economic factors affecting beneficial uses. The analysis also will evaluate whether a designated use could be attained if CSO controls were implemented, or if background conditions or non-CSO sources would preclude uses even if CSOs were completely eliminated. Partial use is the term used to describe waters occasionally subject to short-term impairment of uses, but which generally support those uses. Generally, short-term impairment means that the standards are met at least 75 percent of the time, but DEP will determine the permissible level through the facilities planning process on a case-by-case basis. Partial use can be defined by seasons or a particular storm event when a use such as swimming will be unattainable in CSO-impacted waters. The use must be fully protected downstream, in other seasons, or during smaller storm events.

DEP may find that a permittee has demonstrated that a use is not attainable under circumstances identified in the regulations. Information to support a designation will be developed largely in the facilities plan or environmental impact report. The information contained in the facilities plan and available watershed plans will include most information necessary for the UAA, which must be submitted to EPA prior to the designation.

Change in Classification. Where designated uses can not and will not be met on a permanent and constant basis in the foreseeable future, DEP will consider a change in classification from Class B (or SB) to Class C (or SC) to be appropriate, though this will be the option of last resort. As with a partial use designation, a UAA will be required for a change in classification.

Development of MWRA CSO Control Plan

MWRA's long-term control plan was developed for CSOs that are located in Boston, Cambridge, Somerville, and Chelsea. These CSOs impact Boston Harbor and its major tributaries, including the Charles River. Because of the diversity of the watersheds tributary to the CSO receiving waters throughout the study area and their geographical separation, major waterbodies were divided into 14 receiving water segments. Each segment had distinct characteristics and specific water quality issues to be addressed. Together, the segments support a spectrum of uses that range from bathing beaches and recreational areas to shipping channels and other industrial operations.

As with EPA's 1994 national CSO policy, demonstrating compliance with DEP's CSO policy involved fulfilling the requirements of a CSO control planning process. The process required MWRA to cover nine elements in developing its long-term CSO control plan, including system characterization, monitoring, and modeling; maximizing flows to the central treatment plant, evaluation of a full range of control alternatives, and cost/performance analyses. Consistent with the *demonstration approach* in EPA's policy, compliance with water quality standards to protect designated uses was confirmed through the CSO control planning process.

The demonstration approach involved detailed assessments of receiving waters and the impacts of CSO discharges and other sources of wet weather pollutants on water quality. The MWRA CSO control plan was developed using the demonstration approach because sufficient data on CSO and non-CSO sources of pollution and corresponding water quality impacts were available and were considered in determining appropriate controls on a site-specific basis. If standards or uses could not be met due to background conditions or pollution sources other than CSOs, it was shown that remaining CSO discharges would not preclude attainment of water quality standards if other sources were controlled. In general, the planned control program demonstrated that the maximum pollution reduction benefits reasonably attainable would be provided.

Water Quality Evaluations

Receiving water quality models were developed and applied to compare the performance of varying levels of CSO control to baseline conditions in the receiving waters. Tabular presentations were used to compare predicted hours of violations of the state water quality standards for swimming and boating. Hours of violation were compared for baseline conditions, baseline conditions for non-CSO pollutant sources only (stormwater, dry weather, boundary conditions), the recommended plan, and the recommended plan considering CSO sources only.

The annual percent compliance with the bacteria standard for swimming (200 colonies per 100 milliliters) was calculated to estimate the impact that the remaining untreated CSO discharges would have on water quality. For each receiving water segment, the frequency and volume of untreated CSO discharges remaining in the typical rainfall year were determined using an annual model simulation. Hours of violation associated with each untreated discharge event were conservatively assigned based on the hours of violation associated with the 1-year, 24-hour storm. This methodology was used to calculate the range of percent compliance (based on all sources and CSO-only sources) with the bacteria standard for swimming for all receiving water segments which will continue to have untreated CSO discharges following implementation of the CSO control plan.

RESULTS

Table 2 presents the hours of violation of the fecal coliform bacteria standards for swimming and boating from the 3-month, 24-hour storm for baseline conditions and for the recommended plan. For all of the receiving water segments, the hours of violation after implementation of the recommended plan due to CSO-only discharges is zero for both the swimming and the boating standards. Violations would occur in the Charles River and Alewife Brook, if dry weather sources of fecal coliform bacteria were considered. Comparing the "recommended plan CSO-only" results to the "baseline conditions non-CSO only" results, it is clear that the violations of the bacteria standards remaining after implementation of the recommended plan will be caused by the impacts of non-CSO sources.

As an example, Table 3 summarizes the information used to calculate the annual percent compliance for the Upper Inner Harbor receiving water segment. Under the recommended plan, five storms in the typical year will cause overflows to occur from at least one of the four CSO outfalls discharging to the segment. The total overflow volume for each storm was compared to the volume discharged from the outfalls in the 3-month and 1-year, 24-hour storms. Under the recommended plan, none of the outfalls discharges during the 3-month storm and only two outfalls discharge during the 1-year storm. In the typical year, the volume of CSO discharged during two of the five storms is relatively insignificant, while the volume for each of the other three storms is comparable to the 1-year, 24-hour storm.

For CSO-only discharges, the bacteria standard for swimming is not predicted to be exceeded in the Upper Inner Harbor during the 3-month, 24-hour storm, but is predicted to be exceeded for 8 hours during the 1-year, 24-hour storm. Conservatively assuming that all five storms in the typical year would cause 8 hours of violation, the total number of hours in the typical year that the swimming standard would be violated due to CSO discharges equaled 40 hours. This means that on an annual basis, the swimming standard would be met 99.5 percent of the time. Even assuming that there would be 17 hours of violation per storm based on all sources of pollutants, the compliance is still 99.0 percent.

TABLE 2. HOURS OF VIOLATION OF BACTERIA STANDARDS FOR 3-MONTH, 24-HOUR STORM (based on 96-hour simulation)

Receiving Water Segment	Hours of Violation of Swimming/Boating Standards[1] for Fecal Coliform			
	Baseline Conditions[2] (all sources)	Baseline Conditions (non-CSO only)	Recommended Plan[2] (all sources)	Recommended Plan (CSO only)
North Dorchester Bay	13 / 0	5 / 0	0 / 0	0 / 0
South Dorchester Bay	11 / 0	11 / 0	13 / 0	0 / 0
Neponset River	72 / 35	72 / 35	72 / 36	0 /0
Constitution Beach	25 / 0	24 / 0	25 / 0	0 / 0
Upper Charles River	96 / 86	96 / 86	96 / 86	0 / 0
Lower Charles River[3]	86 / 36	86 / 36	86 / 40	0 / 0
Alewife Brook	96 / 88	96 / 88	96 / 88	0 / 0
Upper Mystic River	88 / 56	88 / 56	88 / 56	0 / 0
Upper Inner Harbor	28 / 0	0 / 0	0 / 0	0 / 0
Lower Inner Harbor	14 / 0	0 / 0	0 / 0	0 / 0
Mystic/Chelsea Confluence	45 / 0	45 / 0	45 / 0	0 / 0
Reserved Channel	24 / 4	0 / 0	0 / 0	0 / 0
Fort Point Channel	45 / 31	27 / 0	28 / 0	0 / 0

(1) Swimming standard = 200 # / 100 ml; Boating standard = 1000 # / 100 ml.
(2) Includes boundary, stormwater, dry weather, and CSO sources.
(3) Includes Back Bay Fens.

The hours of violation for the 1-year, 24-hour storm and annual percent compliance for all receiving water segments is shown in Table 4. The annual percent compliance, even using the extreme case based on hours of violation caused by all sources in the 1-year, 24-hour storm, is greater than 95 percent in all receiving water segments. Using hours of violation based on CSO-only sources for the 1-year, 24-hour storm, the compliance for all segments is greater than 98 percent. The annual percent compliance calculations demonstrate compliance with DEP's requirements for B(CSO) or SB(CSO) designations for minimally-impacted receiving waters. It should be noted that the upper end of the range of percent compliance for the Charles River and Alewife Brook receiving water segments is based on model results, assuming no dry weather fecal coliform bacteria contributions. If dry weather sources were included, the bacteria standard for swimming would be violated all of the time.

TABLE 3. BASIS FOR WATER QUALITY COMPLIANCE
UPPER INNER HARBOR

Outfall	Typical Year Storm Volume (MG)					
	5/3	6/1	9/24	9/27	10/24	Total Volume

All sources: 5 storms @ 17 hours = 85 hours ➪ 99.0%

[1] Includes boundary, stormwater, dry weather, and CSO sources
[2] Stormwater component excluded

DISCUSSION

MWRA's recommended CSO control plan will maximize capture of combined sewage flow and provide treatment at its Deer Island treatment plant or CSO treatment facilities for almost all of the total annual combined sewage volume. Implementation of the recommended plan will reduce the annual volume of untreated CSO discharges by 95 percent compared to baseline conditions. Of the annual CSO volume remaining after implementation of the recommended plan, 95 percent will be treated at MWRA CSO facilities prior to being discharged. When conveyance to the Deer Island treatment plant is considered, 99.7 percent of the total annual combined sewage volume will be captured and treated.

For receiving water segments where CSOs will continue to discharge, calculating annual percent compliance using all sources and CSO-only sources based on the combined system's response to the 1-year, 24-hour storm results in a realistic range of compliance that can be expected in a typical rainfall year. Most of the CSO discharges that will remain following implementation of the recommended CSO control plan are small volume, short duration occurrences which will cause very short-term receiving water impacts. In fact, under the recommended plan, all segments will be more significantly impacted by dry weather conditions, upstream or boundary conditions, and stormwater discharges than by the remaining CSO discharges. Therefore, CSO discharges remaining after implementation of the recommended plan will not preclude attainment of water quality standards or designated uses.

TABLE 4. HOURS OF VIOLATION OF BACTERIA STANDARDS FOR 1-YEAR, 24-HOUR STORM (based on 96-hour simulation)

Receiving Water Segment	Hours of Violation of Swimming/Boating Standards(1) for Fecal Coliform				Annual Compliance % All sources vs CSO only
	Baseline Conditions(2) (all sources)	Baseline (non-CSO only)	Recommend Plan(2) (all sources)	Recommend Plan (CSO only)	
North Dorchester Bay	20 / 6	16 / 0	0 / 0	0 / 0	100(4)
South Dorchester Bay	17 / 0	17 / 0	23 / 0	0 / 0	100(4)
Neponset River	71 / 35	68 / 33	70 / 33	0 / 0	100(4)
Constitution Beach	27 / 3	27 / 1	27 / 1	0 / 0	100(4)
Upper Charles River	96 / 84	96 / 84	96 / 84	0 / 0	98.9 - 100(5)
Lower Charles River(3)	88 / 56	88 / 50	88 / 56	0 / 0	98.0 -100(5)
Alewife Brook	96 / 90	96 / 90	96 / 90	0 / 0	95.6 - 100(5)
Upper Mystic River	90 / 70	90 / 60	90 / 64	0 / 0	100(6)
Upper Inner Harbor	37 / 14	7 / 0	17 / 0	8 / 0	99.0 - 99.5
Lower Inner Harbor	28 / 0	0 / 0	8 / 0	0 / 0	99.6 - 100
Mystic/Chelsea	50 / 17	49 / 16	49 / 15	0 / 0	97.8 - 100
Reserved Channel	30 / 16	0 / 0	0 / 0	0 / 0	100(6)
Fort Point Channel	48 / 34	29 / 14	33 / 18	25 / 13	98.5 - 98.9

(1) Swimming standard = 200 # / 100 ml; Boating standard = 1000 # / 100 ml.
(2) Includes boundary, stormwater, dry weather, and CSO sources.
(3) Includes Back Bay Fens.
(4) CSO discharges are eliminated.
(5) These segments violate the bacteria standard for swimming all the time if dry weather components are included.
(6) Treated discharges only.

MWRA's CSO control plan is one of the first plans to be reviewed under the new state CSO policy. The control plan provides justification for its recommendations for (1) maintaining Class B or SB designations in the most sensitive receiving waters that support critical uses (swimming, shellfishing) by eliminating CSO discharges, (2) making Class B(CSO) and SB(CSO) designations in other receiving waters where compliance was demonstrated to be achieved at least 95 percent of the time, and (3) using a variance for the Charles River while more information on impacts from non-CSO sources can be obtained through on-going watershed planning investigations. Table 5 summarizes the water quality classifications for the 14 receiving water segments.

TABLE 5. DEP WATER QUALITY STANDARDS CLASSIFICATIONS

Receiving Water Segment	DEP WQS Designation	Major CSO Control Method(1)
North Dorchester Bay	SB	CSO Relocation
South Dorchester Bay	SB	Sewer Separation
Neponset River	B	Sewer Separation
Constitution Beach	SB	Sewer Separation
Upper Charles River	Variance	Hydraulic Relief
Lower Charles River	Variance	Sewer Separation/Upgrade Treatment
Back Bay Fens	B(CSO)	Sewer Separation
Alewife Brook	Variance(2)	Partial Sewer Separation
Upper Mystic River	Variance(3)	Upgrade Treatment
Upper Inner Harbor	SB(CSO)	Interceptor Relief/ Storage/Upgrade Treatment
Lower Inner Harbor	SB(CSO)	Interceptor Relief
Mystic/Chelsea Confluence	SB(CSO)	Hydraulic Relief/ Interceptor Relief/Upgrade Treatment
Reserved Channel	SB(CSO)	Storage/Treatment
Fort Point Channel	SB(CSO)	Storage/Treatment

(1) Plan may contain additional controls.
(2) Originally proposed as B(CSO) under MWRA's recommended plan.
(3) Originally proposed as SB(CSO) under MWRA's recommended plan.

DEP found MWRA's recommended CSO control plan to be adequate to support its administrative determinations on CSO-impacted waters and prepared a UAA based on the information MWRA provided. In making its final determinations, DEP carefully considered comments submitted on its tentative decisions for waterbody classifications that underwent public review. Based on public comments, DEP's administrative determinations included MWRA's proposed waterbody classifications except in two instances, where variances were determined to be more appropriate for the Alewife Brook and the Upper Mystic River. DEP agreed with comments stating that more information on causes of water quality violations in these waterbodies should be obtained before changes to water quality standards for CSO-impacted designations are made.

In waters that will continue to be affected by CSOs, DEP's UAA confirmed its determinations that higher levels of CSO control, beyond those recommended by MWRA, were not feasible based on current information. DEP concurred with the cost/benefit analyses in MWRA's plan that showed that the cost for higher levels of control would not yield improved attainment of designated uses. According to its CSO policy, DEP deemed that MWRA's plan demonstrated that more stringent controls would result in "substantial and widespread economic and social impact."

CONCLUSIONS

DEP responded to EPA's new national CSO policy by developing a state policy and regulatory revisions that allow flexibility in developing CSO control plans and demonstrating compliance with water quality standards. DEP's new policy and regulatory revisions reflect the agency's understanding of the realities of wet weather events and the nature of their impacts on receiving waters. The creation of the Class B (CSO) water quality standard provides the regulatory flexibility to acknowledge potential short-term excursions from Class B criteria, resulting from extreme and infrequent storm event conditions, without downgrading water quality standards.

The MWRA prepared its CSO control plan in conformance with DEP's planning requirements and demonstrated compliance with state water quality standards. DEP prepared a UAA that confirmed its approval of MWRA's recommended CSO control plan. DEP's administrative determinations on waterbody classifications included the classifications proposed in MWRA's plan, except in two instances where variances were determined to be more appropriate. EPA has concurred with DEP's UAA and administrative determinations, thereby approving the changes in state water quality standards.

For over five years, MWRA and DEP cooperated in a comprehensive CSO planning process and a regulatory revisions process, both of which involved extensive public review and comment. The joint processes have resulted in an approved CSO control plan which will meet water quality standards and protect designated uses. The coordinated effort undertaken by MWRA and DEP is a successful example of how to effectively regulate CSOs and achieve water quality improvements.

ABSTRACT

Doan Brook serves the cities of Beachwood, Cleveland, Cleveland Heights, Shaker Heights, and University Heights. The watercourse is about 9.4 miles in length and discharges into Lake Erie. The total drainage area is approximately 20 square miles and is comprised of primarily of low-density urban land-use with some institutional and commercial land-use in the lower and middle sections of the watershed. Open spaces, parks, and conservation areas are closely linked to the watercourse.

During wet-weather, a number of combined sewer overflows discharge into Doan Brook and historical water quality and flooding problems are well documented. In order to improve water quality, reduce erosion and flooding problems, and enhance the aquatic habitat of Doan Brook, the Northeast Ohio Regional Sewer District has embarked on a comprehensive watershed investigation. This paper provides a discussion of the development of the water quality monitoring program associated with this investigation and provides a progress report on the early stages of the field program.

The defensibility of the data collected throughout the course of the project represents an important consideration. Therefore, rigorous quality control and quality assurance measures are built into the monitoring program. A comprehensive Quality Assurance Project Plan, or QAPP, was developed for the water quality monitoring program. In support of this effort, appropriate data quality objectives, or DQO's, were developed through a systematic evaluation of the project goals and objectives. An overview of the QAPP development process is provided in this paper. Also, this paper describes how various computer models are going to be used to analyze alternative control options.

INTRODUCTION

Background

During wet-weather, a number of combined sewer overflows discharge into Doan Brook and contribute to water quality and flooding problems. Currently there are 16 combined sewer overflows (CSO's) that discharge into Doan Brook in wet-weather.

There are documented water quality and flooding problems along Doan Brook. Available data shows that there is bacteriological contamination during dry and wet-weather at various locations. Previous surveys of macroinvertebrate communities along Doan Brook indicate poor-quality habitat that is probably due to organic pollution sources. These conditions point to the need for a CSO facilities plan, as well as storm water control facilities, to control discharges to the Brook. The Doan Brook Watershed Study was designed to fulfill this need, as well as to further the community's goal of restoring Doan Brook and Shaker Lakes as assets to the community.

This paper focuses on a fundamental component of this watershed study: the development and implementation of an effective monitoring program. The design of the monitoring program and the development of the quality control procedures supporting the fieldwork are discussed in this paper. Unfortunately, at the time of publication, only limited amount of water quality information from the ongoing

1998 program was available. It is anticipated that preliminary field measurements for dry and wet-weather will be available for the conference presentation of this paper.

Since this investigation was partly funded by an EPA grant, a comprehensive Quality Assurance Project Plan, or QAPP, was required in support of the monitoring program. The relationship between the QAPP, and other quality control documents such as Standard Operating Procedures, Field Monitoring and Sampling Plan, and Data Quality Objectives are outlined in this paper. As a result of the rigorous quality control and quality assurance procedures built into the monitoring program, the data collection efforts will yield high-quality and defensible information that will ultimately provide a solid framework for the final watershed and facilities plans.

The monitoring program was organized into four major categories:

- Flow Monitoring: A flow monitoring program was required for major sewers, sources, and streams.
- Source Monitoring: An assessment of source pollutant loads from combined sewer overflows, storm sewers, and mixed sewer systems was necessary.
- Stream Monitoring: A sediment and water quality program was necessary to assess stream conditions in wet and dry weather.
- Lake Monitoring: A sediment and water quality program was necessary to assess the characteristics of the Shaker Lakes and other impoundment:

Specifically, the monitoring program was designed to support:

- The determination of existing water quality in Doan Brook.
- Comparisons of the water quality of Doan Brook with appropriate water quality regulations.
- The development of stream water-quality and hydraulic models to be used for facilities and watershed planning.
- The estimation of seasonal and annual pollutant loadings for input into a Lake Erie water quality model.
- The definition of water quality and hydraulic relationships between Doan Brook, the Shaker Lakes and Lake Erie.

Study Area

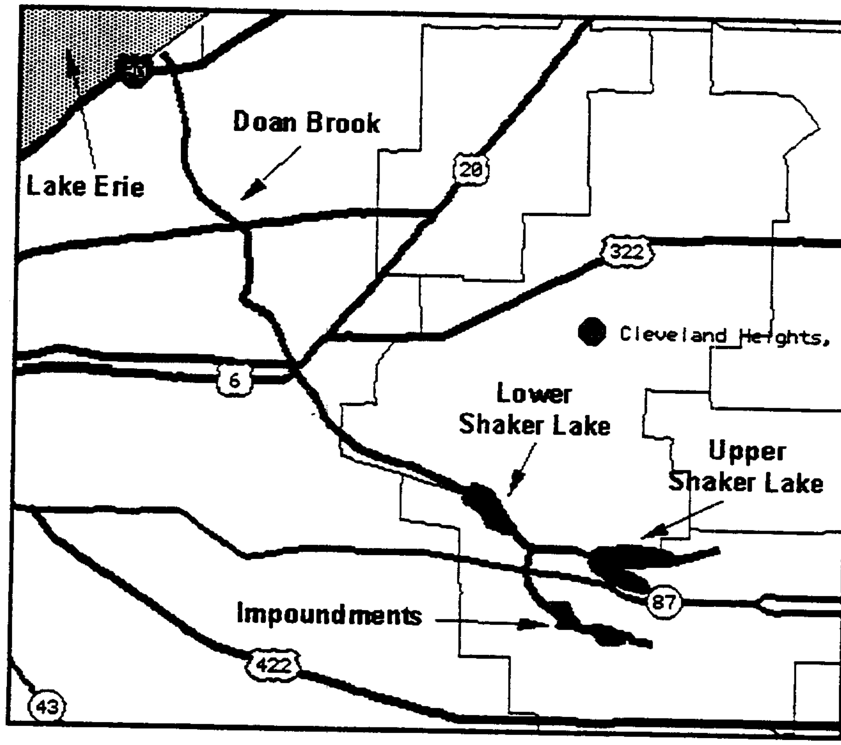
Doan Brook flows through the cities of Beachwood, Cleveland, Cleveland Heights and Shaker Heights. The watercourse is about 9.4 miles in length and discharges into Lake Erie. The total drainage area is approximately 20 square miles and is comprised of primarily low-density urban, institutional and commercial land-use. Open spaces, parks, and conservation areas are integral components of the watercourse. An illustration of the study area is provided in Figure 1.

Overview

This paper is organized into three major sections:

1. *Quality Assurance / Quality Control Planning*: This section provides an overview of the QA/QC planning process and a brief description of the field-monitoring program.
2. *Preliminary Field Measurements*: Initial field measurements of water quality of Doan Brook during dry and wet-weather is presented in this section. Since the field program has recently been initiated, only a limited amount of field information is available.
3. *Summary*: A brief summary of the QA/QC process and preliminary field measurements.

Figure 1. Doan Brook Study Area



QUALITY ASSURANCE / QUALITY CONTROL PLANNING

Since this Doan Brook Watershed Study is funded, in part, by an EPA grant, the defensibility of the data collected throughout the course of the project represents an important consideration. Therefore, rigorous quality control and quality assurance measures are built into the monitoring program. There are four major categories to the quality assurance / quality control process:

1. Data Quality Objectives, or DQO's,
2. Quality Assurance Project Plan, or QAPP.
3. Standard Operating Procedures, or SOP's,
4. Field Monitoring Plan, or FSP, and

A brief overview of the DQO, QAPP, and DQO documents is provided below. The FMP provides detailed instructions for field personnel in terms of where and when to sample or obtain field measurements.

Data Quality Objectives (DQO's)

DQO's were established according to EPA guidelines (EPA, 1994). In general, data quality objectives are designed to match the desired quality of information collected with the intended application of the data. In this case, the data collected through the course of the study will serve as a basis for:

- A datum of existing water quality conditions (to serve as a benchmark for future comparisons) and to allow for assessment of compliance with respect to Ohio water quality objectives.
- Calibration and verification of all hydraulic and water quality models.
- Development of facilities plan alternatives and preferred strategies.

- Development of a Doan Brook Watershed Plan.
- Integration with other water quality investigations in the Cleveland area.

Clearly the scope of the intended application is broad and as a consequence, the quality of the data collected must be relatively high. The systematic approach to determining appropriate DQO's involved:

1. Identification of all significant issues to be resolved in the study. For the Doan Brook Watershed Study issues focused on current status, pollution sources, receiving water impacts, watercourse flooding, erosion, control options and facilities planning.
2. Identification of what information is required to address each issue.
3. Identification of what parameters must be measured, where and when.
4. The development of a suitable approach to data collection that fits within various constraints of the project (time, budget, requirements of larger Easterly project).

As an illustrative example of the process, a summary of the issues surrounding current status and the information required is provided in Table 2. Similar analyses were completed for other relevant topics such as pollution sources, receiving water impacts, and watercourse flooding.

Table 2. Issues and Information Required for Evaluation Of Current Status

ISSUE	INFORMATION REQUIRED
• Is existing water quality in compliance with current regulatory standards?	• Measurements of water quality parameters for which there is a regulatory standard. Measurements needed at various locations along the system in order to gauge the impact of various inputs to the system. • Measurements needed in both dry and wet weather to account for temporal variability.
• How does existing sediment compare with available guidelines or scientific thresholds for protection of aquatic habitat and aquatic life?	• Measurements of sediment quality for parameters for which there is a regulatory standard or scientifically accepted standard or guideline. • Measurements needed at various locations along the system at which sediment deposition occurs. Multiple locations needed within the Shaker Lakes to account for spatial variability in sediment deposition patterns.
• What is the current biological state and quality (i.e. diversity and health of aquatic species) in the system? • What factors other than water and sediment quality may be affecting biological status?	• Sampling and inventory of macroinvertebrate populations at locations along the system, at same locations at which sediment and water quality are being sampled, to allow biological data to be correlated with sediment and water quality data. • Data are to be adequate to allow computation of accepted indices of aquatic habitat diversity, health and quality.
• What is the current trophic status of the Shaker Lakes and what inputs and processes are responsible for present conditions? • What are the effects of existing nutrient loadings on the lakes? • What is the rate of sediment accumulation within the lakes and what are the probable sources of sediment inputs?	• Measurements of biomass productivity, nutrient levels, water clarity, density stratification and water quality at various locations within each lake, to account for potential spatial variability. • Assessment of mixing conditions, using direct measurements and/or hydrodynamic computer modeling. • Measurement of lake bathymetry to provide information on lake depth, geometry and volume, and allow assessment of changes that have taken place over time due to sedimentation or other processes.

Table 3. Parameters of interest and General Approach to Data Collection for Surface Water Quality Of Current Status

PARAMETER	REQUIRED APPROACH TO DATA COLLECTION
Fecal coliform and *E. coli*	• A wet-weather sampling program is required to address stream water quality during and immediately following rainfall. Both spring frontal rainfall events and summer convective storms should be addressed. • A dry-weather sampling program is required to address water quality during extended dry-weather periods. • Regular sampling (regularly spaced through time) is required to address the expected seasonal variability in water quality along the watercourse, and expected variability in water column conditions within the Shaker Lakes.
Metals (Total Recoverable and Dissolved): Cd, Cu, Cr, Fe, Pb, Zn	
TSS, conductivity, hardness Dissolved oxygen and CBOD Nutrients (TP, SRP, TKN) Temperature, pH, Ammonia	

Standard Operating Procedures (SOP's)

SOP's were developed for every sampling or measurement task to be undertaken in the monitoring program. The SOP's were developed according to EPA guidelines and are presently under final review by EPA staff. Every task, from sewer flow monitoring to field instrument calibration, is provided with a SOP. In the case of sample collection, the individual SOP's provide detailed instructions regarding sample tracking and chain of custody. Furthermore, SOP's include procedures for data management and control, as well as detailed field protocols. A list of SOP's prepared for this investigation is presented in Table 1.

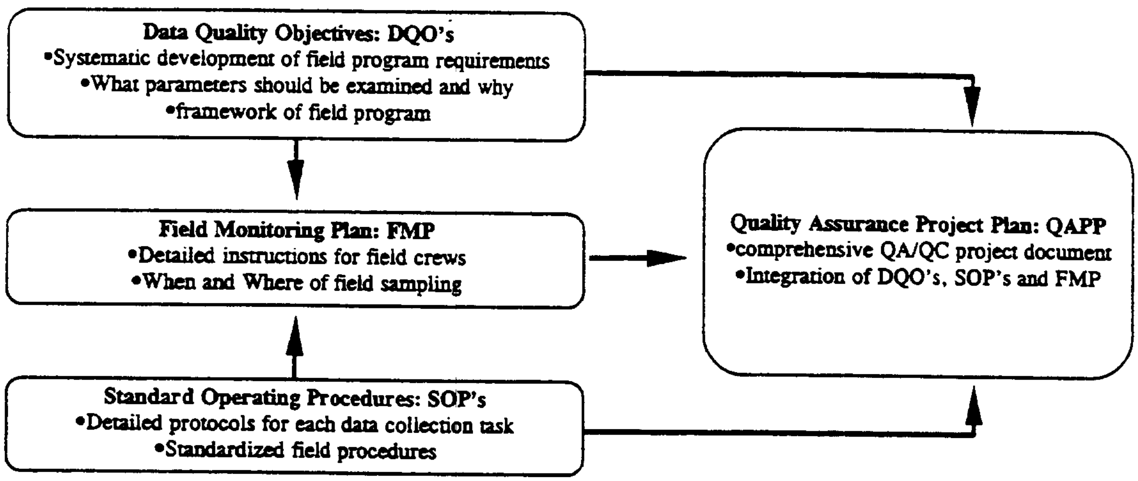
Table 1. Standard Operation Procedures Developed for The Doan Brook Watershed Study

SOP Number	SOP Title
1	Sample Bottle Preparation
2	Sewer Flow Monitoring
3	Stream Flow Monitoring and Gauging
4	Grab Sample Protocol
5	Automatic Sampling Protocol
6	Sediment Sampling Protocol
7	Macroinvertebrate Sampling Protocol
8	Quantitative Habitat Suitability Index Sampling Protocol
9	Lake Water Quality Monitoring
10	Aquatic Macrophyte Survey and Identification
11	Macroinvertebrate Identification and Enumeration
12	Field Instrument Calibration Methods
13	Analytical Procedures
14	Sediment Grain Size Analysis

Quality Assurance Project Plan (QAPP)

The QAPP document sets out detailed plan and procedures for meeting the data requirements defined in the DQO's. The QAPP incorporates a set of SOP's that provide field personnel with detailed instructions on individual sampling and monitoring tasks. THE FSP sets out the precise details of when and where sampling and monitoring are to Take place, including specific requirements regarding QA/QC (e.g. submission of duplicate samples, bottle blanks and field blanks). The linkages of the various documents are illustrated in Figure 2. The QAPP builds on the DQO document by defining detection limits, accuracy goals, and data volume targets for each parameter of interest. Furthermore, the QAPP provides an indication of the number of measurement replicates and the desired measurement precision.

Figure 2. Project QA/QC Documents

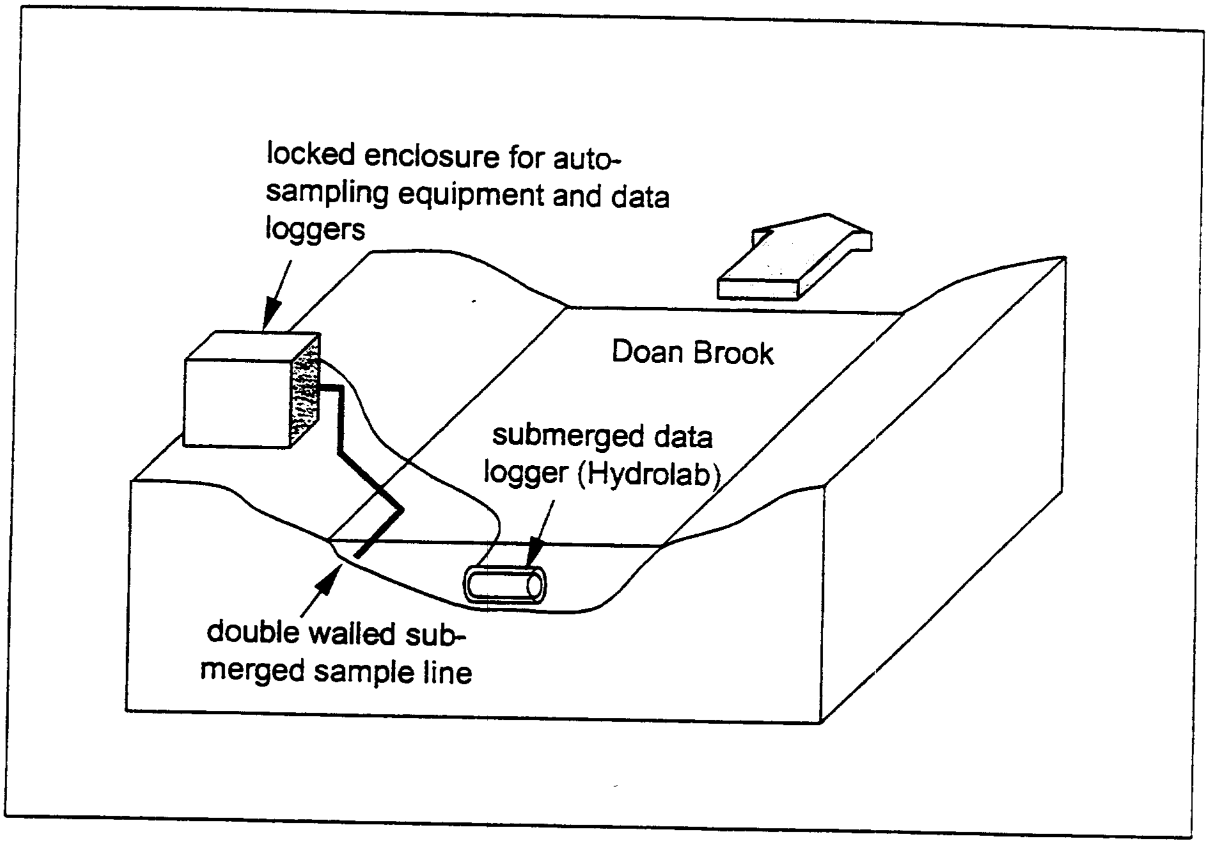


PRELIMINARY RESULTS OF THE FIELD PROGRAM

The field program includes monitoring of sources, Doan Brook, and associated lakes and impoundments. At the time this paper was prepared, no water quality or sediment quality analysis results were available. However, a limited amount of water quality information from in-stream data-loggers (Hydrolab instrumentation) was available. A typical data logger installation is illustrated in Figure 3. This particular monitoring site is near the confluence of the Doan Brook and Lake Erie and is referred as Site 1. Field observations indicate that Site 1 is immediately upstream of normal backwater conditions and water velocity at Site 1 is normally low.

Example monitoring data from Site 1 is provided in Figures 4 and 5. A continuous plot of dissolved oxygen (expressed as an estimate of percent saturation), and temperature is provided in Figure 4, while Figure 5 provides a continuous plot of conductivity and temperature. The dissolved oxygen measurements are preliminary unverified data and the final review has not been completed. Both Figures 4 and 5 cover a monitoring period starting at 16:00 on April 1, 1998 and ending at 15:00 on April 10, 1998.

Approximately 1.5 inches of rain fell on the study area on April 8 and 9, 1998. The impact of this rainfall, in terms of dissolved oxygen and conductivity changes is evident in the plots. As Figure 4 illustrates, the regular diurnal dissolved oxygen cycle is interrupted following the rainfall event. A prolonged period of relatively low dissolved oxygen occurs during and immediately following the rainfall event. In dry-weather, for example form April 1, 1998 through April 6, 1998, the dissolved oxygen rises to super-saturated conditions during the mid-afternoon and drops to below saturation during the night hours. This diurnal cycle is probably due to aquatic plant and algae photosynthesis and respiration. Similar diurnal patterns have been observed in other, low-velocity, nutrient enriched, river systems (Hulley *et al*, 1996).



The relatively low velocity during and after the rainfall event is presumably a result of wet-weather pollutant loads. However, this conclusion has not been confirmed with direct measurements of biochemical oxygen demand.

The conductivity measurements at Site 1 indicate that during dry-weather there is no significant diurnal variability, however, during and following the rainfall, the conductivity drops from about 1700 uS/cm to less than 1000 uS/cm. Presumably the reduction is a result of dilution since the conductivity of CSO inflow and overland runoff is less than ambient in-stream conductivity.

The results presented in Figures 4 and 5 are preliminary and have not been subject to the required quality control review process. Although the absolute values of water quality parameters, such as dissolved oxygen and conductivity, may be adjusted in the final data review, the dry and wet-weather trends illustrated in the Figures provide an indication of wet-weather impacts.

WET WEATHER POLLUTION EFFECTS ON WATER QUALITY IN CRUM CREEK

ABSTRACT

The Crum Creek, running through suburbs west of Philadelphia, shows impacts of wet weather pollution on the health of the stream. The creek is used for water supply and recreation, and it supports wildlife. Significant oxygen deficits have been measured in the creek by volunteer monitors. This paper reports results from an intensive monitoring project on a section of the creek near Swarthmore College to further characterize this problem, and to investigate its causes. Factors found to influence oxygen deficit include elevated BOD in the water column following rainfall events and sediment oxygen demand exerted in pools along the creek. The elevated BOD levels during rain may also be caused by landfill leachate, animal waste, and untreated human waste from leaking sewers. Transient variations in conductivity and turbidity were measured by an electronic sonde during rainfall events. These measurements suggest the existence of a two-part process during the first three hours of runoff: a dissolved solids flush followed by a suspended solids flush.

KEYWORDS

Dissolved oxygen, oxygen deficit, BOD, conductivity, turbidity, runoff, urban stream

INTRODUCTION

The focus of this paper is Crum Creek, a suburban stream west of Philadelphia, in Delaware County, Pennsylvania. The creek is approximately 100 km (~62 miles) long with a drainage basin of 99 km^2 and an average flow of 0.71 m^3/s (DuPolt, 1983). Its headwaters are formed in part by runoff from the town of Paoli, Pennsylvania, and it discharges into the Delaware Estuary in the City of Chester, Pennsylvania. It has one major reservoir, the Geist (Springton) Reservoir, which is operated by the Philadelphia Suburban Water Company (PSWCo). This investor owned utility company supplies drinking water to the northern and western suburbs of Philadelphia. There is a small intake pond downstream from the reservoir at PSWCo's treatment plant and pumping station. All of our monitoring activities on the creek have been carried out within a 2.4 km (1.5 mile) stretch from a point just below the treatment plant to a point just below the Swarthmore College campus.

Just downstream from the treatment plant intake, the creek flows through a county park (Smedley Park) which is used extensively for recreation. Also, the creek is fed by small tributaries that drain a country club, golf course, and the parking lots of a large shopping mall and another major shopping center containing a popular multi-theater cinema complex. A closed landfill in Springfield Township, has a permitted leachate discharge into another tributary which joins the creek in the park. A paper mill was operated during the first half of this century on land just above Smedley Park in an oxbow of the creek. Discharges from the settling ponds of this mill probably contributed significantly in the past to organic sediments, which may still add to the sediment oxygen demand.

Interstate 476, which connects Interstate 95 to the Pennsylvania Turnpike was constructed above the creek bed during 1989 - 1990. The highway crosses over the creek in several places. The construction caused significant sediment runoff into the creek, and now there is potential for runoff carrying gasoline, oil, and, during icy weather, road salt into the creek from many storm sewers that discharge into the creek. The highway serves commuters in the Philadelphia metropolitan area, and a great deal of interstate travel, including large trucks. It frequently experiences lengthy back-ups with traffic coming to a complete stop during peak hours.

Significant oxygen deficits at various points on the stream have been observed during the past seven years through the water quality monitoring activities of a volunteer monitoring organization, the Crum-Ridley-Chester Monitors and an affiliated student group at Swarthmore College called the Crum Creek Monitoring Project (McGarity, 1997). Our program of intensive monitoring on the creek during the summer, fall, and early winter of 1997 has helped to characterize the patterns of and effects on dissolved oxygen levels in the creek, including those caused by wet weather pollution.

METHODOLOGY

During the summer of 1997, data were taken daily at three sites that we call A, B, & C on Crum Creek where it passes through the Swarthmore College campus. The readings included DO (dissolved oxygen), temperature, percent oxygen saturation, BOD (biochemical oxygen demand), water height over a stationary sewer pipe (for flow measurements), and, occasionally, E.coli. During the fall of 1997, weekly measurements of the same parameters were taken at the A, B, & C sites as well as three sites at the landfill leachate discharge in Smedley Park. The park sites are: (U) upstream from the leachate discharge, (L) in a small tributary containing the leachate, and (D) downstream of the leachate discharge. An electronic sonde collected data at site B on oxygen concentrations, temperature, conductivity, and turbidity at 15 minute intervals for thirty five days during December, 1997 and January, 1998. On 12 December, 1997, a "creek walk" was taken to obtain a one-day profile of dissolved oxygen at many additional points along the entire section of the creek involved in our monitoring studies.

Specific Tests

- Dissolved oxygen measurements were taken using a variety of methods, in order to ensure correct calibration of each method. A DO meter (Yellow Springs Instruments model 55) was used regularly, and checked with periodical Winkler titration method DO tests.
- Biochemical oxygen demand tests were performed by filling a 300 mL BOD bottle with sample water and incubating at 20°C for 5 days.
- E.Coli measurements were obtained by collecting samples with Whirl-Pak bags, diluting the samples properly to multiple dilutions, filtering the dilutions and incubating them at 35 degrees Celsius for 24 hours in "m-coli blue" broth from Hach Company.
- The sonde is a Yellow Springs Instruments 6000 multiprobe instrument which took automatic readings of dissolved oxygen, temperature, conductivity, and turbidity. The data were stored in the sonde's internal memory. The sonde was deployed at approximately the midpoint of the water column, at a depth of about 0.46 m (1.5 feet) and about 0.46 m above the stream bottom.

RESULTS

Dry Weather Dissolved Oxygen Profiles

During normal, dry weather flow conditions, oxygen deficits occur downstream from slow moving pools, which occur frequently in the creek. The drop in dissolved oxygen may also be caused by sediment oxygen demand present mainly in the pools. Riffle areas and algae help to replenish oxygen in the water. Figure 1 and Table 1 show data from sites A, B, and C which demonstrate this "pool sag" effect. Site A is above a long pool, site B is below this pool and above a riffle, and site C is below the riffle. Data from all of our readings of DO, percent DO saturation, and temperature were combined to produce the statistical analysis shown in Figure 1. The box plots show the average deficits (the line inside the box), and the ranges of variation in the deficits. In Table 1, which shows the average changes in deficit across the pool and the riffle, data from the summer and fall are separated to show seasonal differences.

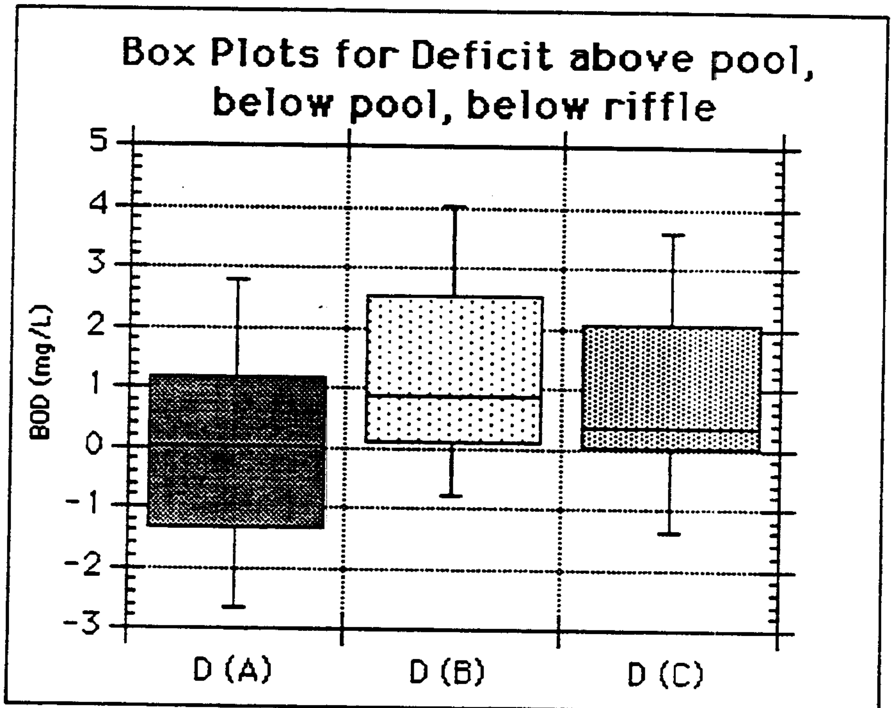

Figure 1. Deficit (D) above pool (A), below pool (B), and below riffle (C), for all measurements

Table 1. Differences in deficit across the pool and riffle	Average increase in deficit through pool (mg/L)	Average decrease in deficit through riffle (mg/L)
Both seasons	1.33	0.50
Summer	1.40	0.46
Fall	1.04	0.61

The "Creek Walk" graph (Figure 2) shows a profile of the DO, deficit, and temperature of the Crum Creek over a 1.5 mile stretch, on one day in mid-December, 1997. Again, the pools contribute to an increase in deficit and the riffles reaerate the water. The areas at sites 33-35, 24U-26, and 1-5 are clear examples of deficit increase along pools. There is also a trend of rising deficit between sites 13 and 23, interrupted only by the confluence with an oxygen-rich tributary named Whisky Run. The areas especially showing riffle effects are 23-24U, and 5-13. The presence of algae, observed in the last riffle, is likely contributing to the supersaturation found at the end of that riffle.

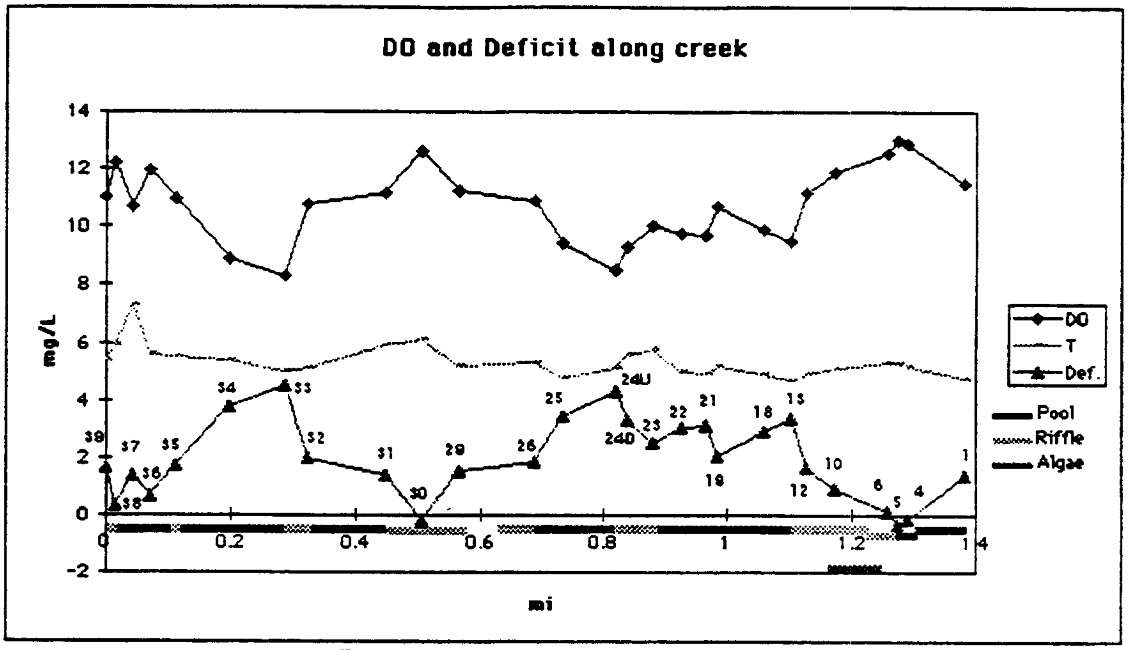

Figure 2. Creek Walk Profile (12/12/97)

Wet Weather Effects on BOD

Measurements of BOD indicate a strong correlation between BOD and rainfall. During dry weather, the ultimate BOD (calculated from the 5-day BOD measurements) at all six sites (A, B, C, U, L, and D) are in the range from 2 to 4 mg/L. However, on days with significant rainfall, the BOD increased. Figure 3 shows ultimate BOD (in mg/L) on the vertical axis with daily rainfall amounts on the horizontal axis. Rainfall was recorded at the Philadelphia International Airport, which is only about ten miles away from the monitored sites (National Oceanic and Atmospheric Administration, 1998).

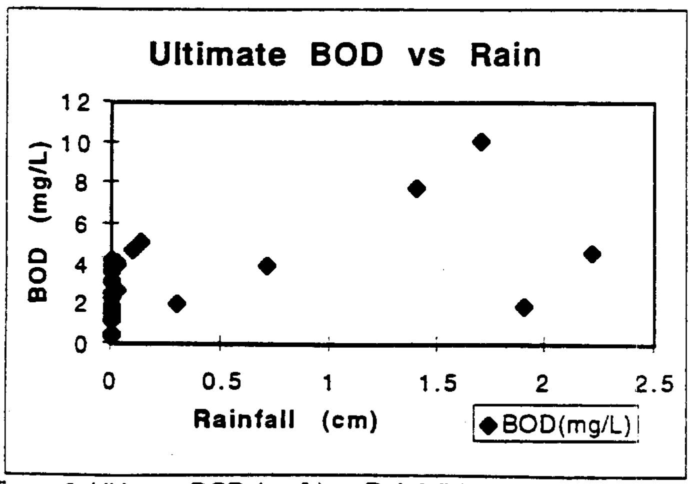

Figure 3. Ultimate BOD (mg/L) vs Rainfall (daily values at airport)
for both Summer and Fall

A possible source of BOD is leachate from the closed landfill, so the leachate was monitored for both BOD and DO. It turned out that the water flowing from the landfill into the creek had significantly higher dissolved oxygen concentrations than the rest of the creek, and during dry weather, the BOD in the leachate was lower than the BOD in the creek upstream of the discharge. However, after a two-day period of rain, the BOD in the landfill leachate was recorded as significantly higher than that in the creek. So, the landfill leachate is probably one source of the wet weather BOD increase in the creek.

In order to further determine the source of BOD, the relationship between BOD and E.Coli is analyzed. Since E.Coli is an indicator of human and animal waste, increases in BOD occurring with increases of E.Coli would show that some of the BOD may be coming from such waste. E.Coli does increase during rain, as seen in Figures 4 and 5 which show how the E. Coli count increases with streamflow. If the one extremely high E. Coli count (more than 10,000 colonies per 100 mL) is removed, an almost linear increase with flow rate is observed.

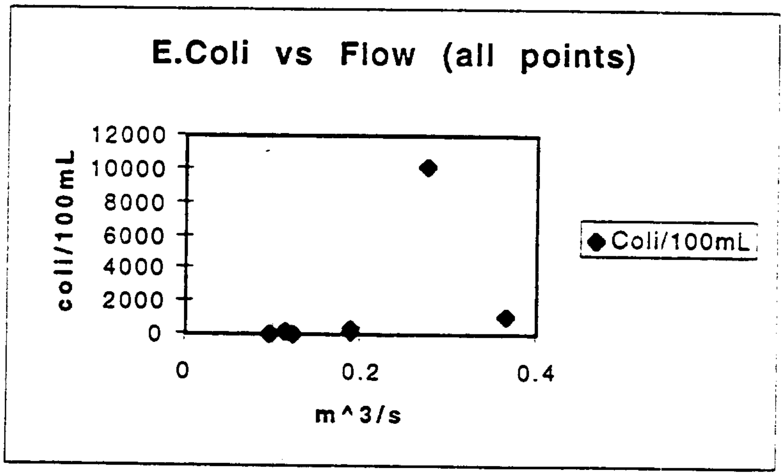

Figure 4. E.Coli count vs Creek Flow Rate (m^3/s)

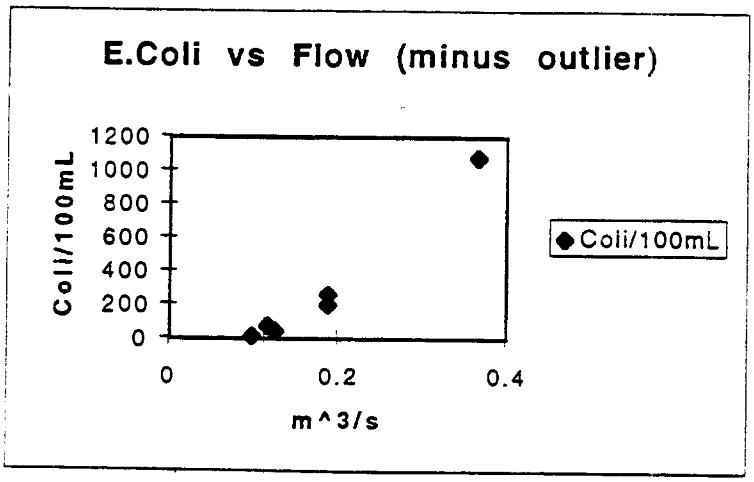

Figure 5. E.Coli count vs Creek Flow Rate (m^3/s) (without outlier)

Figure 6 plots BOD versus the E. Coli count. There is a slight increase in BOD with increasing E. Coli, which suggests that runoff of animal waste or, perhaps, leaking sewer lines may be partially responsible for increased BOD during wet weather. The sanitary sewer system in the area makes much use of the creek valleys as corridors for sewer pipes, and these sewer lines are known to have problems with infiltration during wet weather. Thus there is also potential for "exfiltration" from the overloaded pipes at man holes and at breaks near the top of the sewer lines that do not leak unless the line is nearly full.

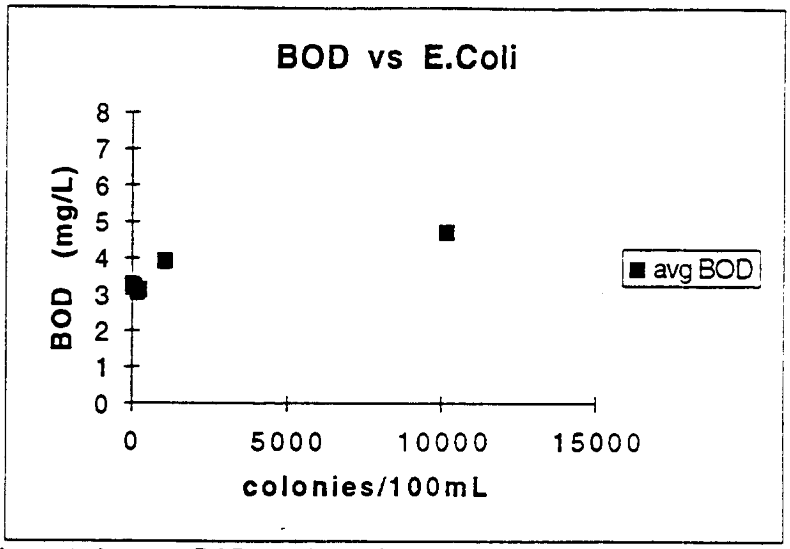

Figure 6. Average BOD (mg/L) vs E.Coli readings taken at the ABC sites

Continuous Monitoring by Electronic Sonde

During most of December, 1997 and the first week of January, 1998, for a period of 35 days, the Crum Creek at site B was monitored continuously using an electronic sonde which recorded data every 15 minutes around the clock.

The reason for deploying the sonde was to catch transient variations in the water quality parameters caused by storm runoff events. Figure 7 shows the daily rainfall totals at the airport for the month of December, 1997. During the rainfall events of December 23, December 25, and December 30, the conductivity exhibited a very interesting transient behavior, first spiking upwards for about one hour, then plunging downwards for the next hour to far below the original value. Figure 8 shows a close-up of the specific conductivity and turbidity on December 23. The specific conductivity is about 580 µS/cm before the runoff reaches the stream, then it rises to 765 µS/cm during the first hour of runoff followed by a drop to 310 µS/cm. The specific conductivity then returns rapidly to 450 µS/cm and begins to decay exponentially until the next rainfall event on December 25, which causes another, less dramatic transient swing.

Abrupt increases in turbidity correspond exactly with the conductivity transients. Close examination of the turbidity data reveals that the turbidity begins increasing at the same time that the conductivity transient begins its upward swing. However, the peak turbidity readings occur when the conductivity reaches the low point of the transient. These results suggest the occurrence of a "two flush" phenomenon in the runoff. The first flush contains high dissolved solids which cause the conductivity to increase. The second flush contains high suspended solids which cause the turbidity to peak and the conductivity to dip.

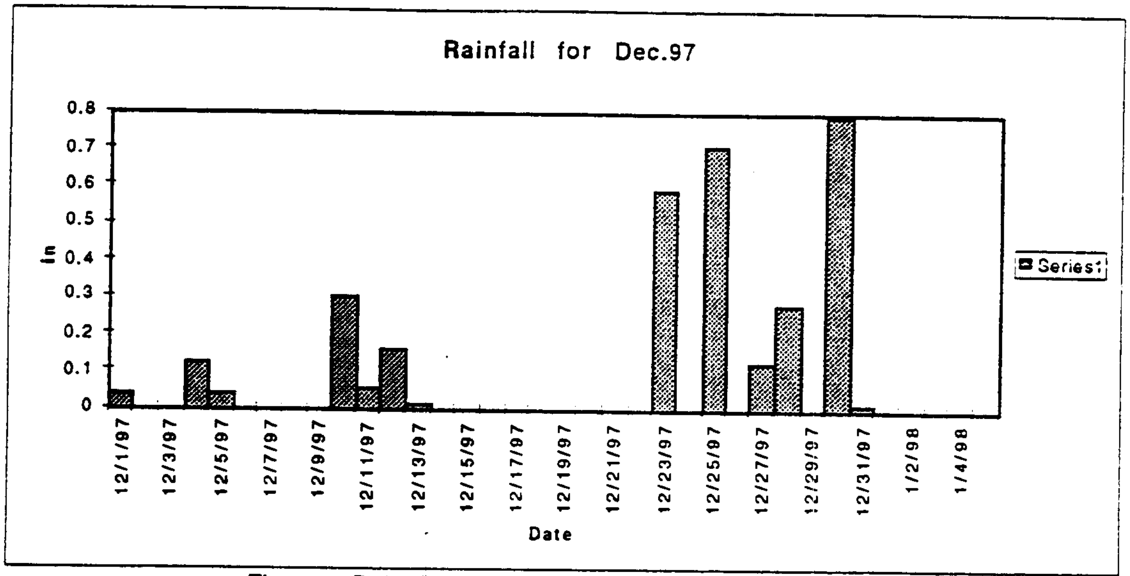

Figure 7. Daily Rainfall Totals in cm. for December, 1997

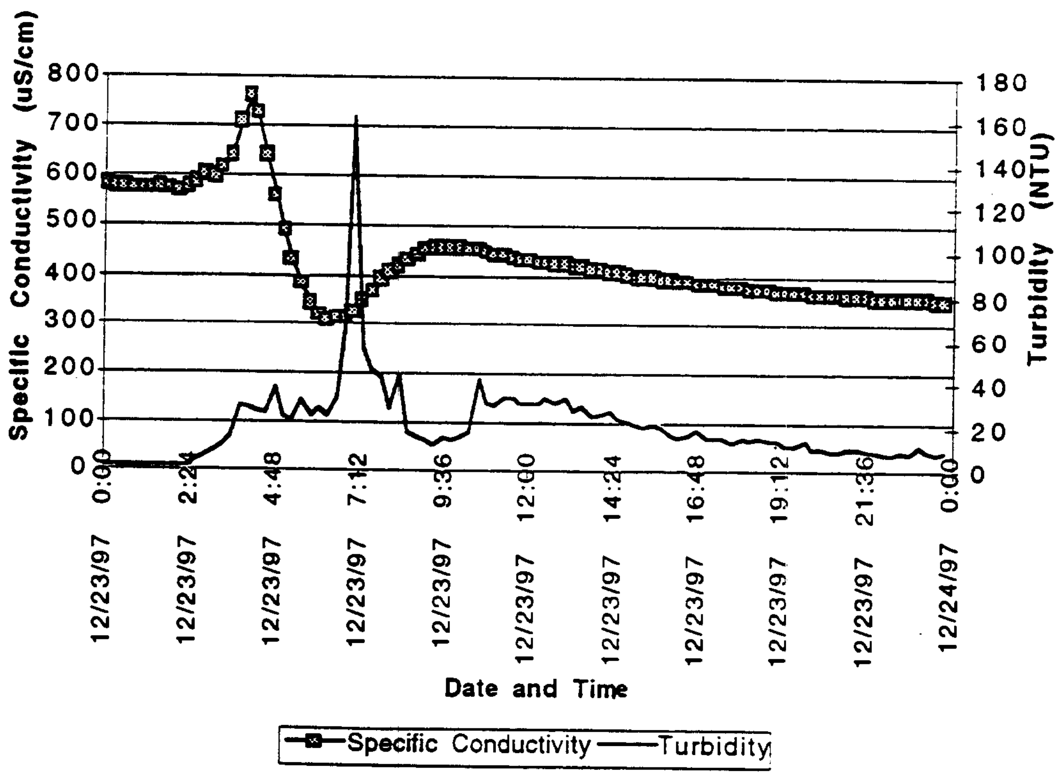

Figure 8. Conductivity and Turbidity Transients for the December 23 Rainfall

The dissolved oxygen data taken with the sonde at site B are displayed in Figure 9. These results show two interesting features, the diurnal cycling of DO, and the effects of rainfall on oxygen concentration in the creek. The diurnal cycling, driving the DO concentration into the supersaturated zone, is probably caused by aquatic plant life and algae upstream from site B, since the peaks occur late in the afternoon or after dark. It is interesting to note that the DO concentration peaks and dips occur at earlier times as the month goes by, suggesting an effect of shorter daylight periods as the winter solstice approaches. The concentration hits its low point between 7:30 and 8:30 AM in the early part of the month and as early as 4 AM, later in the month.

The concentration peaks between 7 and 10 PM in early December, and later in the month, between 3 and 6 PM.

The most obvious effect of rain on oxygen levels is that during periods of heavy rain the cyclical pattern of the DO and deficit is interrupted. As seen in Figure 9, the diurnal cycles are interrupted during rainy days, particularly those with rainfall over half an inch. On 12/13, 12/15, and especially 12/30, the concentration flattened out for several hours.

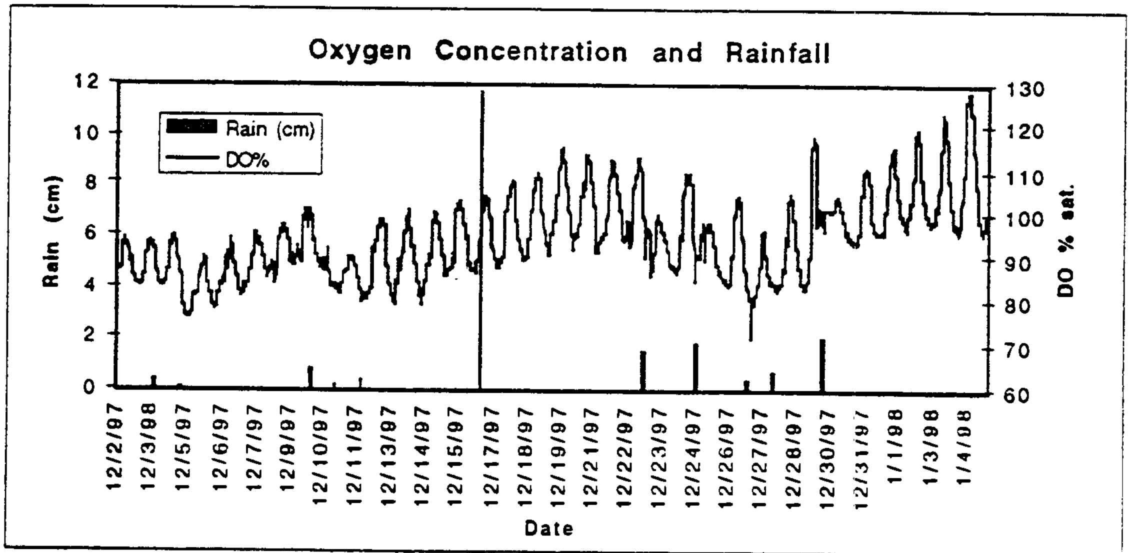

Figure 9. Oxygen Concentration and Rainfall for 12/2/97 to 1/5/98

CONCLUSION

The apparent effect of pools on oxygen deficit in the Crum Creek may be due to several factors. It is clear that in the pools the water is deep and moving slowly enough to allow for the BOD to be exerted, and the rate of oxygen consumption outweighs the rate of reaeration. Then in the riffles, the reaeration rate outweighs the rate of consumption causing the deficit to decrease. Although the BOD in the water column was fairly consistent throughout the sites, sediment oxygen demand may contribute to increased deficit in pools. The creek bottom in pools along the reach examined in the creek walk is nearly always softer, muddier, and covered with more organic material than the shallow, rocky bottom of riffles.

Some indications of the sources of the water column BOD are revealed by this study. Our results suggest that human or animal waste and landfill leachate are partial contributors to the increase in BOD during wet weather. The runoff is probably carrying significant BOD from nearby mall parking lots and Interstate 476, organic materials on the creek banks, and from lawns in neighborhoods through which the creek runs.

While positive and excessive E.Coli counts indicate the presence of animal or human waste in the creek, it is not possible to determine exactly the source of these bacteria from the tests we conducted. There are many Canadian geese living year-round in Smedley park, and their waste may be carried in the runoff from the park during a rain. The possibility that sanitary sewer lines are leaking during wet weather will be investigated further. This type of leak is a common occurrence in other creeks in the area, especially in Little Crum Creeks, which drains most of Swarthmore Borough east of Crum Creek.

QUESTIONS AND ANSWERS FOR SHORT TERM FLOW MONITORING PROGRAMS

Alan J. Hollenbeck, P.E.
RJN Group, Inc.
200 W. Front St., Wheaton, Illinois 60187

Abstract
Improvements in flow meter technology have continued to increase the accuracy of depth, velocity, total flow and surcharge level measurements in sanitary and combined sewer systems. Short-term flow monitoring programs, often conducted in conjunction with I/I, SSES, and CSO studies, are normally faced with the following three questions:

- When is the ideal time to install short-term monitors?
- How long after installation can adequate dry/wet weather data be gathered?
- What data is needed?

These questions and the response to each can have significant impact on the cost and effectiveness of short-term flow monitoring programs. Based on the flow meter interval (distance between short-term monitors) and the duration of the program, the cost of flow monitoring can approach or exceed the cost of physical inspection activities such as smoke testing and manhole inspection.

Short-term flow monitoring data is often utilized for prioritizing basins for I/I source detection activities, balancing flow monitoring data with quantified source data, and inputs for various hydraulic models. Storms which occur during a short-term monitoring program can normally be categorized as follows:

- System response without surcharge.
- System response with surcharge but no overflows (containment).
- System response with surcharge and overflows (non-containment).

The first category of storm (normally greater than 0.15 inches per hour) can provide data on both wet weather peak flow and volume. The second category can provide data on volume but limited useable peak flow data. The third category normally cannot provide useful data on either. Flow monitoring programs should be established (wherever possible) to maximize the likelihood of monitoring as many of the previous conditions as possible within the shortest possible time period.

Keywords – Flow Monitoring, Rainfall, I/I, SSES

Introduction

The implementation of cost-effective successful short-term flow monitoring programs is an integral part of most urban wet weather pollution reduction planning level studies. These short-term flow monitoring programs are a key component of planning level studies for urban wet weather projects for both combined and separate sanitary sewer systems.

Implementation of cost-effective, successful, short-term flow monitoring programs requires an analysis of three key questions:

- When is the ideal time to install monitors?
- How long is required to gather adequate data?
- What data is needed?

The answers to these general questions will vary from region to region and project to project.

Short Term Flow Monitoring Questions - When, How Long, and What Data?

Improvements in flow meter technology have continued to increase the accuracy of depth, velocity, total flow and surcharge level measurements in combined and sanitary sewer systems. Short-term flow monitoring programs, often conducted in conjunction with I/I, SSES and CSO studies, are normally faced with the following questions:

- When is the ideal time to install short-term monitors?
- How soon after installation can adequate dry/wet weather data be gathered?
- What specific data is normally required?

These questions and the response to each can have significant impact on the cost and sucess of short-term flow monitoring programs. Based on the flow meter interval (distance between short-term monitors) and the duration of the program, the cost of flow monitoring can approach or exceed the cost of the balance of the planning level study such as physical inspection activities like smoke testing and manhole inspection.

<u>Short Term Flow Monitoring Answers</u> - Determining Collection System Response to Storm Events

Answers to the key questions are the first step in implementing a cost-effective and successful short-term flow monitoring program. Although sometimes these answers can be generalized by climatic region, there are often project-specific issues that can influence the final short-term flow monitoring program design.

<u>Timing of Initiation of Short term Monitoring</u> – By definition, short-term monitoring programs are designed to gather necessary data in a relatively short period of time. This process therefore involves compromises that result in the collection of less data than "long-term" monitoring programs that cover more than one climatic season.

The challenge in short-term monitoring programs is often to select the best starting date for the flow monitoring. In most cases, the sanitary or combined sewer system is being studied because it cannot convey flow after intense storm events without surcharging and overflows. As shown in Figure 1 and Figure 2 the response of the sewer system to storm events is also influenced by:

- Antecedent soil moisture conditions
- Ground water levels
- Frozen ground conditions.

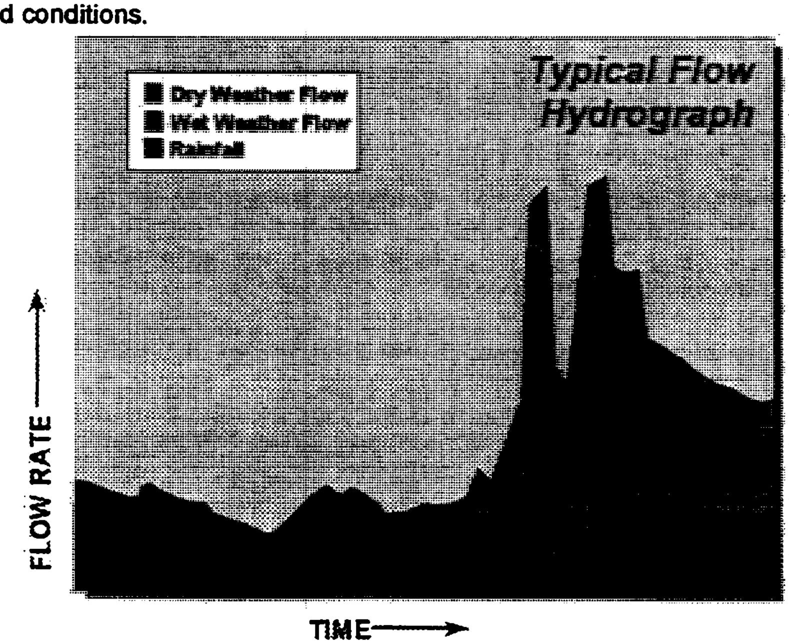

Figure 1

R0025242

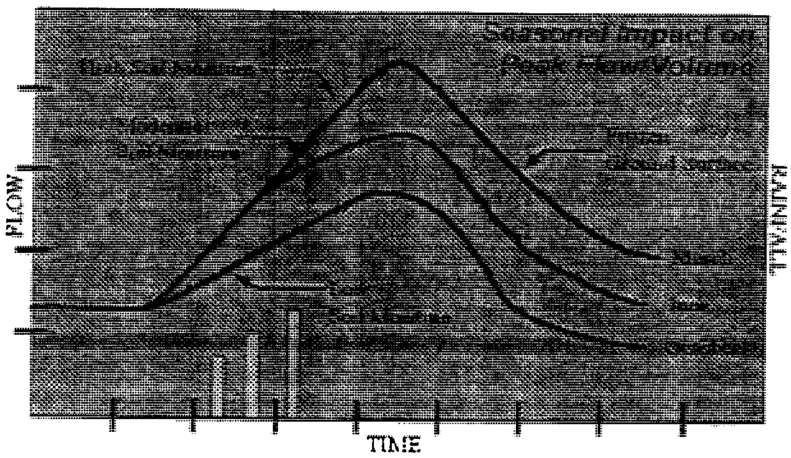

Figure 2

Timing the initiation of a short-term monitoring program is a function of both historical climatic conditions and current year conditions. Timing the programs to start a few weeks before and end a few weeks after seasonal storms provides an opportunity to collect "dry weather" data during the short-term flow monitoring program with a high likelihood of collected data not being influenced by storm events.

Pre-Selection of short-term flow meter locations well in advance of the metering program allows for guide mobilization and installation at the optimal time. The hydraulic characteristics of individual manholes for flow meter installation and operation cannot be properly evaluated without full descent inspection. Completing these flow monitoring manhole inspections well before initiation of the monitoring program prevents the last-minute moving of flow monitors to more suitable locations. Key criteria which normally influence the selection of meter sites include access to manhole, system geometry, localized hydraulics of individual manhole incoming and outgoing line plus bench/trough, close proximity of lift stations, and close proximity of interceptor sewers (especially where collector lines connect to interceptors below the normal flow line in the interceptor).

<u>Short Term Flow Monitoring Program Duration</u>

The ideal short-term flow monitoring program for a sanitary sewer system would be the shortest period in which the following wastewater flow components can be analyzed:

- Base flow (water consumption plus permanent infiltration)
- Peak infiltration (base flow plus peak groundwater induced infiltration)
- Peak inflow (rainfall induced infiltration and/or inflow)

The ideal short-term flow monitoring program for a combined sewer system would be the shortest period in which the following wastewater and urban runoff flow components can be analyzed:

- Base flow (water consumption plus permanent infiltration)
- Peak infiltration (base flow plus peak groundwater induced infiltration)
- Wet weather flow (base flow plus peak groundwater infiltration plus urban stormwater runoff)

Almost every separate sanitary sewer system will experience some level of surcharging after intense storm events, such as a 1-year recurrence interval storm. Analysis of intense storm events requires a reliable methodology for predicting how a wastewater collection system will operate under extreme conditions that cannot be monitored because of system surcharge and sometimes overflows. Any such methodologies are dependent on empirical data analysis and have built-in uncertainties because of the need to project peak wet weather flow and volume up to design storm conditions.

The best mechanism to increase the reliability of any empirical projection technique is to have more data points to correlate. Flow monitoring programs of thirty days or less rarely provide enough data points to produce a reliable correlation. Flow monitoring programs of 90 to 120 days normally do produce 6 to 8 discrete storm events, which typically results in a reliable correlation. Flow monitoring programs between 30 days and 90 days are subject to the uncertainty of local climatic conditions.

The peak flow and volume projection uncertainty requires more research and discussion in relation to SSO regulations. The need to narrow this sometimes large range of uncertainty seems to have been overshadowed by the debate over the relative accuracy of flow meter technology among the major flow meter manufacturers. Calibration of meter sites under high water conditions are critical to establishing peak inflow under design storm conditions. Experience has shown that the hydraulic elements curve (and resulting Manning's equation) is most likely to deviate from actual site hydraulic conditions between 75 percent of full pipe depth and full pipe flow. Adequate on-site calibration of sites after storm events (when flows above 75 percent occur) are necessary to collect this data. It cannot normally be acquired during routine servicing of flow meters.

In some cases, plugging or partial plugging of sewer lines upstream of a meter site followed by quick release of the plug may be necessary to induce high enough flows to do these on-site calibrations. Caution must be exercised, however, to ensure that the sewers downstream of a monitoring site are not subject to hydraulic restrictions that would impact the hydraulics at the meter site. Dye dilution measurements are normally not reliable with a rapidly varying flow rate past a meter site, and are limited by the difficulty in mobilizing quickly and efficiently after a storm event.

The ability of current meter technology to measure "average" flow profile velocity is only one step in the process of predicting sewer system behavior under intense storm events. The other components of SSO events are the volume and duration of the overflow. The relationship between storm recurrence interval and duration and peak wet weather flow volume and duration also relies on empirical data. This relationship is more difficult to quantify than the rainfall and peak flow relationship. The sizing and the resulting cost of deep tunnel storage solutions in large urban systems relies on accurate predictions of wet weather flow volume from the design storm event.

<u>What Specific Data is Normally Required?</u>
Separate sanitary sewer systems have, in most cases, been designed not to surcharge under peak flow conditions. However, the combination of growth and infiltration and inflow (I/I) often results in surcharging after intense storm events. In communities subject to basement backups, detailed modeling of hydraulic grade lines may need to be performed if some level of "acceptable surcharge" is going to be allowed under the design storm, peak wet weather flow. This analysis requires elevation data for manhole rim and pipe inverts along with basement elevations for homes without overhead sewers.

Storm recurrence interval (1-year, 5-year, and others) must always be coupled with storm duration (1-hour, 6-hour, and others) in relation to SSO occurrences. The storm duration most likely to cause SSOs in a sanitary sewer system is approximately equal to the time of concentration of the system tributary to the SSO. On the smaller diameter collection system level, this is often a 30-minute duration storm created by a small storm cell over a small geographic area. On a larger scale, this may be a six-hour duration storm caused by a large storm cell over an entire watershed. The characteristics of the individual system will dictate the "critical" storm duration most likely to cause an SSO occurrence.

Key data needs for each flow component can be summarized as follows:

- Base Flow
Base flow data is normally utilized to compare to water consumption data and then for calibration of hydraulic models. Most systems exhibit repetitive dry weather diurnal flow variations. A large number of dry weather days are normally <u>not</u> required to adequately determine base flow diurnal patterns. Normally, one week of complete data that has not been impacted by storm events is adequate. Ideally, this one week period is isolated by at least three weeks from any significant storm events or snow melt conditions.

- Base Flow Plus Peak Infiltration

Base flow plus peak infiltration data is normally used to evaluate the rate of groundwater infiltration into the sewer system by individual basin as well as to calibrate hydraulic models for base flow plus peak infiltration conditions. A large number of days of base flow plus peak infiltration data are normally not required to adequately determine system flows under these conditions. One week of complete data that has not been impacted by storm events is normally adequate. Ideally, this one-week period is isolated by at least three days from any significant storm events. The three-day period normally allows for rainfall-induced infiltration to taper off after the end of the storm event, leaving the system subject to strictly groundwater level-induced infiltration.

- Base Flow Plus Peak Infiltration and Inflow

This data is dependent on the occurrence of intense storm events. The ideal confirmation of high groundwater levels and intense storm events provides system data under "worst case" conditions for system conveyance capacity.

The determination of how many SSO events per year will occur, and the duration of each event needs to account for the impact of antecedent moisture conditions. SSO system solutions designed around design storm events during low soil moisture conditions typically will result in system surcharge and continued SSO events for the design storm after rehabilitation construction.

This same phenomenon can be observed when a second intense storm event occurs shortly after an initial intense event. The response to the second storm is disproportionally higher and more likely to cause an SSO occurrence than the first storm event.

Intense rainfall occurrences vary dramatically from one region to another. For example, the 5-year, 60-minute duration storm for New Orleans is approximately 8.89 cm/hr (3.5 in./hr), while the same storm in Northeastern Illinois is only 4.83 cm/hr (1.9 in./hr), a difference of 84 percent. If it can be assumed that the occurrence of SSOs is related to rainfall intensity and duration, then it could be far more costly to limit overflows in New Orleans to one SSO event per year than in Chicago.

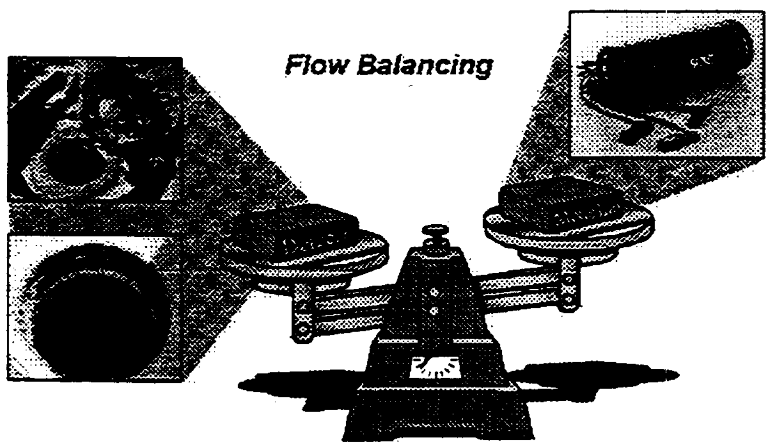

Figure 3

A reliable correlation between rainfall intensity and a stormwater inflow is critical to developing a source data/flow data balance. As shown in Figure 3, this flow balance compares the peak one-year storm inflow (or other appropriate storm reoccurrence interval) to the sum total of all qualified I/I source defects. This reliable correlation is also important in evaluating post-rehabilitation flow monitoring data. As shown in Figure 4, the system response to intense storm event must be compared at the same flow monitoring locations both before and after system rehabilitation to accurately determine the magnitude of wet weather flow reduction as a result of system rehabilitation.

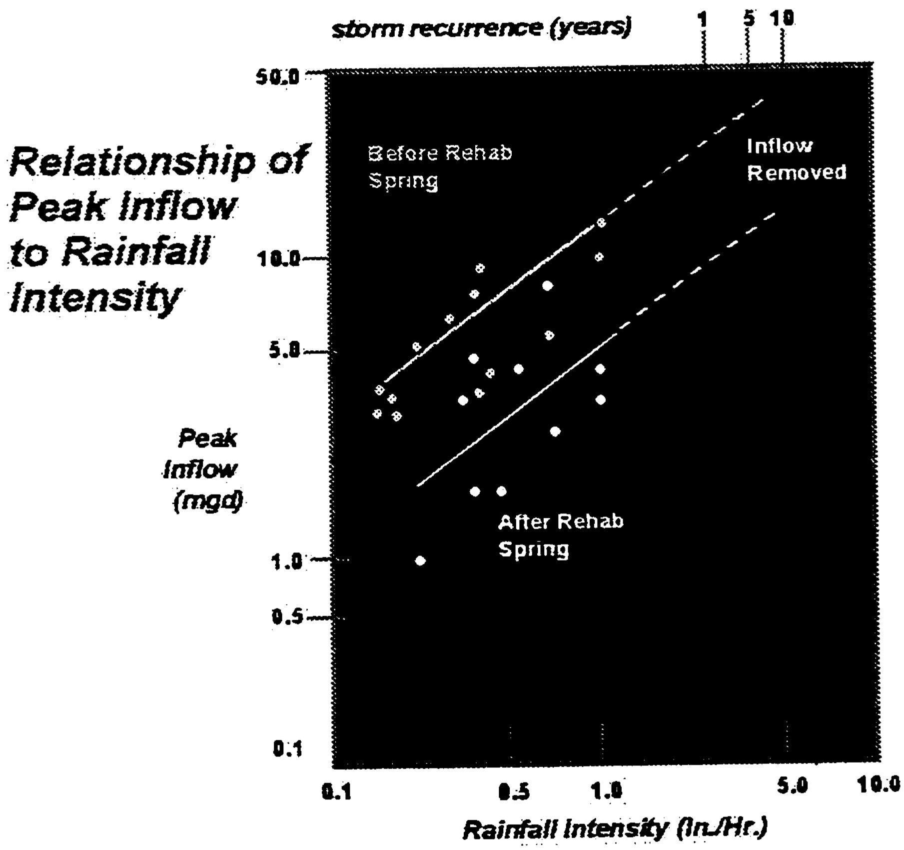

Figure 4

Conclusions

Short-term flow monitoring programs should be designed to focus on the purpose for which the data will be used. The nature of local climatic conditions will influence both the starting date and the duration of the program. Starting dates approximately two weeks prior to initiation of the normal "storm season" are preferable. A minimum of 90 days and preferably 120 days of short-term monitoring are necessary to determine a reliable relationship between rainfall intensity and stormwater inflow.

Expanding the Coverage of the NPDES Storm Water Program: The Proposed Phase II Rule

John Kosco, P.E.
Environmental Engineer
U.S. EPA, 401 M St., S.W. (4204), Washington, DC 20460

ABSTRACT

On January 9, 1998 EPA published in the Federal Register "Proposed Regulations for Revision of the Water Pollution Control Program Addressing Storm Water Discharges", or commonly referred to as the NPDES Storm Water Phase II proposed rule. EPA requested comments on this proposed rule until April 9, 1998. The proposal designates two classes of facilities for automatic coverage on a nationwide basis under the NPDES program, (1) small municipal separate storm sewer systems located in urbanized areas (about 3,500 municipalities would be included in the program); and (2) construction activities (pollutants include sediments and erosion from these sites) that disturb equal to or greater than one and less than five acres of land (about 110,000 sites per year will be included in the program). Those facilities designated above would need to apply for NPDES storm water permits in 2002. EPA is anticipating that most permittees would be covered under general permits.

EPA is also proposing to conditionally exclude from the NPDES storm water program Phase I facilities that have "no exposure" of industrial activities, such as industrial products, processes, or raw materials, to storm water, thereby reducing application of the program to many industrial activities currently covered by the program that have no industrial storm water discharges.

KEYWORDS

storm water, Phase II, NPDES

FINAL RULE

<u>NOTE</u>: The Phase II rule was proposed on January 9, 1998 and is currently scheduled to be finalized by March 1, 1999. This paper discusses the requirements in the proposed rule. For information on the final NPDES Storm Water Phase II rule after it is published in March 1999, contact EPA's Office of Water (web site http://www.epa.gov/ow).

BACKGROUND

Congress added Section 402(p) to the Clean Water Act in 1987 which requires implementation of a comprehensive approach for addressing storm water discharges. This section requires NPDES permits for storm water discharges associated with industrial activity and municipal separate storm sewer systems (MS4s) serving populations greater than 100,000. EPA issued final regulations for these 'Phase I' sources on November 16, 1990.

Section 402(p)(6) requires EPA, in consultation with States and local officials, to issue regulations for the designation of the remaining unregulated discharges to be regulated to protect water quality based on studies conducted under section 402(p)(6). These studies resulted in a Report to Congress on potential phase II discharges (EPA, 1995), which recommended that the storm water program focus on the 405 "urbanized areas" identified by the Bureau of the Census.

EPA developed the proposal with extensive outreach and stakeholder involvement. Valuable input was received from a cross section of interested stakeholders including members of a subcommittee under the Urban Wet Weather Federal Advisory Committee (Phase II FACA Subcommittee). The Phase II FACA Subcommittee included representatives from municipalities, industrial and commercial sectors, agriculture, environmental and public interest groups, States, Indian Tribes, and EPA. The FACA subcommittee has met thirteen times between September 1995 and April 1997, providing valuable comments and feedback.

EPA also convened a Small Business Advocacy Review Panel to evaluate and minimize the potential impact of the proposed rule on small entities.

The proposed rule was signed by Administrator Browner on December 15, 1997 and published in the Federal Register on January 9, 1998. The comment period was open until April 9, 1998 with a final rule scheduled to be signed by March 1, 1999. The following sections summarize the three main components of the rule: the Phase I no exposure revision, small construction sites, and regulated small MS4s.

PHASE I NO EXPOSURE REVISION

"No exposure" means that all industrial materials or activities are protected by storm resistant sheltering so that they are not exposed to rain, snow, snowmelt, or runoff. Industrial facilities (except for construction) which document that they have "no exposure" to storm water could apply for a conditional exemption from the Phase I storm water requirements. EPA has proposed a two page checklist for no-exposure certification for NPDES Storm Water Permitting in the proposed rule. The owner or operator must submit a written certification to the NPDES permitting authority once every five years.

SMALL CONSTRUCTION

The proposal extends existing Phase I regulations to apply to construction activities including clearing, grading, and excavating activities that result in land disturbance of equal to or greater than one acre and less than five acres. Sites disturbing less than one acre are included if they are part of a larger common plan of development or sale with a planned disturbance of equal to or greater than one and less than five acres. The permitting authority may also designate sites less than one acre based on the potential for contribution to a violation of a water quality standard or for significant contribution of pollutants to waters of the United States. The operator of the construction site would be responsible for applying for the NPDES permit. EPA anticipates that most permittees would be covered under general permits.

The permitting authority may waive the requirement for a notice of intent (NOI) under a general permit for construction sites less than 5 acres. In addition, to minimize redundancy in the construction permit requirements, permitting authorities can incorporate by reference the requirements of qualifying State, Tribal or local erosion and sediment control programs.

The NPDES permitting authority may waive the otherwise applicable requirements for a storm water discharge from construction activities that disturb less than five acres where:

(1) The rainfall erosivity factor ("R" in the Revised Universal Soil Loss Equation) is less than two during the period of construction activity. This is the "low rainfall" waiver provision. The owner/operator must certify that construction activity will take place during the period when the rainfall erosivity factor is less than two;

(2) On a case-by-case basis the annual soil loss for a site will be less than two tons/acre/year. The owner or operator must certify that the annual soil loss for their site will be less than two tons/acre/year through the use of the Revised Universal Soil Loss Equation, assuming the constants of no ground cover and no runoff controls in place; or,

(3) Storm water controls are not needed based on either: (i) Wasteload allocations that are part of "total maximum daily loads" (TMDLs) that address the pollutants of concern. The owner or operator must certify that the construction activity will take place, and storm water discharges will occur, within an area covered by the TMDLs; or, (ii) A comprehensive watershed plan, implemented for the waterbody, that includes the equivalents of TMDLs, and addresses the pollutants of concern. The owner or operator must certify that the construction activity will take place, and storm water discharges will occur, within an area covered by the watershed plan.

Within urbanized areas, construction activities are proposed to be covered by the municipal storm water program, which is discussed in the next section. The waivers discussed above and the ability to incorporate by reference qualifying State, Tribal, or local erosion and sediment control programs also apply to the municipal construction minimum measure.

REGULATED SMALL MUNICIPAL SEPARATE STORM SEWER SYSTEMS

The proposed Phase II rule would apply to owners or operators of small municipal separate storm sewer systems (MS4s) located within an "urbanized area" (defined below). Permitting authorities are required to evaluate for potential designation all small MS4s located outside of urbanized areas with a population of at least 10,000 and a population density of at least 1,000. In addition, permitting authorities may designate small MS4s that contribute substantially to the storm water pollutant loadings of a physically interconnected MS4 that is regulated by the NPDES storm water program or based on significant contributor of pollutants to waters of the U.S.

The municipal component of this proposed rule applies to urbanized areas as determined by the latest Decennial Census by the Bureau of the Census. An urbanized area is generally defined as "a place and the adjacent densely settled surrounding territory that together have a minimum population of 50,000 people." The "densely settled surrounding territory" generally has a population density of at least 1,000 people per square mile and is contiguous with other qualifying territory. There are 405 urbanized areas in the U.S. that cover 2 percent of the total U.S. land area and contain approximately 63 percent of the nation's population (these statistics include Phase I cities).

The owner/operator of the regulated small MS4 must develop, implement, and enforce a storm water management program designed to reduce the discharge of pollutants from the MS4 to the maximum extent practicable (MEP) and protect water quality. The storm water management program must include the six minimum control measures described below and identify BMPs and measurable goals for each minimum control measure. The program can incorporate by reference qualifying local, State or Tribal requirements and there is a requirement to evaluate program compliance, the appropriateness of the identified best management practices, and progress towards achieving the identified measurable goals.

MINIMUM CONTROL MEASURES

The following six minimum control measures must be a part of the storm water management program developed by the regulated small MS4. The permitting authority will issue a menu of regionally appropriate and field-tested BMPs that they believe to be cost-effective. This menu of BMPs can be used by the municipality to select BMPs for the minimum control measures.

(1) *Public education and outreach on storm water impacts*. The municipality must implement a public education program to distribute educational materials to the community or conduct equivalent outreach activities about the impacts of storm water discharges on water bodies and the steps that can be taken to reduce storm water pollution.

(2) *Public involvement/participation*. The municipality must comply with State, Tribal and local public notice requirements. For example, provide opportunities for the public to participate in program development.

(3) *Illicit discharge detection and elimination*. The municipality must develop a sewer system map of major pipes, outfalls and topography; effectively prohibit illicit discharges and implement appropriate enforcement procedures; implement a plan to detect and address illicit discharges; and inform the public of hazards associated with illegal discharges and improper disposal of waste.

(4) *Construction site storm water runoff control*. The municipality must develop, implement, and enforce a program to reduce pollutants in storm water runoff to the MS4 from construction activities of greater than or equal to one acre. The municipality must also use an ordinance that controls erosion and sediment to the maximum extent practicable and control other waste at the construction site that may adversely impact water quality, such as discarded building materials, concrete truck washout, and sanitary waste. The program must also include, at a minimum, requirements for construction site owners or operators to implement appropriate BMPs, provisions for pre-construction review of site management plans,

procedures for receipt and consideration of information submitted by the public, regular inspections during construction, and penalties to ensure compliance.

(5) *Post-construction storm water management in new development and redevelopment.* The municipality must develop, implement, and enforce a program to address storm water runoff from new development and redevelopment projects that result in land disturbance of greater than or equal to one acre and that discharge into the MS4. The program must include a plan to implement site-appropriate and cost-effective structural and non-structural BMPs and ensure adequate long-term operation and maintenance of such BMPs. The program must also ensure that controls are in place that would prevent or minimize water quality impacts.

(6) *Pollution prevention/good housekeeping for municipal operations.* The municipality must develop and implement a cost-effective operation and maintenance program with the ultimate goal of preventing or reducing pollutant runoff from municipal operations.

PROPOSED DEADLINES

Proposed Rule Becomes Final	3/1/99
Permitting Authority Issues Menu of BMPs for Regulated Small MS4s	3/1/01
Permitting Authority issues General Permits	3/1/02
Regulated Small MS4s submit permit applications	5/31/02
Small Construction submits permit applications	5/31/02
Regulated Small MS4 programs Developed and Implemented	2007

TOOL BOX

EPA is developing a "tool box" to assist States, Tribes, municipalities, and other parties involved in the Phase II program. EPA is committed to having a preliminary working tool box by the time the proposed rule is finalized in March 1999 and a fully operational tool box at the time of the general permit. The tool box will consist of the six main components: fact sheets, guidances, an information clearinghouse, training and outreach efforts, technical research, and support for demonstration projects.

SUMMARY OF MAJOR COMMENTS RECEIVED

EPA received 500 comments from States, Tribes, municipalities, Federal agencies, environmental groups, contractors, industries, and associations representing all stakeholders.

No exposure provision
Many commenters expressed strong support for the no exposure provision. Some commenters wanted the change implemented quickly rather than waiting for the phase 2 rule. There were also numerous comments and requests for clarification on specifics of the no exposure check list.

Small construction site requirements
Municipalities and contractors submitted extensive comments on the requirements for small construction sites. Many of these commenters stated that EPA does not have data that demonstrates a need to regulate small construction sites. EPA also received comments asking for additional waivers and complaints about the difficulties involved in implementing the proposed waivers.

Permitting approaches
Most of the commenting States and some municipalities supported the use of State alternatives to the NPDES approach. The environmental groups along with a few States and municipalities supported requiring an NPDES approach. Many commenters expressed strong support for general permits and for not requiring NOIs for small construction sites. Many commenters wanted the rule to be clearer about implementation issues such as allowing Phase 2 municipalities to work together in developing their programs and submitting their NOIs.

Six minimum measures
Municipalities and DOTs commented that EPA or the State should be responsible for public education. Several municipalities and States asked for clarification on the illicit discharge requirements. Municipalities and contractors stated that the new development/redevelopment measure is impossible to achieve.

Municipal coverage
A number of States and municipalities asked for revisions to Appendix 6 or clarifications on urbanized areas and incorporated places. They also had numerous comments about the designation criteria, stating that it is too burdensome to apply and EPA has no justification for designating municipalities based on population. Several of these commenters also stated that the rule pushes development outside of urbanized areas, thereby encouraging urban sprawl. Commenters made various suggestions for expanding municipal waivers to exclude more small municipalities.

Municipal storm water management program
Many municipalities commented that municipal regulation of construction sites is redundant; the rule violates the 10th amendment; and the rule interferes with local land use planning. They also said that there should be no effluent limits or monitoring and the rule should not mention TMDLs.

Costs and benefits
Many municipalities and contractors stated that EPA underestimated the rule costs and overestimated the benefits while environmental groups stated that EPA overestimated the costs and underestimated the benefits. Municipalities also stated that the rule is an unfunded mandate. Several States and municipalities mentioned that they could not implement the rule without additional funding.

Overall
Municipalities stated that EPA should consider agricultural sources when regulating storm water and that EPA needs to better evaluate Phase 1 before issuing Phase 2. They also commented that EPA should only regulate places with known water quality problems. Municipalities and several municipal associations stated that EPA should not mention flow while environmental groups and some Tribes stated that flow must be addressed.

Differences among MS4s
Several groups commented on specific issues that they believe should allow them to have different requirements or more flexibility in implementation. These include State DOTs, military facilities, and cities with CSOs.

ADDITIONAL INFORMATION

This rule fulfills a major part of the commitment made by the President's Clean Water Action Plan announced on February 19, 1998 (information on this is at http://www.epa.gov/cleanwater). Copies of the proposed rule can be obtained from the January 9, 1998 Federal Register, EPA's web site at http://www.epa.gov/OWM/sw2.htm or limited paper copies are available by calling the Water Resource Center at (202) 260-7786. If you have questions on the proposed rule, please email them to sw2@epamail.epa.gov or call (202) 260-5816.

EFFICIENT/EFFECTIVE DATA COLLECTION PROGRAM YIELDS A RELIABLE HYDRAULIC MODEL

Gregory Anderson, PE, Woolpert LLP

Woolpert LLP, 5040 Corporate Woods Dive, Suite 120
Virginia Beach, VA 23462 U.S.A.

ABSTRACT

Hydraulic modeling of wastewater utilities has become a critical component in the overall assessment of the operational characteristics of sewerage collection and conveyance systems. Modeling allows for identification of conduit capacity limitations and locations within the systems that may be more susceptible to overflows. While the findings of modeling have become more critical, the importance of providing defendable conclusions is sometimes overlooked. Models are routinely developed from outdated, or unreliable data, and although the modeling results greatly affect the decisions to perform costly improvements, the need to build a precise model sometimes becomes a secondary issue. In many cases, the detailed attribution, which is necessary to develop a reliable model, exceeds the cost of the modeling effort itself and therefore the necessary activities are not performed. The question then becomes, how much of the existing data should be checked, and when does it become imperative that new data be collected? The importance of constructing a model that emulates real life hydraulics should be intuitive, but in some instances the lack of operational data has forced modelers to establish conservative initial assumptions, which in fact sway the results before any actual modeling is undertaken. While the impacts of improving system hydraulics has a relatively high price tag, the cost to assemble a reliable model is rarely factored into a matrix that could justify its worth.

This paper discusses how a hydraulic model can be developed that will ensure the level of accuracy that should be required as part of any hydraulic evaluation of wastewater piping systems. When properly assembled, the achieved model will not only be reliable, but also defendable if required.

KEYWORDS

Modeling, Inflow, Infiltration, Flow Monitoring, GPS

INTRODUCTION

How many times have you heard the saying "Garbage In, Garbage Out"? Never has it been more true than when one looks at hydraulic modeling. Routinely during some phase of a hydraulic modeling endeavor the validity of the data being input has been questioned. Much of the concern evolves when systematic hydraulic inadequacies are displayed onto the computer screen during the modeling process. The problems identified are generally caused by relatively flat or negative pipe slopes for gravity systems, or insufficient pipe size for both pressure and gravity systems. While the model may have been developed from some archaic scroll dating back to the 1940s, or 'as-built' information from several projects with different vertical datums, the actual piping size, slope and configurations are rarely field verified.

Having spent a significant portion of their respective careers completing Sewer System Evaluation Surveys, the authors recognize the importance of having accurate data to help establish the specific hydraulic characteristics of wastewater collection/conveyance systems. Groundwater infiltration and storm water inflow (I/I) volumes are easy to attain, but determining the impact of the additional flows is nearly impossible if the location and elevation of the piping system have not been established. In far too many cases the mapping used to select the flow monitoring sites was outdated and did not reflect the actual piping configuration. Without conducting inventory/condition surveys of the structures it is nearly impossible to determine the limits of a drainage basin, or the flow direction of the piping system. The most essential part of building a reliable model is the proper establishment of the existing system hydraulic parameters. These parameters include location of the piping systems; appurtenances, pipe size, material, and depth; and miscellaneous pumping conditions including wet well size, pump capacity, and cycle times.

DISCUSSION

There are numerous means for accurately establishing the actual location of the piping systems. Conventional surveying methods can be utilized, but the fastest growing method involves the use of global positioning systems (GPS), or a combination of both conventional means and GPS. It has been established that GPS surveys can be completed up to 50 percent faster than traditional methods; however, many limitations exist that may make this method cost prohibitive. Limited satellite coverage and working under dense vegetation is probably the greatest restriction for the GPS method, but fortunately there are several ways to utilize the equipment effectively for most circumstances. Before GPS, traversing between a known point to the point of interest was required. Depending on the distance between the two points a survey crew could spend the better part of a day just locating one point. With GPS, this point can be established in most cases in less than an hour and in some cases in as short of time frame as five seconds. Because of the various modes of operation for GPS surveys—static, real time kinematic, and kinematic—various levels of precision can be attained and are primarily dependent upon the time of occupation. With location accuracies ranging from sub-meter to centimeter the proper mode of operation is usually established by the specific requirements of each contract. As with most commodities, as the precision increases the cost for the additional accuracy also increases. An established standard of 3-5 centimeter accuracy, for both vertical and horizontal components, has been utilized on many utility inventory projects, but the cost for this level of accuracy can in some cases exceed the cost of the modeling effort, depending on the size of the system being modeled. On other projects, a cost effective approach has been to establish a known point within the system being modeled with a high-end accuracy GPS survey and to use a faster, less accurate GPS mode to establish the horizontal locations. After the location of the structures has been identified a traditional leveling survey is completed to establish the vertical component. The approach is fairly simple and can be conducted efficiently for most projects. Several hundred structures can easily be horizontally located within a day and a sub-meter level of accuracy is adequate for most modeling efforts. It is important to note that establishment of the vertical element requires a much higher level of accuracy because differences of several centimeters will in some cases drastically affect the modeling results.

The faster, less accurate GPS surveys utilize single frequency receivers and are generally implemented on utility mapping projects. The photograph below (Figure 1) shows a two-man crew with single-frequency GPS receivers mounted on bicycles. This crew can easily locate 500 utility elements in a day, including limited attribution.

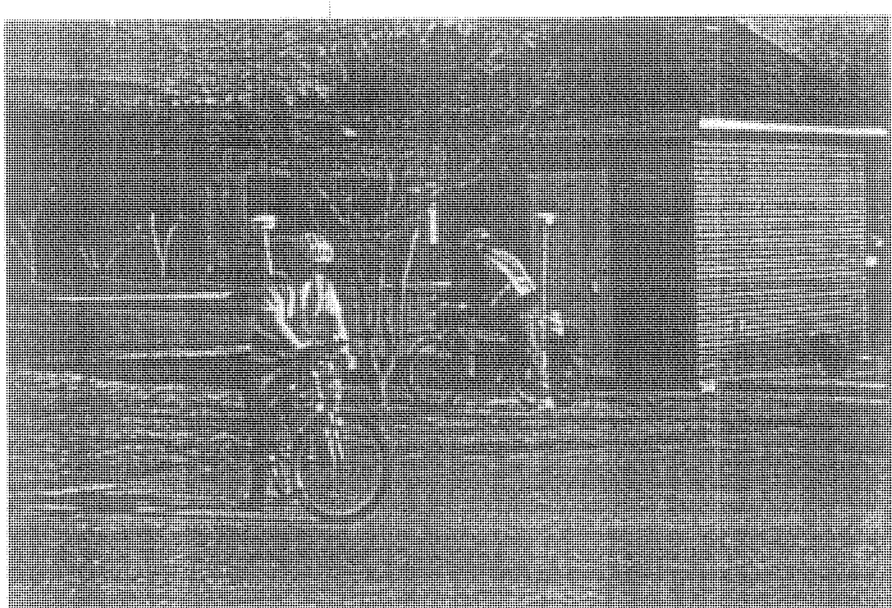

Figure 1 Two-man crew with single-frequency GPS receivers

Upon completion of the GPS activities, a map is produced that identifies the location and unique identifier of each utility element. This map is created electronically and can be overlaid onto any digital mapping file. Electronic mapping can be attained from a variety of sources, including United States Geological Survey, (USGS), or ADC, Inc., but the important aspect of the overlay is that the final attribution crew can easily determine where they are on the map and that the structures being inspected correspond with the unique numbering system established during the initial GPS survey. Final attribution establishes piping size, depth, material characteristics and hydraulic, or structural, deficiencies. In most cases, the final attribution requires confined space entry, but trying to accurately determine pipe size and material from 20 feet above the piping system is nearly impossible. To help build the model efficiently, it is recommended that a project database be created that stores all the attribution data. It is also recommended that the database be accessible from the hydraulic modeling software. For most SSES projects, the goal is to bring back accurate data from the field, and to store it in a easily retrievable format. Numerous off-the-shelf software systems have been developed for this exact purpose and can be interfaced with most modeling systems. The image below (Figure 2) depicts a computer screen from the Hansen Infrastructure Management System (IMS) Sewer Module, Version 7, and highlights the various attribute information that is stored from an internal pipeline inspection. When compiled with the manhole inspection data, this information can be electronically implemented to create the hydraulic model.

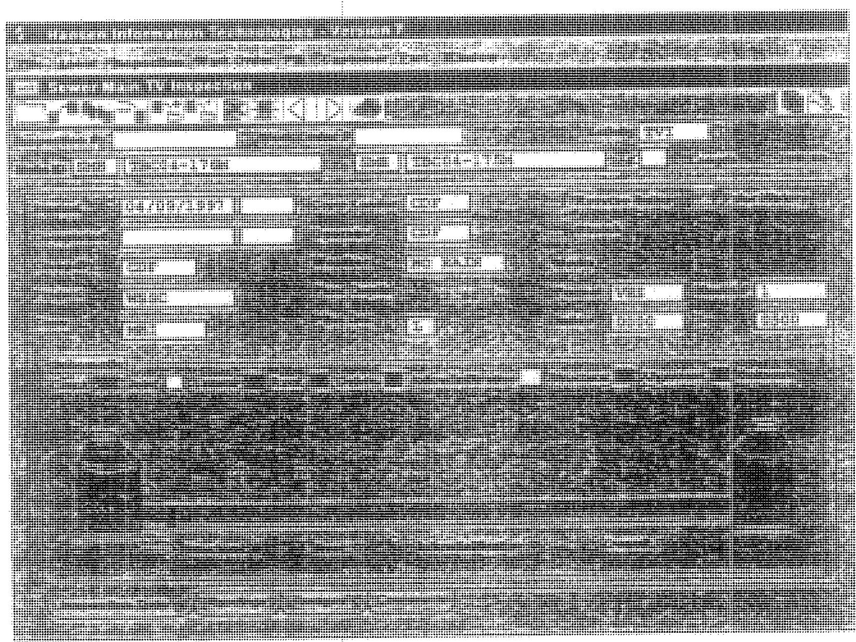

Figure 2 Computer screen from the Hansen Infrastructure Management System, Version 7

With the map created and the final attribution completed, the model can then be developed utilizing most standard CAD files, from a point and click environment. The modeler can select the limits of the systems being evaluated and begin inputting flow data. In most cases, accurate data exists for establishment of average hourly dry weather, and peak dry weather flows. Dry weather flow patterns can be established by utilizing water usage records and by introducing flows into the system on a pipe section-by-pipe section basis that correlates building addresses with piping location. These results, when compared to metered flow rates within the system, should be comparable and may be used to calibrate the model. It is important to establish which facilities within the study area are utilizing metered water and are not returning it to the wastewater system, and potentially which facilities are utilizing well water and are discharging into the conveyance system. If an accurate portrayal of the hydraulics cannot be established for dry weather flows it will be impossible to model the impacts of any wet weather event.

By utilizing open channel flow meters and comparing water usage records to dry weather flow rates, a quick analysis can be completed to identify the potentiai of excessive groundwater infiltration. By isolating flows during non-peak water usage hours (1:00 a.m.-5:00 a.m.), it is fairly easy to identify which piping systems experience significant infiltration. Because the open channel flow meters are usually installed in a mini-basin-by-mini-basin application, and each mini-basin generally has in excess of 10,000 linear feet of gravity piping, additional evaluation is required to quantify the volume of infiltration entering each piping run. Night flow isolations are performed using pre-calibrated weirs or other means to determine the infiltration rates for each piping run. The isolations can be completed from manhole to manhole, or can be completed for several piping sections. The infiltration rates established from the night flow isolations are then added to the flows determined by water usage records and the total flow measured by the open channel flow meter should be comparable. It is important to realize that the actual volume of water entering the collection piping from system users may vary from that being metered at the curb and that an allowance for this occurrence must be made. If accurate groundwater infiltration rates are established, the required variance will establish itself. Groundwater elevation establishment is also very important and in some cases has led to the development of individual models for both high and low groundwater conditions.

A reliable model has now been developed and capacity limitations for average hourly dry weather and peak dry weather flows can be determined. Locations where SSOs are more likely to occur can accurately be depicted and the cost of remediation generated. With the model for dry weather conditions established the impact of inclement weather on the collection/conveyance system can now be evaluated. The overall storm water inflow quantification of an individual rainfall event is simple to measure, but the effect of different magnitudes of rainfall of varying durations is much harder to predict. To property establish these effects it is imperative that the modeler have at least three metered events to use for model calibration. For this reason collection of accurate rainfall data becomes a very important aspect of the calibration procedure. It is very important that incremental rainfall over the mini-basin being monitored is accurately measured and that flow spikes caused by direct inflow are separated from increased volumes associated with rainfall induced infiltration (RII). If the inflow volumes warrant identification of the source(s) a smoke/dye testing program is usually undertaken. Without these activities the modeler has relatively no idea where in the piping system the additional flows are being introduced, and therefore what the impact of removal will have on individual potential overflow locations. Upon completion of the smoke and dye testing activities the model can be rerun without the established direct inflow volumes and the impact of only RII can be measured. If there was an abundance of funding for system rehabilitation this would not be a great issue, but because the most expensive element of reducing wet weather flows pertains to elimination of RII it is one of the most important features to establish. Utility owners and operators want to know how much it will cost to eliminate the overflows and the total cost savings of performing the remediation.

CONCLUSION

In summary, the following elements are key to successfully completing a hydraulic modeling project:

- Accurately map the piping system- GPS is an efficient tool
- Perform the necessary attribution - Properly retrieve the data
- Conduct open channel flow metering - Ensure proper calibration/operation
- Establish a dynamic dry weather model - Utilize infiltration data
- Determine impacts of wet weather events - Complete smoke/dye testing

With the establishment of an accurate model built on real data, a powerful tool has been created—a tool that will allow for proper recommendations to be made for improving system hydraulics and thus minimizing the negative environmental affects caused by SSOs. The model will also serve as a great tool to gauge the impact of future development and to identify potential future operational needs. If a project involving hydraulic modeling is to be successful the basic informational needs to build a reliable model must be understood and accepted by everyone involved in the project. If the proper steps are not completed, and the operational data not validated, the modeling results should be accompanied by a disclaimer that identifies the data sources utilized, the assumptions made and the potential limitations of the model, because everyone should recognize "Garbage In" does equal "Garbage Out" when it comes to modeling.

OPTIMIZATION OF OFF-LINE STORAGE TANK OPERATION USING REAL TIME CONTROL MODELING

Neil R. Moody, Montgomery Watson
Andrew Baldwin, Montgomery Watson

7742 Office Park Blvd, Baton Rouge, LA - 70809

ABSTRACT

Hydraulic modeling is becoming an integral process of sewer planning studies. Dynamic models are being used to simulate flows and depths in complicated sanitary sewer systems and analyze the operation of storage facilities controlled by real time control (RTC) systems. The modeling process involves calibration against dry weather and storm flows ensuring processes such as storage tank filling and emptying are modeled correctly. Applications for the calibrated models include predicting spill locations, improving tank storage operation and pre-design of major capital projects.

KEYWORDS

Sewer, hydraulic, dynamic modeling, operations, force mains, pump stations, real time control, maintenance, in-system storage, peak flows, optimization

INTRODUCTION

In 1989, two off-line sewage storage tanks were constructed in the pumping station no. 50 (PS 50) basin of the Baton Rouge sanitary sewerage system which was prone to frequent SSO activation. Since the tanks were commissioned there has been a significant reduction in SSO spillage, however the tanks have not been as effective as expected in eradicating SSO's.

A component of the Baton Rouge SSO corrective action plan has been to develop dynamic hydraulic models of the sewerage system calibrated against recorded flow and rainfall. Model construction included the development of Real Time Control (RTC) code to simulate the operation and performance of two major off-line storage facilities during the recorded storm events.

Once the model was calibrated, a series of historical storms were simulated on the model to analyse the current system operation. From this analysis a number of operational modifications and system augmentations were proposed and simulated on the model to optimize the use of the tanks and reduce the frequency of SSO spillage.

BATON ROUGE SEWER SYSTEM

The Baton Rouge sewerage collection system consists of over 36,000 manholes, approximately 2516 km (1564 miles) of gravity sewer, over 400 pumping stations, two major pressurized collection systems containing approximately 307 km (191 miles) of forced mains, two off-line storage tanks and three major waste water treatment facilities which discharge to the Mississippi.

The PS 50 basin has a contributing area of over 2000 ha (5000 acres) and is located in the north east portion of the South Consolidated Sewer District (SCSD). Pumped flow from PS 50 is directed into a gravity trunk main located due south via a 480m (1580 ft) long 500mm dia. (20 inch) force main. Average dry weather flows through PS 50 are 0.20 m^3/s (4.56 MGD) with peak wet weather pumping capacity of

0.41 m^3/s (9.4 MGD). Figure 1 illustrates the major components of the PS 50 sewer system included in the model.

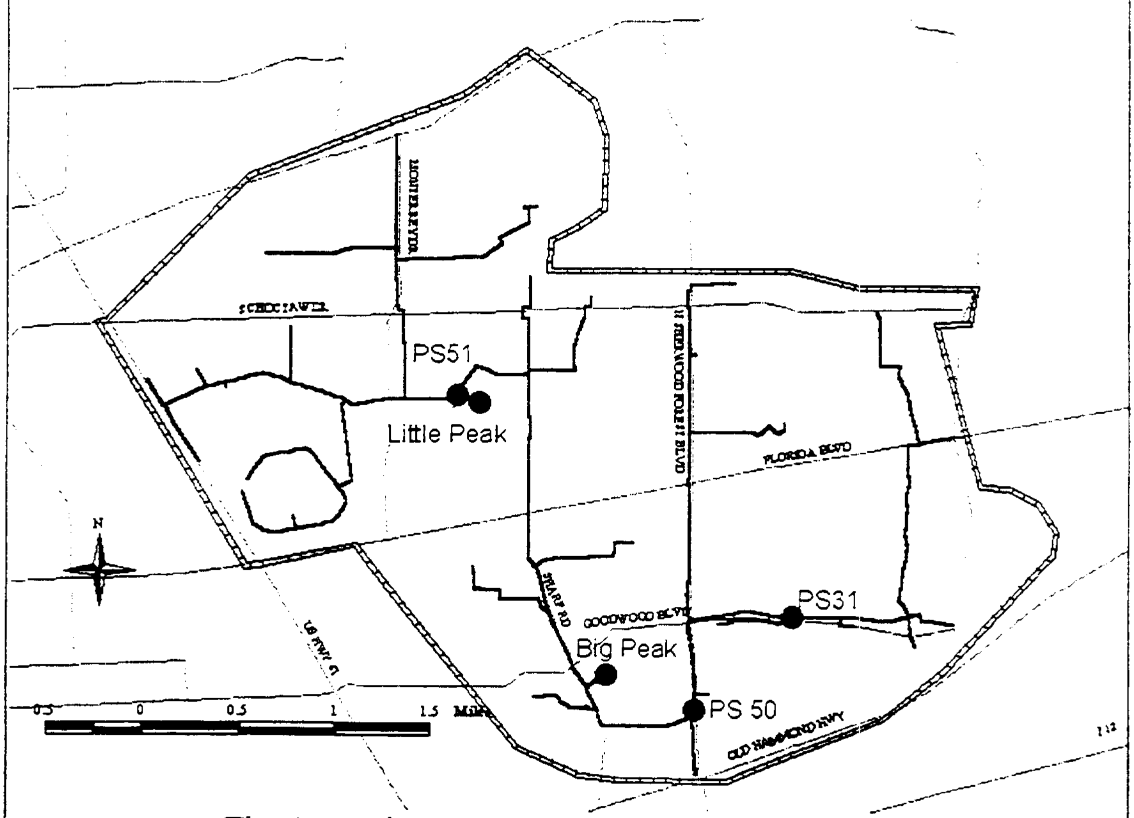

Fig. 1 Major Sewer Components in PS 50 Basin

SEWER MODELING USING HYDROWORKS

The sewer model used for the hydraulic analysis of the Baton Rouge system is HydroWorks™ (Version 3.3). The package simulates time-varying flows and depths generated from dry weather and wet weather flow inputs. The selection of the software was based on the accurate and robust simulation engine, ease of linkage to GIS, data viewing facilities, graphical views and real-time control (RTC) modeling functionality.

The PS 50 portion of the model includes 12 pumping stations and two off-line storage tanks which have three RTC controlled gates to regulate filling and emptying as well as 5 RTC regulated pumps. The Hydroworks™ RTC functionality enabled the modeling of the complex operational features of the two off-line storage facilities for both existing and future alternative scenarios.

EXISTING OFF-LINE STORAGE FACILITIES

The off-line storage facilities located in the PS 50 sub-basin are referred to as Little Peak and Big Peak. These off-line storage tanks are designed to store excess wet-weather flows in the system whilst reducing the effects of surcharging and spills upstream and further downstream in the system. The storage tanks use a combination of sluice gates, pumps and control systems to automatically fill, store and empty during

R0025260

and following major wet-weather events. The location of both structures is shown in Figure 1 with further details described in the following and displayed in layout schematics in Figures 2 and 3.

Little Peak Storage Facility

The Little Peak storage tank is located adjacent to Pumping Station No.51 (PS 51) which serves an upstream contributing area of 601 ha (1484 ac) and an equivalent residential population of 8145. The storage facility comprises a below-ground tank with a maximum capacity of 4.4 ML (1.16 MG), two storage tank filling pumps that extract water from the existing pump station wet-well, force main / gravity return drain, motorized sluice gate, two elevation sensors located in the wet-well and storage tank, and a PLC unit programmed to fill, store and empty the tank following a sequence of pre-defined operational rules. The tank is also equipped with a sophisticated washing / cleaning system that activates following the filling and emptying sequence.

The 'set-points' (i.e.; pre-determined elevations that trigger pumps or gates) were determined from discussions with Baton Rouge operational / maintenance staff supported by analysis of wet-well and tank elevations recorded during dry and wet-weather periods. The following is a summary of the commands used to control the operation of Little Peak storage facility.

1. Normal operation : Pumping station maintains wet-well elevations below fill pump switch-on level. Storage tank empty.

2. Tank filling : Wet-well elevation exceeds fill-pump switch-on level and starts filling tank. Tank stops filling when; i) wet-well elevation falls below fill-pump switch-off
   ii) tank is full

3. Tank storage : Tank stores water until emptying conditions are satisfied.

4. Tank emptying : Tank empties when; i) wet-well elevation below fill pump switch-off, and
   ii) 2 hours after wet-well elevation reaches normal level.

5. Wash cycle : When tank is empty, wash cycle flushes tank and discharges effluent to the wet well.

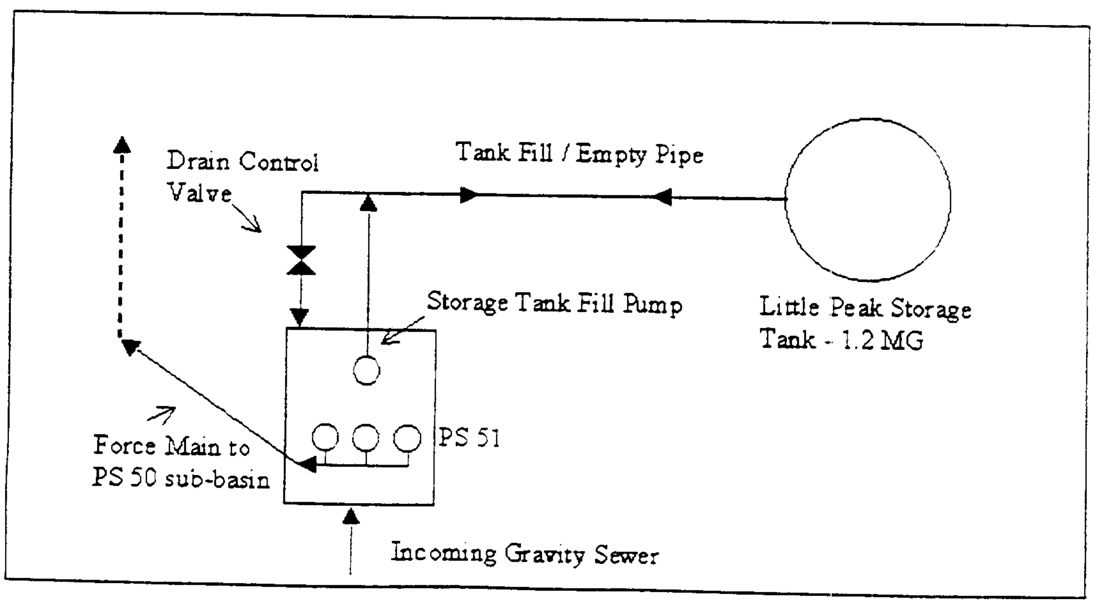

Fig. 2 - Little Peak Storage Facility Layout

Big Peak Storage Facility

The Big Peak storage facility is located downstream from Little Peak, off-line from the 900mm (36 inch) main sewer which drains to PS 50. The facility is much larger than Little Peak providing off-line storage of 17.4 ML (4.6 MG) which is filled via a gravity line and a lift pump station. The flow is controlled by a motorized sluice gate situated on a side branch from the main sewer which opens and closes depending upon system water elevations measured in the main sewer at the off-take. The sewage flows by gravity into the lift pump station then is pumped up to the storage tank. The tank elevation is above the main sewer pipe which allows the tank to empty via gravity . The emptying flow rate is controlled by a sluice gate situated on the outlet from the tank.

The tank is also equipped with a washing facility which flushes sediment and debris deposited on the tank floor during the storage period. This process operates every time the tank is utilized regardless of the storage time or the amount of water stored.

At the completion of tank emptying and washing routines a sump pump located in the base of the pumping station drains the water remaining in the pump wet well and gravity pipes back into the sewer system.

The following details the operational sequence of Big Peak storage facility.

1. Normal operation : System elevation remains below 'tank-fill' set-point.
   Storage tank empty.

2. Tank filling : System elevation exceeds tank-fill set-point and opens sluice gate.
   Flow drains via gravity to lift pump station.
   Lift pump station activates and begins to fill storage tank
   Tank stops filling when; i) system elevation falls below set-point, and
   ii) sluice gate closed, or
   iii) tank is full.

3. Tank storage : Tank stores water until emptying conditions are satisfied.
   Sluice gate is closed and lift pumps switched off.

4. Tank emptying : Tank empties when; i) system elevation falls below set-point, and
   ii) 2 hours after system elevation reaches normal.

5. Wash cycle : When tank is empty, wash cycle flushes tank and discharges effluent to the wet well.

MODEL CALIBRATION

The models were calibrated with data from the following sources:

- Flow, depth and rainfall data from a comprehensive temporary flow monitoring survey of the gravity sewers and SSO's conducted from Jan to March, 1993 involving 19 temporary in-sewer flow monitors and 5 SSO monitors.
- Flow, depth and rainfall data from permanent flow monitors and rain gauges located at key locations in the gravity system.
- Wet well depth charts from the major pumping stations
- Charts recording water levels at key locations in both storage tanks.

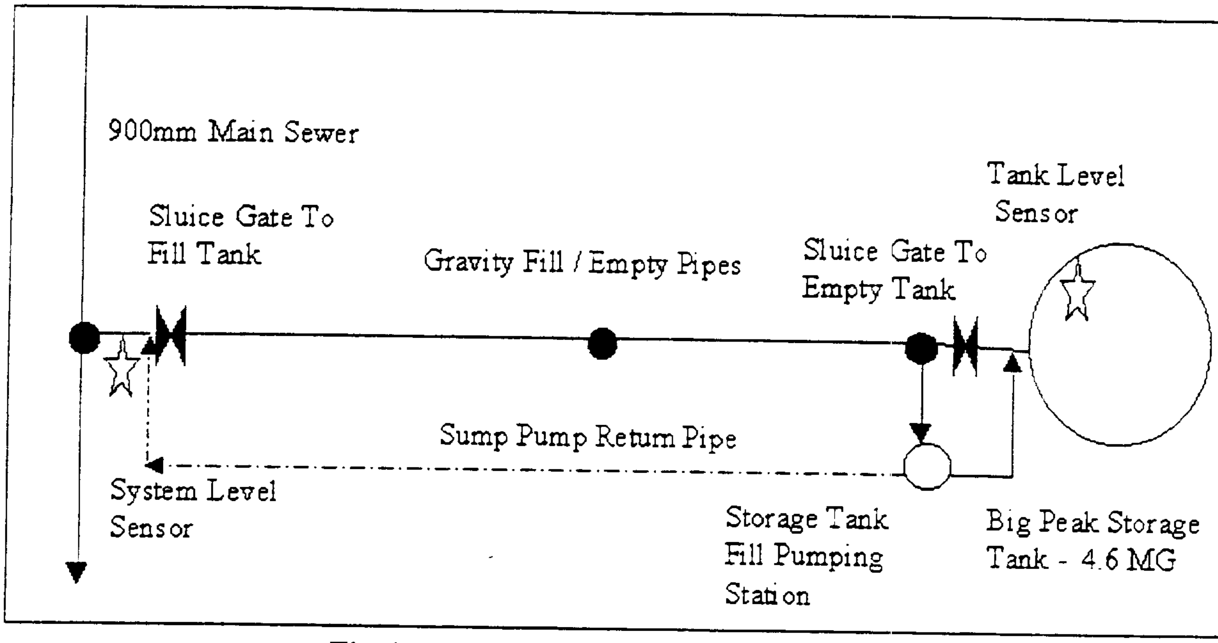

Fig. 3 - Big Peak Storage Facility Layout

To confirm the validity of the model for present day conditions the model was verified with data from the City Parish permanent flow monitoring network and the charts from the storage tanks for storms occurring in later half of 1997.

Dry Weather Calibration

The models were first calibrated to accurately simulate the weekday and weekend diurnal dry weather flow patterns using an integrated facility within the Hydroworks™ modeling software called the "Waste Water Generator" (WWG) . Advantageous features of developing dry weather flows using the WWG tool included:

- Ability to differentiate between different types of sanitary flows and ground water infiltration.
- An internal clock which references the actual dates and times of the simulation event. By this means the appropriate weekday or weekend diurnal dry weather profile is automatically applied to a historic simulation trial.
- Ready linkage to the project GIS–data management system to facilitate an effective audit trail and efficient model updating for future scenarios.

Wet Weather Calibration

Following dry weather calibration, the model was calibrated against a range of wet weather events from the flow monitoring survey conducted in 1993. Wet weather calibration was achieved using a run-off and routing algorithm within the HydroWorks™ model well suited for the simulation of I/I response characteristics. Interesting aspects of the wet weather calibration process undertaken include:

- The process for producing wet weather response hydrographs is internal to the model as opposed to the traditional method applied in the U.S. where the wet weather hydrographs are generated external to the hydraulic model.

- Routines were developed to calculate the additional surcharge storage volume available from the unmodeled pipes and manholes and to distribute and apply the additional storage to the modeled manholes.

During calibration the model results were compared to both the recorded flow and depth to assist in the differentiation between hydrologic processes and the hydraulic attenuation of flows. With the model's integrated hydrologic and hydraulic routines it was possible to calibrate the model to adequately simulate both flow and surcharge depth for a range of events.

Real Time Control Modelling

The operation of Little and Big Peak storage facilities was modeled using the real time control (RTC) feature in HydroWorks. The modeling process involved creating an RTC file containing rules, logic statements and control parameters which control the operation of the variable sluice gates and pumps according to the sequence of rules specified by the modeler.

The hydraulic model simulated the filling, storage and emptying cycles for the observed wet-weather events recorded during the flow monitoring period. To enable simulation of the operation rules to closely mimic the observed operation it was necessary to closely simulate both the flows and surcharge depths in the mains sewer.

The model results were compared with measured flow and depth data recorded in the tanks as well as at flow monitors upstream and downstream of the storage facilities for a number of different storm events. Figure 4 shows flow and depth hydrograph comparisons from flow monitor NE 15 located approximately 500m (1620 ft) downstream from the off-take to Big Peak storage tank. Note the saw-tooth pattern on the depth hydrographs resulting from the opening and closing of the sluice gate to fill Big Peak storage tank.

STORM ANALYSIS

To verify the validity of the model to current conditions a number of storms from late 1997 were simulated on the model. Simulated flow and depth data compared favourably with data from the 5 long term flow monitors located in the basin. Fig 5 illustrates flow and depth comparisons from permanent monitor SD 10 located 1000m (3200 ft) downstream of the off-take to the Big Peak storage tank

In addition the model was run with a series of historic rainfall events with average recurrence intervals (ARI's) of 1, 2 & 5 years and duration's of 2, 3, 6, 12 & 24 hours.

Analysis of the results from the verification storms and the historic rainfall series identified the following problems in the system:

- With a peak pumping capacity of just over twice ADWF, PS 50 is a major hydraulic throttle in the system and will need to be augmented if the system is to handle the large one year plus storms.
- During smaller storms, flooding occurs in a number of locations prior to the storm tanks commencing to fill.
- Due to hydraulic restriction in the gravity pipes upstream, the water level in PS 51 at which the fill pumps to Little Peak switch on can only be reached if the hydraulic gradeline is within a few feet from ground level 540 m (1770 ft) upstream of the pump station.
- Rather than being activated by the water levels immediately adjacent to the facilities, both tanks appear as though they would provide greater protection from flooding if they were activated by depth sensors strategically located near manholes that flood.

DEVELOPING SOLUTIONS AND SYSTEM IMPROVEMENTS

The calibrated hydraulic model was used to investigate various scenarios for improving the operation and performance of the sewer system. The focus of the improvements was on the reduction (i.e. frequency and volume) of spills occurring due to hydraulic deficiencies and excessive inflows entering the system. The objective of the sewer planning study was to develop working solutions that provide a significant level of improvement whilst minimizing design and construction costs.

An innovative solution currently being developed requires the modification of the existing RTC systems operating both Little and Big Peak storage facilities. The process involves relocating the 'control' sensors to critical sites within the sewer system (e.g. nearby a region where significant surcharging and spill occur), increasing storm tank pumping rates, and modifying the control algorithms to capture an increased amount of storm flow.

Initial results of these developments show reductions of spill volumes and frequencies for typical annual storms. However, large storm events generate excessive inflows, which exceed the capacity of the system causing major spills and surcharging. Further capital improvements including increased pump capacity for PS 50 and a large in-line storage tunnel are being tested using the hydraulic model.

CONCLUSIONS

1. The development of a well calibrated dynamic hydraulic model was a key component of the study. Without such a model, a clear understanding of how the system operated and behaved, along with the development of cost-effective solutions could not have been obtained.

2. Model calibration and verification are essential for developing accurate and reliable hydraulic predictions. Ensuring the model predicted reasonably accurate surcharge depths was vital for this modeling study.

3. Modeling existing and proposed RTC systems enables the engineer to predict the behavior of the off-line storage facilities and improve the system operation by making adjustments to the algorithms and sensor configuration.

USING REAL-TIME CONTROLS TO EXPLORE ALTERNATIVES TO RELIEF SEWER CONSTRUCTION

Bradley (Brad) T. Pierce

ABSTRACT

Using real-time control (RTC) to regulate the movement of flows into and out of flow storage or diversion facilities (wet weather facilities), certain alternatives can be fully analyzed, possibly eliminating or minimizing the need for traditional parallel relief sewers. Through the use of RTC, utility owners can realize significant cost-savings when solving hydraulic capacity problems.

KEYWORDS

Real-time control (RTC), hydraulic model, SSO abatement, HYDROWORKS, wet weather storage

INTRODUCTION

While used throughout Europe, the concept of real-time control (RTC) is fairly new in the United States as a viable solution to sewer system problems. Even when real-time control has been thought of or implemented, it has commonly been in conjunction with combined sewer or storm drainage systems. Also, with the advent of more advanced, capable & dynamic hydraulic modeling software in the recent years, hydraulic modeling of potential RTC solutions prior to implementation has made RTC solutions even more attractive than ever. Due to increasing demand from the municipal and consulting community for knowledge regarding the capabilities and applicability of RTC, this paper will explore some uses and benefits of some real time controls in today's separate sanitary sewer systems by modeling them with an advanced hydraulic modeling software package.

Detailed objectives for this paper include:

- Answering the industry's need for knowledge about what real-time control is and how it might benefit collection system owners throughout the United States.
- Evaluating real-time controls and associated facility scenarios on an actual existing sewer system.
- Investigating the benefits of real-time control vs. traditional approaches in dealing with capacity problems.

Answering the Industry's Need for Knowledge about RTC

For this discussion, Real Time Control (RTC) in a sewer collection system is simply defined as the ability to manipulate various flow control structures in the collection system based upon conditions elsewhere in the collection system. The pumps in a pump station are undoubtedly the most common flow control structures found in sewer systems today.

Just like in a pump station with a float switch, Real Time Control is implemented by placing some kind of sensor where it can obtain data about the sewer system or its hydraulics. The sensor then "triggers" some kind of reaction from a control structure when the data it obtains meets certain pre-set criteria, such as a rising water level tilting a float switch enough to turn a pump on.

On one level, RTC can be applied to manipulate isolated, individual flow control structures such as constant speed pumps, variable frequency drive pumps, variable height gates, variable crest and width weirs, and inflatable dams to provide localized control of flows.

R0025269

Alternatively, RTC can be used to globally manage flows throughout an entire sewer network. A sensor can be placed anywhere in the system, and using telemetry, data from the sensor can be acted upon elsewhere in the system to restrict or divert flow, increase usage of available storage and, hopefully, stop sanitary sewer overflows (SSOs).

Why should a sanitary sewer system owner consider managing system hydraulics using RTC? This is an explanation found in the HYDROWORKS On-line Technical Documentation by Wallingford Software, Ltd.:

"As the standards for the performance of sewer systems become more stringent, engineers need better tools and techniques for planning the reduction of flooding and pollutant spillage." Real Time Control "...allows engineers to make the most of the latest in-sewer technology, in order to optimize the performance of existing sewage networks and to design more cost-effective new systems."

While experimenting with control structure locations, sensor locations and operating rules can be done without first modeling, it can result in very unsatisfactory results if a mistake is made and there still might be a more effective solution. By modeling several scenarios with a dynamic hydraulic modeling software package before implementation, many more scenarios can be developed, tested and evaluated at a fraction of the construction costs.

The scenarios that can be tried are only limited by the engineer's imagination. The HYDROWORKS RTC model provides sensors that can be placed throughout the system to sense a variety of parameters. The available parameters in the model are: flow, velocity, depth, rate of change of flow, rate of change of depth, level, rate of change of level, 10-minute average rainfall, pump state, adaptive pump control, regulator state, date-time, and the values of a variable, a lookup table, a range or a logic (true/false) record.

Evaluating Real-Time Controls

For the confines of this technical paper, the authors have selected a sample sewer system to evaluate. The sample used is a real, existing sewer system. It is projected that for the year 2020, this sample sewer system will have a problem: Several significant SSOs due to a lack of hydraulic capacity in pipes and inadequate pumping in a downstream pump station. The authors have selected a few likely scenarios for this system that have the best opportunity to eliminate or significantly reduce overflows and also utilize real time controls.

Real-Time Control Vs. Traditional Approaches In Dealing With Capacity Problems

As with all new technologies, there is a time to implement them and a time to go with more traditional methods. RTC is no different. Sometimes a larger or parallel sewer line can be constructed with open-trench methods to resolve capacity problems relatively quickly and inexpensively. Often, however, due to limited access, traffic disruption, "NIMBY" (Not in My Back Yard) attitudes, or just a large amount of sewer that would have to be paralleled, options can be limited and costs can be prohibitive.

Modeling with real time control as an alternative provides the municipality and its engineers yet another tool to discover more options. Instead of constructing long, large diameter relief lines to conduct more flow, more quickly, RTC offers the engineer the option of managing hydraulics by diverting peak flows into storage facilities or other parts of the system.

An added benefit to using RTC vs. traditional relief line approaches is that with relief lines, more flow is just passed downstream faster. That may solve a local problem, but it often passes the problem downstream. The eventual impact on downstream pipes may also warrant relief sewer construction, bigger pump stations, or worst of all, even increasing treatment plant capacity. With RTC, flows can be "managed", not passed downstream. Flows can be stored, or even diverted to elsewhere in the system that can handle it.

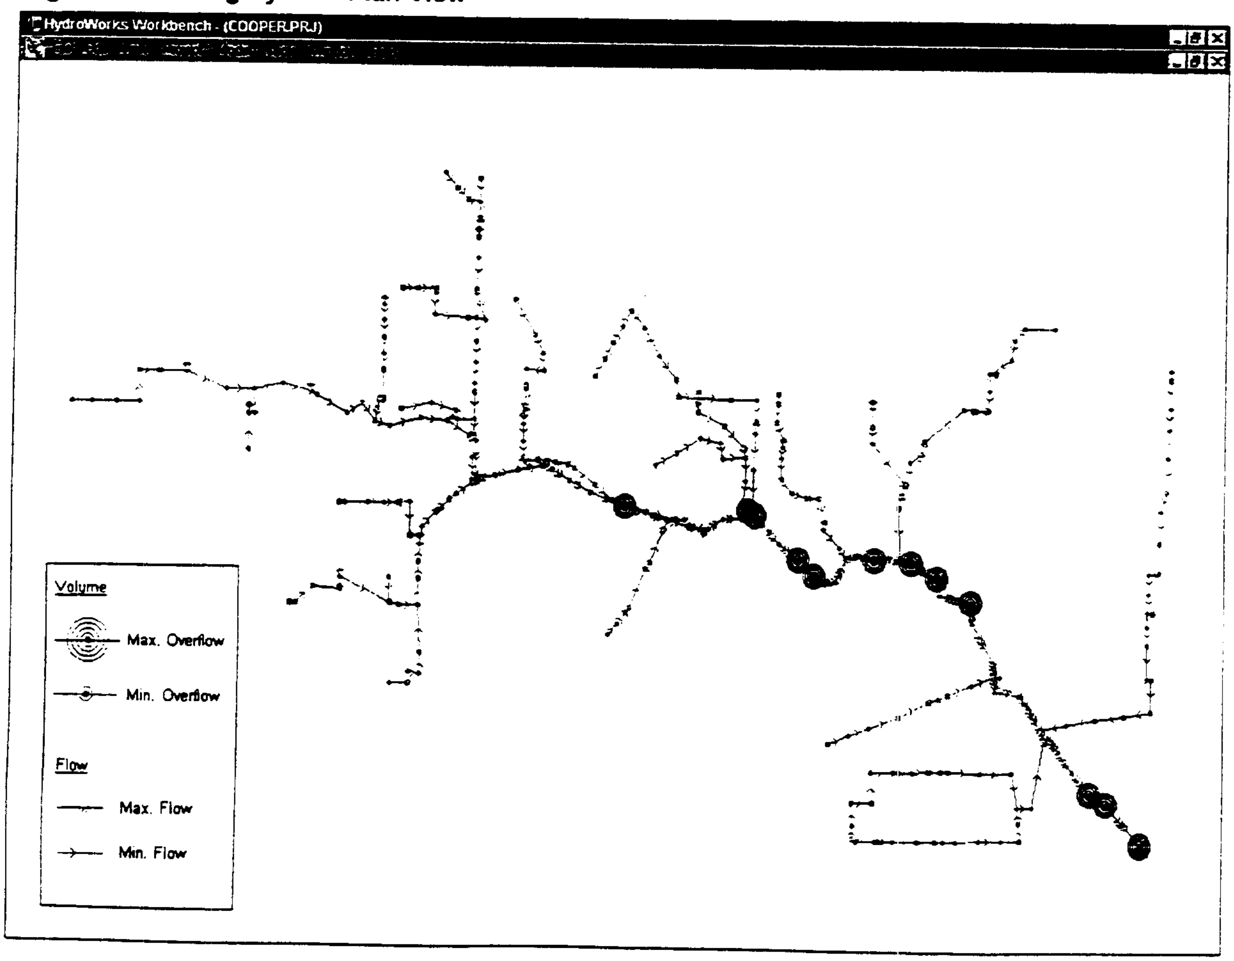
METHODOLOGY

With the power of modern day hydraulic modeling software, the simulation of RTC can be readily performed. This provides the engineer the capability to explore numerous options for optimizing flow movement in a sewer system. For this analysis, the authors utilized the HYDROWORKS™ hydraulic model with the HYDROWORKS™ RTC module by Wallingford Software, Ltd. of the United Kingdom.

The sewer system used is a separate sanitary sewer system, located in North Central Texas. The system's physical attributes, diurnal unit hydrographs, and per capita wastewater contributions were converted to HYDROWORKS from a static hydraulic modeling software, completed as part of a previous study by others. The model was calibrated using observed dry weather flow meter data and one observed wet weather event. Drainage area population was updated to estimate year 2020 conditions. All models runs reported on here are based on these parameters.

The existing system was modeled first. This model projects that the system will have numerous sanitary sewer overflows (SSOs) with significant volume in the year 2020 with the selected design storm. (See Figure 1) Conventional design approach would be to plan relief sewers to provide additional hydraulic capacity in order to carry wet weather flows and reduce overflows. This paper considered RTC measures to increase storage capacity for wet weather flows, in lieu of adding relief sewer capacity. Three different RTC scenarios were modeled to accomplish this. Each RTC scenario is configured to provide sufficient storage volume and control for reduction in SSO locations and volume, while maintaining the existing pump station pumping rate.

Figure 1: Existing System Plan View



R0025271

The modeled system is a gravity system outfalling to a large pump station and force main. The force main flow rate cannot be allowed to increase above current levels, due to significant hydraulic constraints downstream. The cost of relieving these downstream hydraulic constraints were assumed to be too great, due to large amounts of relief sewer piping that would be required in congested areas. The pump station has a total pumping capacity of 0.20 m^3/sec (4.6 MGD). Attributes of the modeled separate sewer system and the simulation design storm are shown in Table 1.

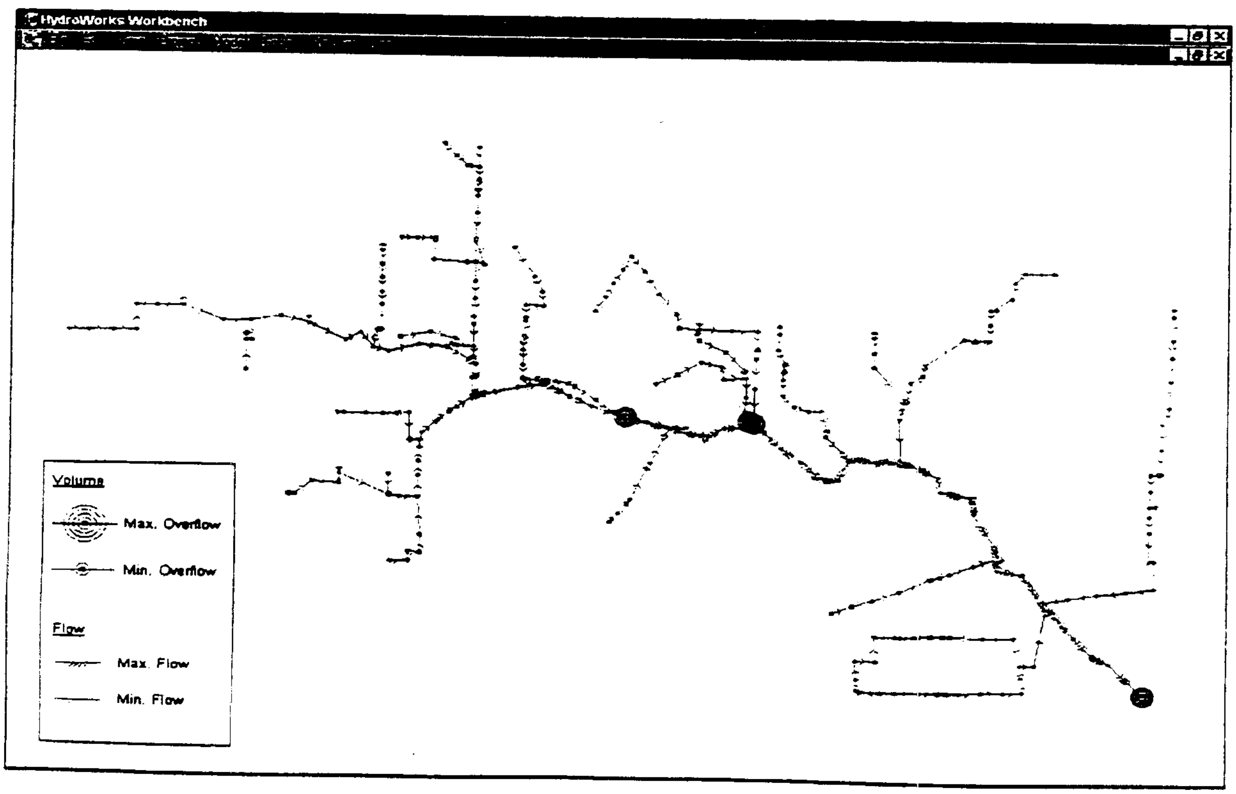
Table 1: Modeled Sewer System and Simulation Design Storm Attributes

Population:	20,968
Number of Manholes:	311
Drainage Area:	9,952 hectares (4,028 acres)
Larger Pipe Diameter:	690 mm (27 in.)
Smallest Pipe Diameter:	250 mm (10 in.)
Storm Modeled:	10 year, 2 hour
Storm Volume:	1,407,567 m^3 (371.8 MG)
Peak Intensity:	130 mm/hr (5.1 in./hr)
Total Rainfall:	86 mm (3.4 in.)
Total I/I:	4,692 m^3 (1.3 MG)
Simulation Duration:	48 Hours

RTC Scenario One

This scenario centered on a wet weather storage facility adjacent to the pump station. The facility is located in line, just upstream of the drainage basin discharge into the pump station. This location allows the storage facility to act as an extension of the pump station wet well, and subject to the pump controls located there. (See Figure 2)

Figure 2 – Scenario One Plan View

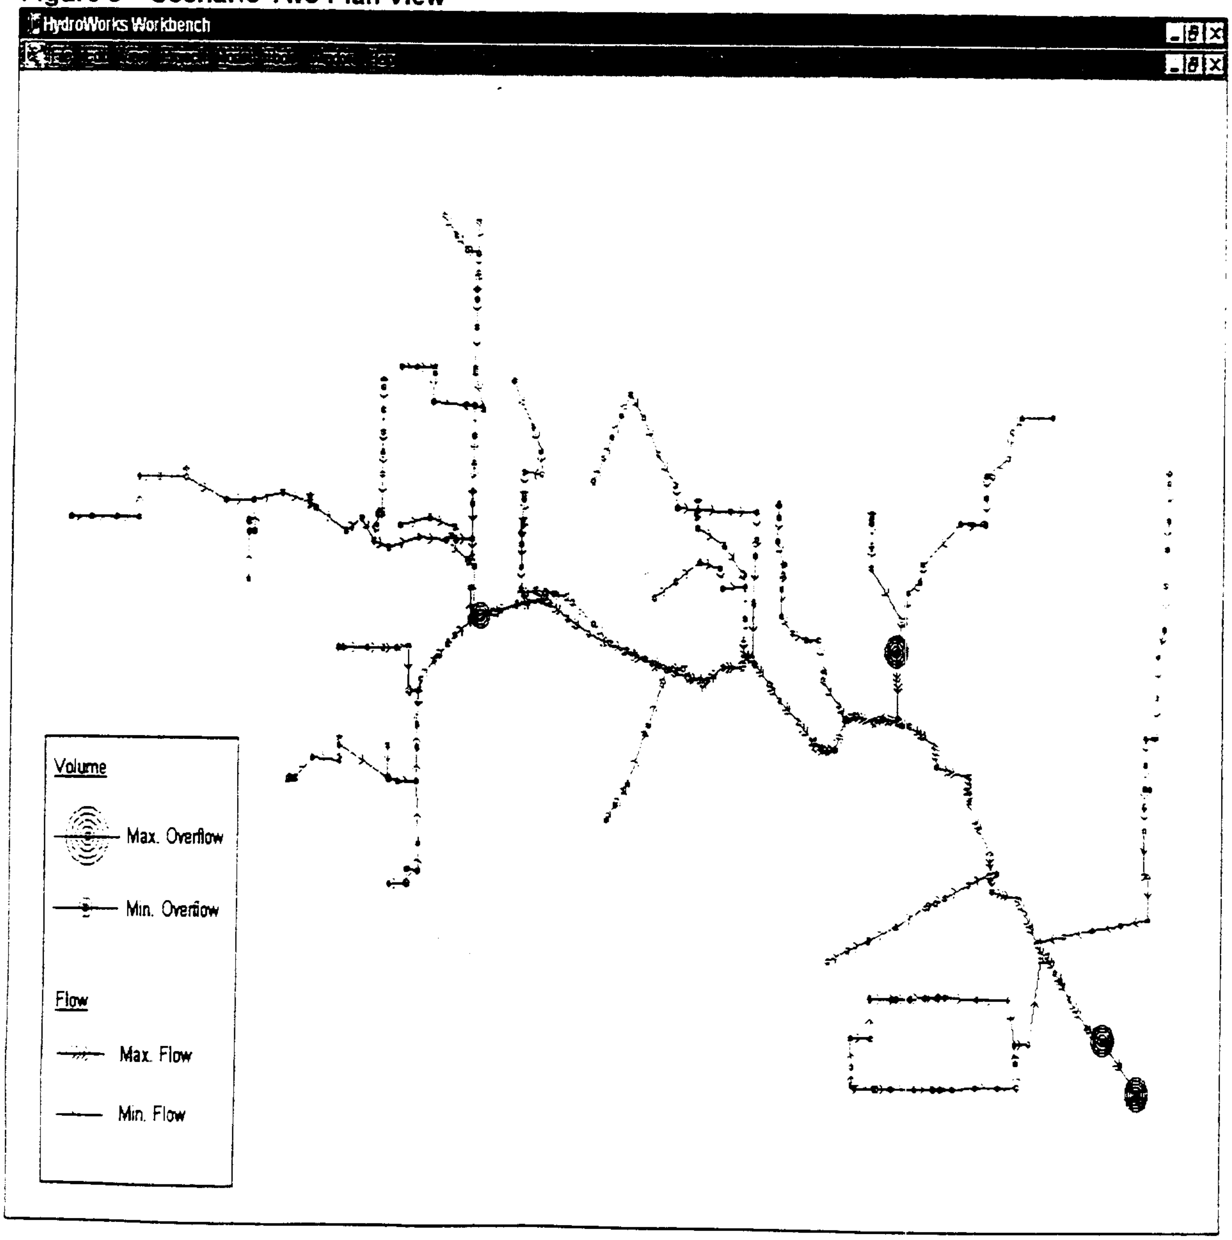


This location was chosen due to its proximity to some of the large volume SSOs in the sewer system, and that land and maintenance resources were available from the existing pump station.

RTC Scenario Two

The second scenario consisted of two in-line storage tank locations, in place of the pump station wet weather storage facility. The mid-section of this drainage area also contained several SSOs. One tank was located in the upper part of the drainage basin on the main collector line, upstream of most SSOs. The second in-line tank was located on a major branch line in the mid-section of the drainage area, just upstream of the main line and the larger SSO locations. Tank location was selected based upon proximity to SSOs, consideration for land space, and proximity to large branch flows entering the main collector line. (See Figure 3)

Figure 3 – Scenario Two Plan View

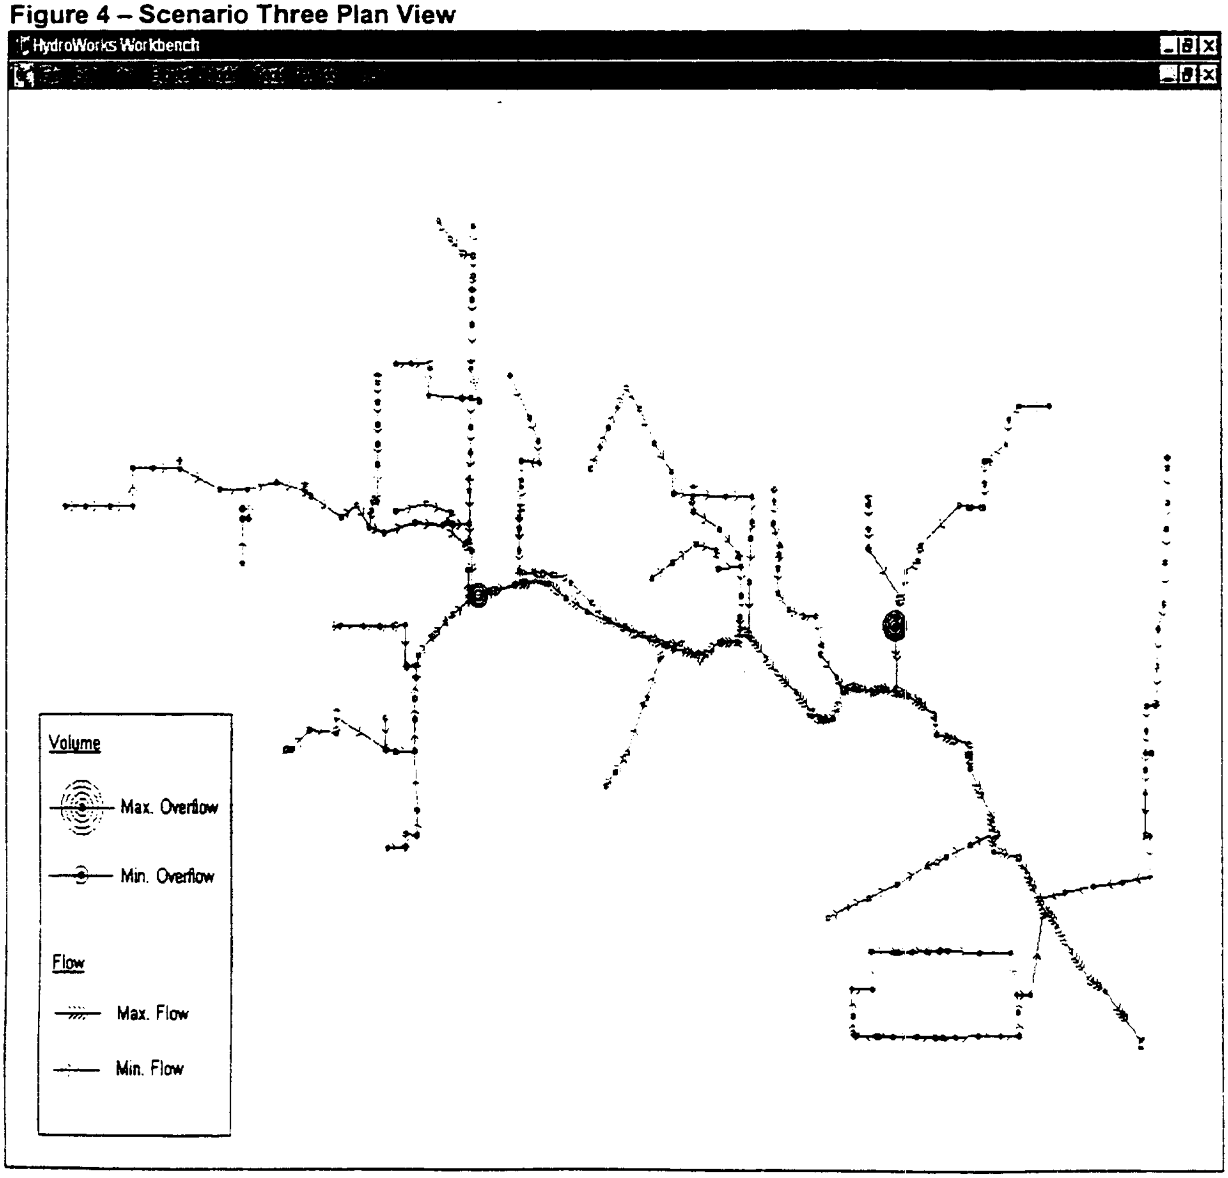


Each in-line tank had RTC gates located at the downstream end. Each gate is controlled to react to a downstream water level sensor. The sensors have been placed in locations with quick reacting hydraulic grade lines. Once the water level in these sensor points rises past the trigger elevation, the RTC gates are closed and wet weather storage volume is utilized. Each tank also has an upstream safety override sensor that reopens the RTC gate if excessive backup occurs in the sewer system upstream of the in-line tanks.

RTC Scenario Three

The third scenario combined scenarios one and two. The desired effect would be to minimize SSOs, with the combined storage volume being less than that of alternatives one and two combined. (See Figure 4)

Figure 4 – Scenario Three Plan View



R0025274

RESULTS

The HYDROWORKS™ hydraulic modeling software was utilized to simulate the existing condition, as well as the three RTC scenarios.

Table 2 displays the results of the simulation runs. Maximum discharge is the peak flow rate determined in the downstream pipe segment of the drainage basin, just prior to entrance into the pump station wet well. The results indicate that the existing system simulation and scenario two have the highest discharge, while scenario one is significantly lower. Total discharge volume is the volume discharged out of the drainage area into the pump station wet well over the 48 hour simulation duration. All simulations have essentially the same discharge volume. Number of SSOs is the count of manholes which overflow at any time during the simulation. Total SSO volume is the cumulative volume of all the overflowing manholes. The results indicate that all scenarios significantly reduce the number and volume of SSOs, compared with the existing simulation.

Table 2: Simulation Results

Scenario	Maximum Discharge	Total Discharge Vol.	# of SSOs	Total SSO Volume
Existing	0.24 m^3/sec (5.4 MGD)	19,952 m^3 (5.3 MG)	12	2,076 m^3 (0.55 MG)
1	0.10 m^3/sec (2.2 MGD)	19,676 m^3 (5.2 MG)	2	6 m^3 (0.002 MG)
2	0.24 m^3/sec (5.5 MGD)	19,886 m^3 (5.3 MG)	5	582 m^3 (0.15 MG)
3	0.21 m^3/sec (4.8 MGD)	19,900 m^3 (5.3 MG)	2	0.01 m^3 (0 MG)

The tank volumes displayed in Table 3 provide an indication of how efficiently each scenario accomplishes the goals of reduced SSO locations and volume, while not exceeding existing pump station capacity. The largest single required storage volume is the wet weather facility located near the pump station in scenario one. The smallest required storage volume is the second in-line storage facility used in scenarios two and three. Scenario two has the lowest total storage volume.

Table 3: Simulation Storage Tank Volumes

Scenario	Wet Weather Facility	In-Line Storage 1	In-Line Storage 2	Total
Existing	0	0	0	0
1	2282 m^3 (0.6 MG)	N/A	N/A	2282 m^3 (0.6 MG)
2	N/A	640 m^3 (0.17 MG)	466 m^3 (0.12 MG)	1106 m^3 (0.29 MG)
3	867 m^3 (0.23 MG)	640 m^3 (0.17 MG)	466 m^3 (0.12 MG)	1973 m^3 (0.52 MG)

The results displayed in Tables 2 and 3 provide the criteria to evaluate the RTC scenarios.

DISCUSSION

RTC Scenario One

Scenario one achieves the goal of significantly reduced SSOs while not exceeded the existing pump station capacity. This is accomplished with one large tank. A tank of this size could pose certain maintenance and "NIMBY" concerns. This scenario is most effective at reducing the peak flow rate into the pump station. Advantages and disadvantages are shown in Table 4.

Table 4: Scenario One Advantages and Disadvantages

Advantages	Disadvantages
Essentially eliminates SSOs	Largest tank volume
Does not exceed existing pump station capacity	Large footprint required
Single tank location	Highest maintenance
Outlet discharge rate is lowest of all scenarios	

RTC Scenario Two

Scenario two also achieves the simulation goal, but somewhat less successfully since there are still some SSOs in the lower reaches of the basin. The RTC gates have effectively provided storage sufficient enough to reduce SSOs (particularly those in the middle and upper reaches), while not incurring "new" SSOs upstream. However, it appears that some downstream storage is required in order to fully eliminate all SSOs. Advantages and disadvantages are shown in Table 5.

Table 5: Scenario Two Advantages and Disadvantages

Advantages	Disadvantages
Lowest total storage volume	Highest drainage basin outlet discharge; no change from existing and higher than LS capacity
Does not exceed existing pump station capacity	Reduces, but does not eliminate SSOs
Lowest maintenance	Multiple tank locations

RTC Scenario Three

This scenario also essentially eliminates SSOs, but accomplishes this goal with less total storage volume than scenario one. Most notably, the downstream storage facility at the pump station is about one-third the size of the facility in scenario one, making it less expensive and more suitable for many locations. Even though the basin discharge is not reduced as much as in scenario one, the discharge has been reduced to match the pump station pumping capacity. Advantages and disadvantages are in Table 6.

Table 6: Scenario Three Advantages and Disadvantages

Advantages	Disadvantages
Essentially eliminates SSOs	Total storage volume greater than Scenario Two
Does not exceed existing pump station capacity	Discharge greater than Scenario One
Total storage volume less than Scenario One	Medium maintenance
Drainage basin outlet discharge equivalent to LS capacity	Multiple tank locations
Footprint required less than Scenario One	

CONCLUSIONS

As demonstrated by these three RTC alternative simulations, RTC can provide an alternative to traditional approaches for handling wet weather flows in separate sanitary sewers. The three simulations have all met the specific constraints of this example sewer system: reduction in the number and volume of SSOs without exceeding the existing pump station capacity at the drainage outlet. These constraints improve the overall quality of service a utility provides, avoid simply "passing the problem" downstream, and negate the need for costly relief sewer construction within and downstream of the modeled drainage area.

Scenario one does the job, but may be unfeasible in certain neighborhoods. The RTC gates in the in-line storage tanks of scenario two provide some reduction without creating new SSOs, but as configured are unable to fully eliminate SSOs in the lower reaches of the drainage basin. Scenario 3 seems to provide an optimized combination of underground, in-line storage in the upper and middle reaches of the basin with a downstream storage facility that is almost one-third the size of the storage facility in alternative one. The results of these simulations add credence to the consideration of RTC solutions in separate sanitary sewer systems.

Modeling with real time control as an alternative provides the utility and its engineers yet another tool to discover more solutions.

REAL TIME CONTROL MODELING FOR SEWER SYSTEM OPTIMIZATION

By

Mike N. Agbodo*
Richard E. Nelson

ABSTRACT

Flooding and overflows of untreated wastewater can occur even when there is sufficient storage in the sewer system to contain the volume of flow during a storm event. In many sewer systems, the flows are not effectively routed, failing to take advantage of available storage. Real Time Control (RTC) enables effective use of the latest technology in sewer systems modeling to optimize the performance of existing systems and to design more cost-effective systems. RTC makes it possible to determine the best locations for sewer appurtenances and the most efficient operating patterns under a wide range of hydraulic and hydrological conditions.

This paper illustrates the benefits of using RTC for flow control in sewer systems for the optimum and most cost-effective operation, with significant cost savings, and pollution reduction. The paper also demonstrates that RTC modeling enables multiple "what if" scenarios to be evaluated using hydraulic computer models of the sewer systems before investing in costly and sometimes disastrous improvements.

KEYWORDS

Real Time Control (RTC), optimization, in-system storage, overflows, SSOs and CSOs.

INTRODUCTION

Real Time Control (RTC) can be used to optimize the performance of existing systems. The optimization frequently involves the use of in-system storage in the sewer system to reduce the frequency of Combined Sewer Overflows (CSOs) and Sanitary Sewer Overflows (SSOs). RTC modeling allows sewer appurtenances to be modeled, using rules which are specified by the user, to regulate flows at a location in the sewer system related to flows, depths, or rainfall intensities elsewhere in the sewer system.

RTC management of sewer systems involves the use of sensors to monitor flows continuously, telemetry to pass measurements from sensors to flow regulating appurtenances such as pumps, movable gates and weirs, and controlling devices which can change the state of appurtenances during a storm event. RTC can be applied to individual appurtenances to provide local control of flows, as well as to make global management of flows possible throughout the sewer system: a level meter at the most upstream of the sewer system may operate a penstock near the treatment works.

RTC modeling parameters can be combined to build complex rules, giving engineers the enormous scope to explore the potential storage capacity and optimal operating patterns in the sewer system. Engineers can evaluate the system under a wide range of "what if" scenarios for numerous dry and wet weather conditions by varying the duration and intensity of the rainfall, or the wetness of the catchment, or the spatial variability of the rainfall event.

By using telemetry in actual system RTC implementation, the engineer can implement a control system using local or global operating rules. This involves the installation of sensors such as rain gauges, flow and level meters, and appurtenances such as penstocks, variable level gates, pumps, or weirs to monitor and regulate flows through the sewer system.

WHY USE RTC?

As regulatory agencies tighten the rules governing pollutant discharges to receiving waters, and as the standards for the performance of sewer systems continue to become stringent, engineers need increasingly innovative and sophisticated tools and techniques for planning the reduction of flooding and pollution. RTC allows engineers to make the best use of technological advances in sewer systems modeling to optimize the performance of existing sewer systems, and to design more cost-effective new systems.

In order to design an RTC system, it is necessary to test and evaluate the different RTC measures and their impacts on the collection system. It is impractical to test the RTC measures on a real system. Applying untested RTC measures to the real system would be not only impractical, but also a high risk-investment. Different RTC strategies have to be evaluated under a wide range of conditions, including storm events of different intensities, durations and spatial variability to minimize the risk of failure when implemented on an actual system. Such conditions are impossible to generate on the actual system within a reasonable time frame. For this reason, mathematical modeling is an obvious choice and a critical part of any sophisticated and complex RTC system design. Several years of available time series rainfall data covering a wide range of hydrological conditions can be used to evaluate the RTC system prior to actual implementation.

HydroWorks and MOUSE are the only hydraulic models that have the RTC option allowing engineers to investigate possible options, such as diverting flows from one part of the system to the other utilizing a logic which specifies that if flows in a given sewer exceed a certain rate, excess flows are diverted to another interceptor sewer, or if rainfall exceeds certain intensity, certain penstock gates within the sewer system will open to divert the excess inflow to a creek or a river. RTC makes it possible to evaluate the merits of various improvement schemes to identify the most economical solutions, and testing of planned flow management strategies under fully dynamic hydraulic and hydrological conditions and control instructions for local and global appurtenances. Planning and designing the operation strategy is a vital stage in the introduction of any RTC system, and modeling is a critical part of the planning and design process.

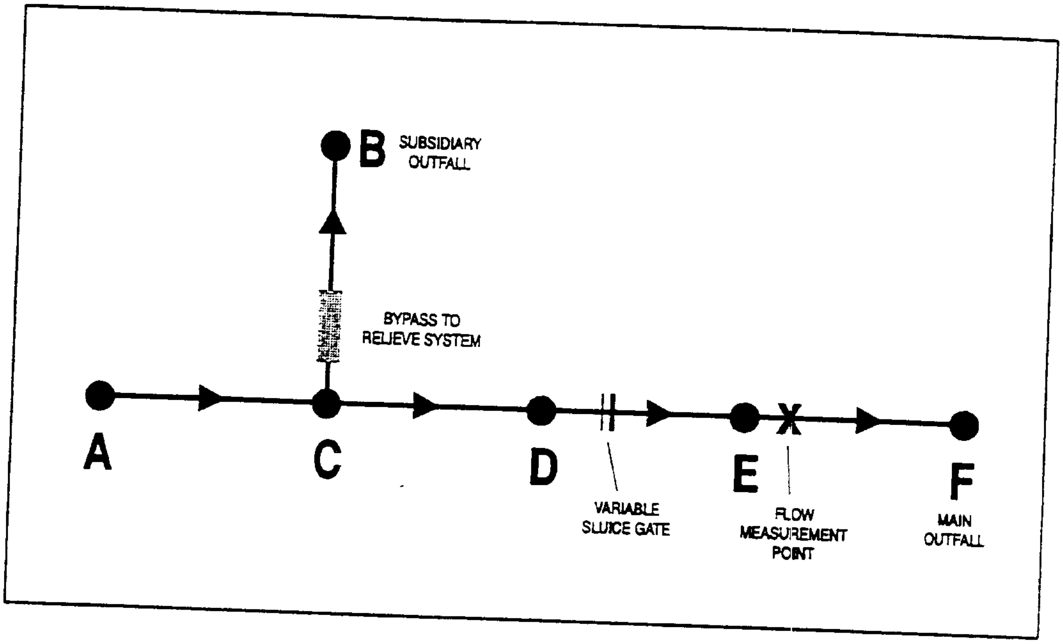
RTC SYSTEM COMPONENTS

The RTC system consists of the following components:

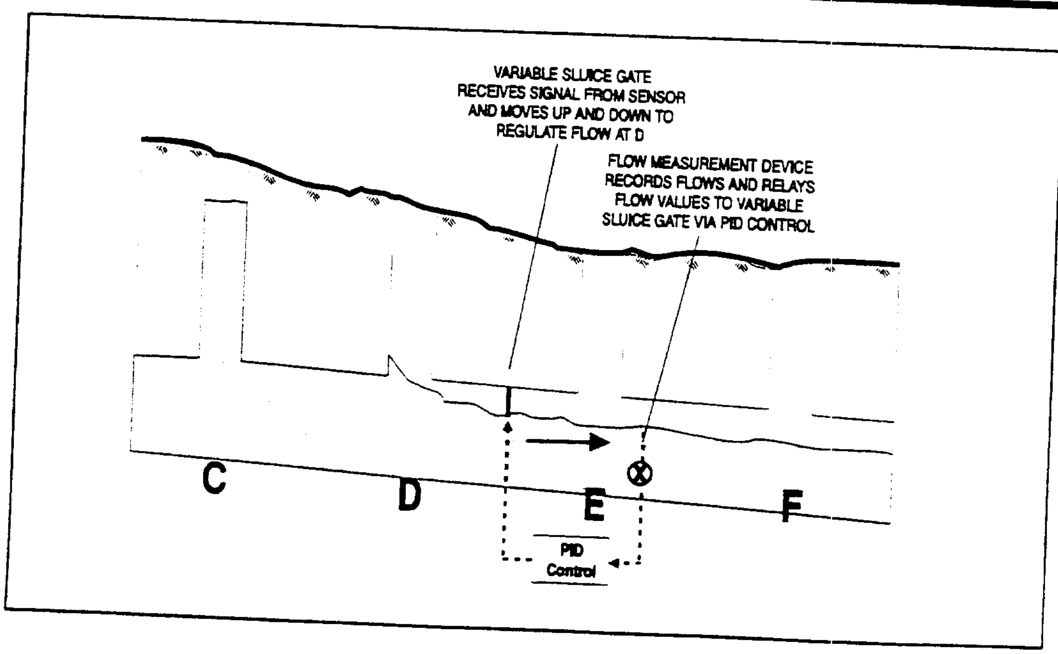
- Regulators: Control structures which can physically constrain the flows, they can be either continuous, where the variable can take any value within a permitted range such as a sluice gate, or discrete, where the variable can be only "off" or "on" such as a pump. A regulated variable is controlled by a regulator - either the physical position of the regulator, (for example the opening of a gate), or the flow at the regulator.
- Setpoint: The desired flow condition to be maintained by regulators, or the target value of the regulated variable which a regulator is to achieve.
- Range: Trigger levels for measured variables such as flow, depth, or rainfall.
- Conditions: Logical conditions which can be true or false depending on whether ranges have been triggered.
- Rules: Combinations of one or more ranges which allocate a setpoint to a regulator. An incremental rule moves the regulator by a fixed increment to either increase or decrease the setting of the regulator. A rule gives a value to a setpoint based on the value of the output condition.
- Controllers: Devices which define the detailed operation of how a regulator meets a set point.

A condition is a logical variable which has a label and a value of true or false. It can be output by a measurement range or by a logical operator, and can provide the input to a local regulator. A logical operator is a combination of logical conditions which provide an output condition.

Direct control is used where the structure is under the direct control of a regulator. For example, if the target is to control the flow to treatment works, then a discharge control would do this directly. A sluice gate can be controlled indirectly by relating the gate position to the flow through the gate.



Typical PID Controller to Regulate Flow
Figure 1



PID Control
Figure 2

R0025281

A Proportional Integral Differential (PID) controller is a method of controlling a regulator to achieve a setpoint by placing a measurement sensor at the point where the defined condition is required and using this to control the movement of the gate. The controller takes into account the rates of change of the measured variable and the regulator. For a PID controller, the measurement interval is the time step at which the controller compares the setpoint and the actual variable to set a new value of the regulator.

Figure 1 shows a PID controller for regulating flows. The objective of the PID controller is to regulate flows through sewer segment EF, by raising or lowering the variable sluice gate regulator at D, so that flows in segment EF do not exceed 1.0 m^3/s. In the hydraulic model, a sensor is placed at location E to measure flows through sewer segment EF. A PID controller uses the information from this sensor to vary the opening of the sluice gate to achieve the setpoint flow of 1.0 m^3/s in sewer segment EF. At the next time step during the simulation, the PID controller again checks the flow through segment EF and adjusts the position of the sluice gate accordingly to maintain the flow through segment EF at 1.0 m^3/s. This process is repeated throughout the simulation at each time step. This example demonstrates how a PID controller can be used to evaluate the backwater effects caused by regulating flows to the treatment plant at 1.0 m^3/s in sewer segment EF. The excess flow can be backed up in the sewers upstream from the variable sluice gate or discharged through the bypass in segment CB.

The combination of RTC rules gives engineers the ability to investigate multiple options of optimizing the operation of the sewer system.

For the PID controller described, a maximum and minimum range is defined in the RTC file. The range for the sensor is used as a scaling factor for the variable E, which forms a part of the equation used by the PID controller.

$$E = \frac{Observed - Setpoint}{Range} \qquad (1)$$

Where:	E	=	Scaling factor for measured variable
	Observed	=	Value from the sensor
	Setpoint	=	Value to be maintained (1.0 m^3/s)
	Range	=	Trigger levels for measured variables

The equation used by the PID controller to calculate how much change to make to the operation of the regulator is given by equation 2:

$$\Delta S = P\ (E + I\int E dt + D\frac{\partial E}{\partial t}) \qquad (2)$$

Where:	ΔS	=	Action to be performed by regulator
	P	=	Proportional coefficient
	E	=	Scaling factor variable (See equation 1)
	I	=	Integral coefficient
	D	=	Differential coefficient

R0025282

DATA REQUIREMENTS

The data required for defining RTC facilities in HydroWorks hydraulic model for example are the physical structure geometry and the operating limits. The physical structure of the regulator and the operating limits are defined with the network inventory. The sensors and control rules are described in a separate RTC file. For a regulator, the data required may consist of crest level of a variable crest weir, width of the variable sluice gate, height of gate (sluice gate or penstock), vertical opening of the gate, and maximum or minimum discharge. An initial value of the regulated variable can be defined which gives the initial state of the regulator. The minimum and maximum settings, the speed or the rate of change of the regulated variable, and the thresholds of the regulator can all be defined in the RTC file. If the change which is to be made by a regulator in a time step is below this threshold, the action will not be performed.

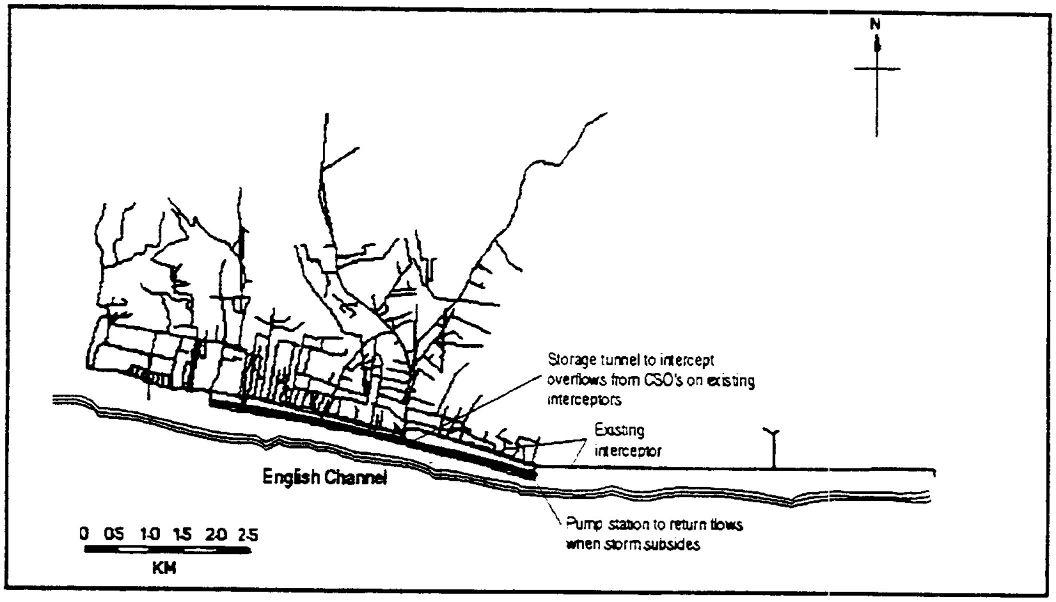
RTC APPLICATIONS

During the past few years RTC has been emerging as an alternative approach to reducing CSOs, SSOs, and pollution problems. Although there are still only a few applications of RTC in collection systems throughout the world, on many projects the cost of RTC system has been found to represent only a small fraction of the cost of constructing such alternatives as parallel or replacement sewers, or new storage facilities. Sewell and Schultz[3] in 1986, found that the cost of developing an RTC system would be between \$0.21 and \$0.31 per gallon per year, while the costs of building storage facilities to provide equivalent reduction in CSO would be between \$1.50 and \$2.00 per gallon per year. Examples of RTC applications in system optimization are:

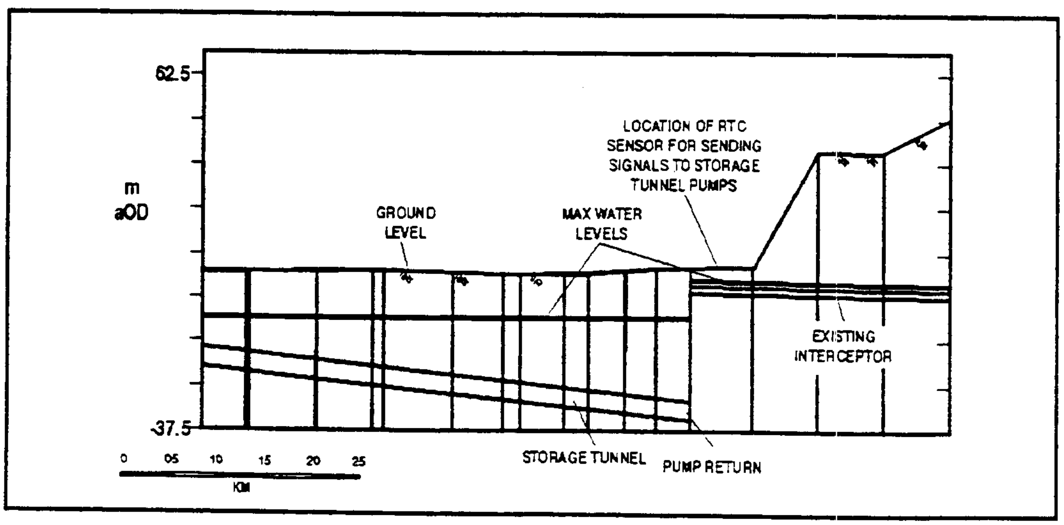
- Seattle, WA - Control of flow in sewer system to reduce CSOs.
- Brighton, England - Control of flow from a storage tunnel to an existing interceptor.
- Bradford, England - Management of numerous storage tanks and CSOs.
- Bilbao, Spain - Interceptor management to minimize pollution.
- Paris, France - Management of CSOs and flows through to the treatment works.

Brighton is a coastal town and a popular holiday resort in southern England. The existing interceptor sewer, which runs along the beach, is overloaded during wet weather, causing discharges to sea. In order to alleviate the impact of CSO discharges, a 150,000 m^3 storage tunnel was to be constructed along the beach to intercept flow from eight CSOs during wet weather. The intercepted flows are to be returned to the existing interceptor from a pumping station located at the outfall of the 5.1 km storage tunnel when the storm subsides. The HydroWorks model of the sewer system developed for this analysis includes the RTC option, which allows the control system of the outfall pumping station to be modeled. Thus, the return of flows from the storage tunnel to the existing interceptor is realistically represented in the model. The extent of the system serving approximately 250,000 residents is shown on Figure 3. Figure 4 shows the longitudinal profile of the storage tunnel, the location of the pumping station to be controlled for the optimum utilization of the storage tunnel, and the location of the RTC sensor which triggers the operation of the pumping station. Figure 5 shows the return pump which turns on to begin emptying the storage tunnel when spare capacity becomes available in the existing interceptor. Spare capacity becomes available when flows in the existing interceptor fall below 3.0 m^3/s. In effect, the RTC system involves maintaining flows to treatment at 3.0 m^3/s. Figure 6 shows how flows to the treatment plant are maintained through pumping from the storage tunnel whenever there is capacity available in the interceptor. The objective of the study is the RTC of return pumping from the storage tunnel to minimize: pumping; flooding; pollution; and combined sewer overflows. The RTC provided a platform for studying a range of options for improvement of the sewer system, allowing full evaluation of the performance of the storage tunnel and the hydraulic performance of the existing sewer system. This enabled the potential investment in the sewer system to be tested thoroughly so that cost-effective solutions could be confidently developed. The following are the main benefits of the Brighton RTC modeling:

- Optimizing in-system storage on existing interceptor and new storage tunnel facility.
- Equalizing and maintaining flows to treatment at 3.0 m^3/s.
- Preventing surcharge conditions in the existing interceptor sewer.
- Minimizing the number and volume of overflows from the storage tunnel.
- Optimizing the operation of the outfall pumping station on the storage tunnel, thereby minimizing energy consumption of the pumping station.



Optimization of storage tunnel using RTC
Figure 3



Location of RTC sensor for storage tunnel optimization

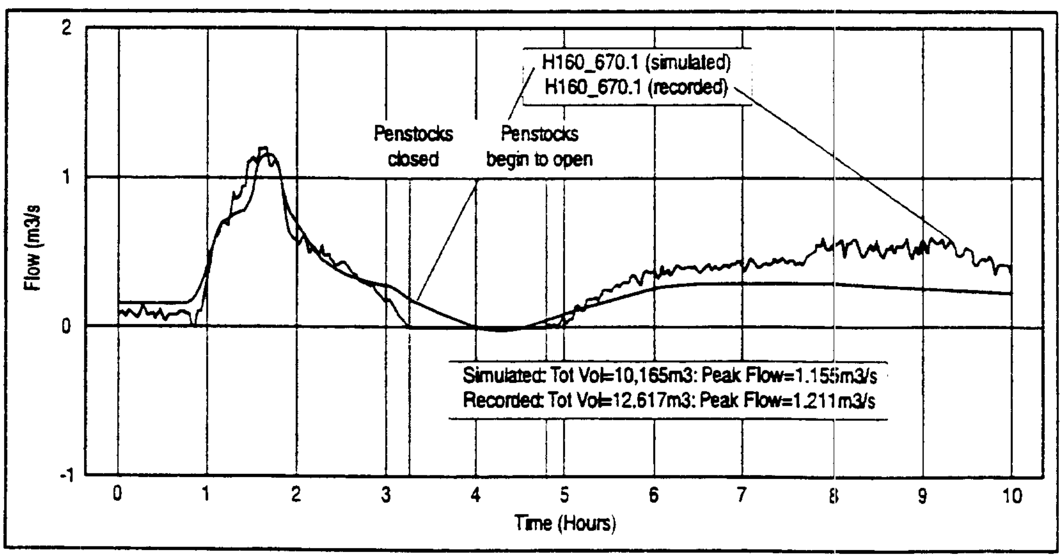
RTC for maintaining flows to treatment
Figure 6

Many existing collection systems have limited RTC systems, such as variable discharge pumping stations, variable sluice gates, and automated penstocks. The objective of such systems is to adjust pump speeds, and gate positions during a storm event to increase the use of in-system storage in response to changes in rainfall patterns and flow conditions within the sewers. In most real time control systems, the decision making process is computerized. In a computer-controlled system, a pre-programed computer decides when and how regulators are to be operated, though it is supervised by operators and can be manually over-ridden at any time. During a hydraulic model calibration of such systems, it is important to accurately represent the RTC system and calibrate the operation of the RTC system against operational data, providing confidence in the operation of the RTC system, prior to using the model for hydraulic evaluation. The calibration is achieved using a hydraulic model with the RTC option. During model calibration for the Derby Improvement Strategy Project in England, it was necessary to use the HydroWorks RTC module to accurately represent the real time behavior of penstocks protecting the treatment works at the outfall of the sewer system. The penstocks are closed when the flows to the treatment works exceed the plant capacity. When the gates are closed, the interceptors upstream from the treatment works are utilized for storing excess flow until the storm subsides, and the gates begin to open.

It can be seen from Figure 7, that the penstock gates are closed at approximately 3 hours into the storm event and remain closed for about 2 hours. The gates begin to open about 5 hours into the storm event.

By using HydroWorks RTC, the real time behavior of the penstocks was accurately modeled during model calibration, thus gaining valuable insight into the operation of the penstocks, before using the model for further evaluation of the sewer system. Without accurate representation of the RTC rules in the model, it would not have been possible to realistically predict the behavior of the penstocks, and to recommend improvements to the system.



RTC for modeling penstocks protecting sewage treatment works
Figure 7

CONCLUSIONS

Real Time Control (RTC) modeling enables sewer system controls, such as penstocks and movable weirs, to be modeled in a sophisticated manner, with consideration to their real time functioning. Even if the sewer system has adequate capacity to contain the flow, flooding and spills of untreated wastewater can occur. In many systems, the flows are not effectively routed, failing to take advantage of the storage capacity in the system. RTC enables effective modeling techniques for planning preventive measures against flooding and pollutant spills and for optimizing the performance of existing systems, as well as aiding in the design of more cost-effective and efficient systems. It enables the selection of the best locations and operating patterns for sewer system appurtenances under a wide range of hydraulic and hydrological conditions. RTC modeling requires the use of accurate and sophisticated models to a much higher standard than ordinarily used for sewer studies. The governing equation of the hydraulic model must be St. Venant's flow routing unsteady state equation, capable of simulating full backwater and attenuation in the sewer system. Of the major hydraulic modeling software programs available (HYDRA, HydroWorks, MOUSE, and SWMM), only MOUSE and HydroWorks have full RTC capability. It is not only impractical, but also a high-risk investment to implement an untested expensive RTC system in a collection system. Thus, modeling provides the obvious choice for testing the RTC system prior to implementation, enabling the investment in the sewer system to be throughly tested so that cost-effective solutions are confidently developed. The cost of developing an RTC system is usually between \$0.21 and \$0.31 per gallon per year, while the costs of building storage facilities to provide equivalent reduction in CSO could be between \$1.50 and \$2.00 per gallon per year [(3)]. Thus, the cost of RTC systems represent only a small fraction of the cost of constructing such alternatives as parallel or replacement sewers, or new storage facilities.

ABSTRACT

Real Time Control (RTC) is viewed more and more as a very effective and inexpensive solution for CSO control, by maximizing the use of in-line and off-line retention, and wastewater treatment capacity. While Municipalities and Water Commissions are realizing that RTC would be advantageously applied to either reduce CSO and/or reduce the size of their CSO control infrastructures, few are well prepared to integrate this technology in their overall plan, the different type of RTC system could adapt better to their situation, and how it can be implemented.

Real time control systems can take many configurations, from local control, with or without supervision, to global integrated automated predictive real time control. Each of these configurations is best applied to specific network conditions. The potential advantage of each configuration must be evaluated against the level of sophistication and automation that can be supported locally. A more centralized, integrated, and predictive system, improves the gain from the management of a complex network of stations, but entails the implementation of more diverse software and equipment.

Asseau BPR has been involved in many studies and application of CSO control projects that involved RTC applications since more than ten years in the city of Laval (Canada), the Quebec Urban Community (QUC, Canada), the Ile-de-France Region (France), the Northeast Ohio Regional Sewer District (Cleveland, Ohio). While realizing the QUC RTC system in the early 1990s, we realized tools to analyze RTC operation were unexistant and available RTC technology were deficient in many respect when applied to sewer network applications. Compared to most industrial operations, the context of RTC of sewer network is quite different: local stations are spread over a large territory, working conditions are septic and highly corrosive, and events highly variable in time and space.

This is the reason why Asseau-BPR initiated a five year R & D project, ending in June 1998, to develop methods, software, and technology specifically designed to realize CSO control projects with coherent and integrated tools that cover all phases from the monitoring, diagnosis and design phase, to implementation of real time control. We present here the technological evolution that lead to the development of some of these tools and technology and now make real-time control a more feasible and accessible solution than ever before.

INTRODUCTION

Real Time Control (RTC) is viewed more and more as a very effective and less expensive solution for CSO control, by maximizing the use of in-line and off-line retention, and wastewater treatment capacity. While Municipalities and Water Commissions are realizing that RTC would be advantageously applied to either reduce CSO and/or reduce the size of their CSO control infrastructures, few are well prepared to integrate this technology in their overall plan, the different type of RTC system could adapt better to their situation, and how it can be implemented.

Real time control systems can take many configurations, from local control, with or without supervision, to global integrated automated predictive real time control. Each of these configurations is best applied to specific network conditions. The potential advantage of each configuration must be evaluated against the level of sophistication and automation that can be supported locally. A more centralized, integrated, and predictive system, improves the gain from the management of a complex network of stations, but entails the implementation of more diverse software and equipment.

The potential of RTC implementation must be assessed rapidly, as another element of a CSO plan alternative. This was shown extensively in the previous WEF Wet Weather Specialty Conference in Quebec City (June 1996). The most difficult element to define to assess the potential application of RTC, is to evaluate the control rules or algorithm that will best regulate the flow for specific network layouts. Hence, it is most valuable to have within a hydraulic model not only the capacity to simulate dynamic flow control devices, but also an engine that can find, through an optimization process, the best control logic for each configuration that is tested.

When RTC potential is assessed, its implementation must be resolved and must translate the potential into reality, which involve the following elements: the control strategy; the configuration of the control system; each element of a control system; the choice of technology; the robustness required; etc.

Asseau BPR has been involved in many studies and application of CSO control projects that involved RTC applications since more than ten years in the city of Laval (Canada), the Quebec Urban Community (QUC, Canada), the Ile-de-France Region (France), the Northeast Ohio Regional Sewer District (Cleveland, Ohio). While realizing the QUC RTC system in the early 1990s, we realized tools to analyze RTC operation were unexistant and available RTC technology were deficient in many respect when applied to sewer network applications. Compared to most industrial operations, the context of RTC of sewer network is quite different: local stations are spread over a large territory, working conditions are septic and corrosive, and events highly variable in time and space.

This is the reason why Asseau-BPR initiated a five year R & D project, ending in June 1998, to develop methods, software, and technology specifically designed to realize CSO control projects with coherent and integrated tools that cover all phases from the monitoring, diagnosis and design phase, to implementation of real time control We present here the technological evolution that lead to the development of some of these tools and technology and now make real-time control a more feasible and accessible solution than ever before.

A SURVEY OF EXISTING REAL-TIME CONTROL SYSTEM

Real-time control systems (RTC) applied to the control of sewers and CSOs has been developed since as early as the late 1960s. The idea is not new. At the time, RTC seemed a very worthwhile venture to reduce the risk of flooding and the impact of combined sewer overflows. Because of the risk involved in developing these new systems, the US Environmental Protection Agency helped finance some demonstration projects.

The first US EPA demonstration project in this field started in 1966 and was implemented in Minneapolis-Saint-Paul. Other projects followed. In the United States, nine real time supervision and control projects have been found in the literature. Most of them were initiated in the 1970s and implemented in the 1980's. Among them we have : Seattle, Wa; Rochester, NY; Cleveland, Oh; Detroit, MI; Chicago, IL; Milwaukee, WI; San Francisco, Ca; Minneapolis-Saint-Paul, MI; Lima, Oh.

All these projects have implemented supervisory systems and, except for Seattle, all their control systems operate gates, inflatable dams, and pump stations with local reactive control logic. Seattle is the only remaining automatic central control system in operation, although many others had planned to implement such centralized control. Reasons for not going forward with central control include : unreliable communication (Cleveland); hardware failures (Detroit); operators resistance (Rochester, Detroit); the control system never worked as planned (Minneapolis-Saint-Paul); abandon (San Francisco). Reference (Schilling, 1987; Gonwa and Novotny, 1993).

In Europe, real time control projects lagged behind the North American experiences. It was not until the 1980's that such project emerged, although from the few experiments of the 1980's, such as in Hamburg (Germany) and Seine-Saint-Denis (France), the impetus has never vanished, and has even gained momentum in recent years.

In France, there are presently 8 real time control systems in operation in Bordeaux, Hauts-de-Seine, Marseilles, Metz, Nancy, Seine-Saint-Denis, Val-de-Marne, and the Paris agglomeration. In Germany, we found 4 real time control projects (Bremen, Hamburg, Munich, and Stuttgart), while in Switzerland there are also 4 RTC systems in operation (Berne, Fribourg, Geveva, Lausanne), in Sweden one (Göteborg), and in Denmark (Copenhagen). The objective of these systems is mostly for flood control, although the most recent applications are for CSO control. The configuration of these systems are quite similar to those in the U.S. : they all have central supervisory systems, and except for four applications, all have implemented local reactive control rather than centralized control. This list is certainly not exhaustive and will grow steadily in the future.

CRITERIA FOR NEW REAL-TIME CONTROL TECHNOLOGY

Since the development of the first RTC systems, the computer and information technology has taken a giant leap in processing capacity, in user-friendliness, in accessibility, robustness and in reliability. This has helped increase the capacity and reliability of all elements of RTC systems, most notably in the speed and memory of local stations, of telecommunications systems, and of central computing and polling capacity. Rapidity of processing is key to many real time control projects. Where concentration time is small, decisions have to be made rapidly, say each 5 minutes, and this for all control sites.

Many of the original technological hindrances in implementing RTC systems now form part of the folklore of the past, although there still remains some deficiencies to be addressed. Technology failures are still present in any system. Hence, often in early systems, many RTC systems were never put into operation because everything had to be in perfect order before it could properly function. Because of the multitude of components involved, equipment failures occur. Instead of overlooking this aspect, or declaring forfeit before trying, we now realize that RTC systems must handle downgraded modes that is, still perform when for example, a sensor or a local station is not responding, when some data did not reach the central, when a gate is blocked, when sensors send erroneous or diverging data, etc. Reliability is also built into a RTC system by applying data validation – not only data filtering – , and by adding some redundancy in the most crucial places. The reliability of RTC systems is best analyzed during the design phase. At that stage, it is crucial to test the effect of the loss of each component in the system or their malfunction. Risks must be assessed and addressed at an early stage.

Data management has also evolved much. Now, huge amounts of data can be processed and stored in real time, data organization has changed from the past linear file format, to relational database organization and even object oriented databases. Hence, data can be easily stored, organized and accessed, during and after events. This improves reaction time during events and the capacity to analyze and improve control performance based on past events. To do post event analysis, it is best if the on-line control software can be the same as the design, or off-line, software, hence more readily ensure that what we see during the design is what we get during operation. This capacity to continuously improve the performance of control can be best approached when the control logic software is used both for analysis and for operation.

The capacity of local stations have also improved much. Local PID units have more memory, they can be programmed in C language, they can handle more data, and be left unattended for longer periods of time. Hence, the control logic can be decentralized a lot more than few years ago. And because much information is better accessible at the local level, new real time control system configuration must take advantage of this.

When considering central control, telecommunications speed and reliability are key to the whole performance of the RTC system. Decision making is based on the accuracy and reliability of field monitoring data, on information on the state of the system. Furthermore, control set points are transmitted back at the flow regulation stations at each time step. The pressure on the telecommunication system makes it difficult not to develop new telecommunication protocols and management programs to find an equilibrium between reliability and speed of transmission.

We will see in the next section how it is possible to address these criteria to design and develop a family of integrated tools for real time control design and operations.

A COHERENT AND INTEGRATED APPROACH TO RTC

A the end of the 1980's and beginning of the 1990's, Asseau-BPR was involved in two CSO control design projects in Quebec : for the Quebec Urban Community (QUC) and the city of Laval. Both these systems were good candidates for introducing real time control. In Quebec, a centralized system seemed to yield better results, while the city of Laval could initially do with local reactive controls. At the time, no hydraulic software represented dynamic regulation. To analyze RTC operation, we asked the National Research Institute (INRS-Eau) to developed a *non* linear simulation-optimization model that could rapidly simulate and optimize central dynamic control and be put into operation. This system was custom made for the QUC application. For modeling local reactive control in the Laval project, we limited our works to programming local reactive logic and integrated the module into SWMM.

The more we advanced in the design of these two systems, the more we found we could not readily find systems that could well adapt to the kind of specifications we developed to make these RTC systems work properly with all the robustness and performance we expect. Furthermore, we recognized the great potential of RTC applications to reduce CSO control costs and the need to develop an integrated system that could be applied to many applications elsewhere, save money and time in its development, and not to start anew everytime.

We then initiated in 1992, a $ 10 million R & D project. Half of the funds were attributed to the development of sewer analysis and CSO control plan design methodologies and software – among which, a standardized diagnosis methodology, a simulation-optimization software for CSO control plan development including real time control operation aspects. Another important part of the project consisted of real-time control systems components, such as local stations configuration, control programs, data validation programs. Also, telecommunications protocols, communication management software, and speed and reliability tests during storm events. Finally, real time control database, and configuration of supervisors. Most of these components have been completed and tested in the realization of projects (Ile-de-France, QUC, Laval).

We describe below the main characteristics of the resulting integrated system. This will show how we address some of the problems identified in some of the existing RTC systems presently in operation. The integrated approach using system called MED, for Minimization of Effluent Discharge. Each components or modules have been given names addressing the affiliation to MED. *Just keep in mind that solution is based on approach, technologies, and experience; modeling tools are like pipe wrench for a pipe fitter, only a tool.*

CSO control design tools

The design of a CSO control long term plan is performed in four complementary phases:

1. Characterization of the existing network
2. Diagnosis of the existing CSO problem, usually through modeling and calibration
3. Design of a CSO control strategy (long term plan)
4. Tests of the performance of the control strategy.

This process involves many different specialists and the processing of an important amount of data.

Adding treatment, transfer, or retention capacity to control CSOs can be very costly. Therefore, it is essential to ensure maximum use of the existing system and any additional facilities needed to comply with the control requirements. Real time control proves to be a very efficient and economic solution whenever some capacity transfers within a sewer network submitted to heterogeneously distributed real rainfall events are possible.

Furthermore, it is most advantageous to be able to design, test, and operate a real time control system with the same tool. Conceptually, the system can be compared to a robot assembly line. At each stage of the assembly line, each robot produces an action which adds a sub-part to an object constructed from a succession of robot action. When the process needs to be modified, system engineers design new routines and test them off-line with dedicated simulation tools. System efficiency can be best adjusted off-line and implemented whenever it is fine tuned. Necessarily, the simulated program is the one to be implemented in the assembly line. The same design and implementation process applies to the CSO control field. This is also why, off-line simulation capabilities are useful even after the implementation of real-time control in order to learn from experience and continuously fine tune the control procedures. This concept was retained in the development of MED-SOM, a linear simulation-optimization model software used for the design optimization of CSO control long term plans and the operation of RTC systems. MED-SOM can simulate and optimize the main flow regulation control modes that is, static control, local reactive control, and global predictive control. (See Colas, 1998 for more information on MED-SOM) *MED-SOM is a design tool, connected to your preferred modeling software (MOUSE, HYDROWORKS, SWMM, XP-SWMM, which can be used as real time decision making tool, but does not keep your organization as a slave.*

DIAGNOSIS AND DESIGN

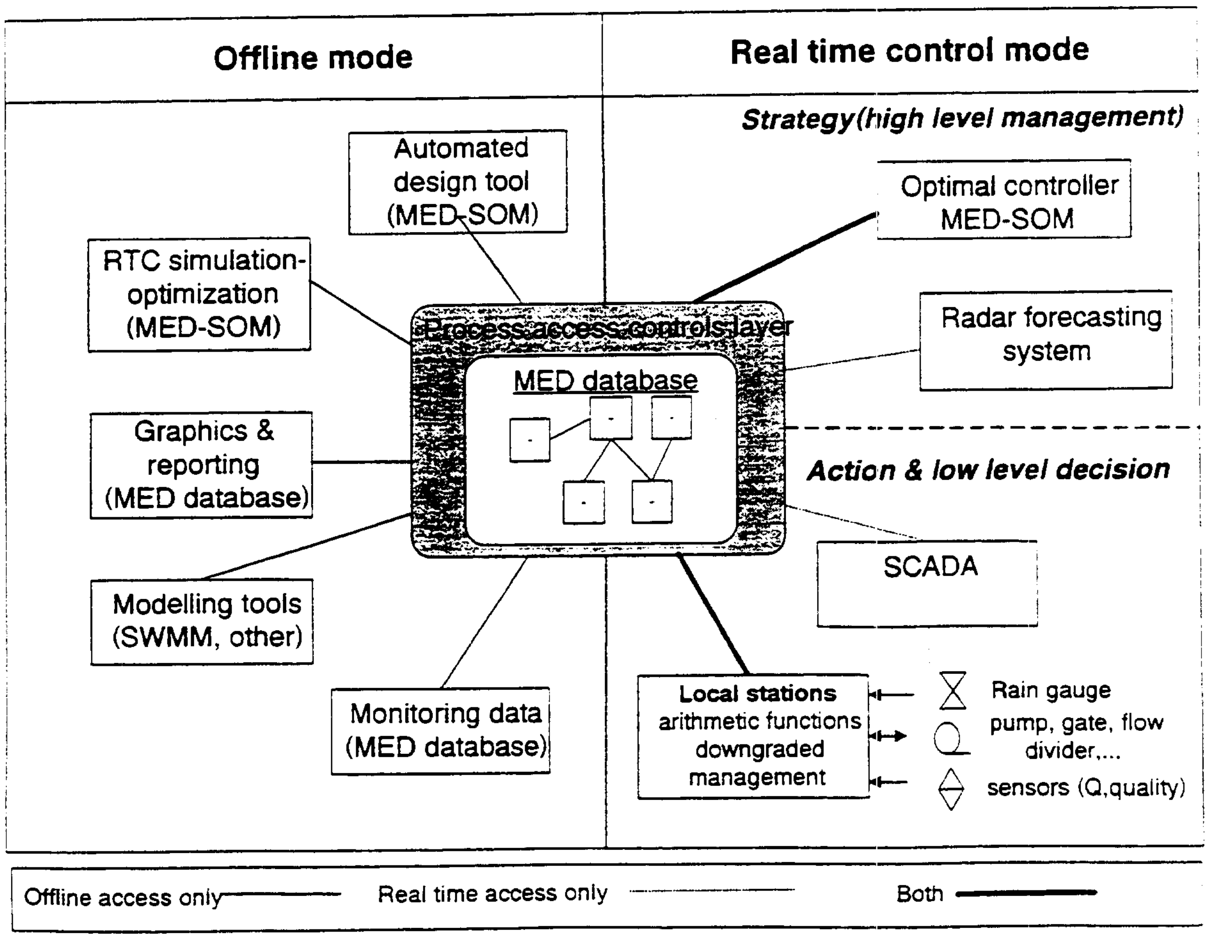
Real time control is applied to maximize the use of facilities. Because it may not be the panacea for all situations, the potential benefit of real time control must be assessed first. Long term planning also involves a complete analysis of the network to find the most feasible, reliable, and economical set of solutions that fulfills the overflow requirements. Solutions include: adding conveyance capacity to locally restrictive sections of the network; adding control gates for in-line retention; adding detention tanks with inflow and outflow control gates; modifying and/or adding capacity to wastewater treatment plants; adding online treatment at overflow sites.

Based on the behavior of the modified network. the next step consists of identifying distribution constraints imposed to the simulator-optimizer, in order to favor overflow at selected sites and eliminate overflows at other more sensitive sites. MED-SOM simulation-optimization results help demonstrate the power and the flexibility of the real time control tool since it can transfer overflows from one site to another, impose and respect constraints and manage simple optimal actions from control strategies. Furthermore, those control strategies enable managing the filling and draining of retention tanks without creating any surcharge on the interceptor network and/or at the wastewater treatment plant.

Architecture of the integrated MED system

The MED system architecture is shown in Figure 1. The MED database system serves as the central bond between various tools and processes required for off-line simulations and for on-line real-time control. Some of the dedicated processes are used in the two modes, off-line and on-line, while others are more specific. Finally, the urban drainage network model, once designed, is read from the database by the real time control system and it becomes the network to control.

Figure 1. **Functionalities of the integrated MED system throughout the design and operation process**



As it can be seen in Figure 1, there is a set of tools for each activities.

R0025294

Monitoring :

Field data can be received online from local stations and recorded into the database, and/or entered manually. The data include rainfall, water depth, flow velocities, and water quality (SS, BOD, COD, Cu, Pb, ...). These measurements can be validated by a skilled technician with the help of specialized graphical tools. Once validated, the data can be easily manipulated to produce statistics, data series at any time steps, graphics, tables, and reports. Different data series can then be superimposed to facilitate the analysis of results, and the choice of events for calibration, validation, and design. This data is then available to calibrate models. The MED Monitoring data management module can work on its own or with the complete package. It is a powerful monitoring data management tool that was designed for analysis and design purposes, not only for visualization of data.

Diagnosis :

Within the integrated system, the diagnosis of combined sewer overflows requires three sets of tools. All data input and output are handled by the MED database. This enables the user to interface with a variety of modeling and simulation software, such as SWMM, HYDROWORKS, MOUSE, CAREDAS, etc. As such, modeling tools will assist the user in defining the characteristics of the sewer network, catch basins, and other facilities. The simulation tools provide the functionality to easily define the simulation framework, identify a simulation package among those available, provide the input files to the simulator and read back the results into the database. Graphics and report tools can then be used to visualize results. The integrated system includes a built-in simulator, a real-time simulator-optimizer, MED-SOM. Parameters are then set according to the choice of simulators. Consequently, the same network can be simulated with different simulators.

Planning and testing a CSO control strategy :

As it was presented above, the dynamic simulation-optimization model, MED-SOM, is used to maximize the use of existing capacities, with or without the use of real-time control. This dynamic model is able to auto-calibrate itself on a fully non-linear hydraulic model that runs in parallel. Retention and or treatment capacities can then be added, if necessary, to attain the desired level of CSO control. The design strategy can be handled manually, by a trial and error method, or automatically processed based on a set of optimization techniques. With this automatic procedure, one has to define the physical locations, type, cost curves and performance parameters of potential facilities. An optimization routine chooses among this framework the least costly solution set that satisfies CSO control criterias. The size and location of the new facilities are then defined. This routine is coupled with the dynamic simulation-optimization model for the analysis of performance. The modified network can then be tested through simulation against various rainfall events to ensure fine tuning of the *optimal* solution set. All types of monitoring errors or other equipment failures can be simulated. The resulting performance can then be compared to see how the operating strategy will perform under downgraded situations.

Modules for the operation of a real-time control system

An integrated predictive RTC system operates the general state of the network. In order to accomplish this task, these types of systems need to be central remote control systems. The network control is distributed over three hierarchical levels. At the first control level, local stations are responsible for automatic regulation of flow regulators and the network monitoring. At the second level, the supervisory system acts as an interface between the operator and the network. It also is responsible for task scheduling and programming, and for alarms management. At the third level, the decision support system (DSS) is responsible for the optimization of flow regulation control set points Communications between level two and three is ensured by radio or modems and telephones lines. Level one and three communicate through a local area network (LAN). A radar rainfall prediction system completes the architecture of the system (figure 1). This system is also linked by a LAN to the DSS. The heart of the system is composed of a relational database management system (RDBMS) that stores all information and is the center for data exchange among level three and level two programs. The data model contains the description of all elements of the system : local stations and sensors; the sewer network and all its possible configurations; the parameter of the DSS and the control objectives. It also stores all time dependant data, such as all measurements and flow regulation set points.

Local stations :

There are as many local stations as there are data acquisition and flow control sites. Local stations are typically composed of sensors, flow regulators and data logging and communication apparatus. Local stations perform arithmetic functions during rainfall events, such as: transformation of local signals into data, local and remote communication, transformation of control set-points into field implementation, and implementing default or local flow control strategies in case of communication failures or equipment breakdowns. Also, a local data validation routine has been designed to ensure the transmission of locally validated data.

Data validation :

Data validation is crucial to real time control. In the Asseau-BPR system, data validation responsibilities is shared amongst the three levels. At the field level (level one), data validation is based on redundancy or cross validation among the sensors and flow calculation methods. It is mostly applied at critical locations for decision making. Redundant data are processed by a statistical method derived from quality control in industrial processes. Measurements are declared valid with an associated probability, giving as such a confidence level to the data. Traditional data validation techniques do not permit determination of the data validity, although the local station needs reliable data to operate local regulators under downgraded modes. Furthermore, without reliable data the DSS would receive erroneous information on downgraded states and transmit back false control set points to local stations. Both at level one and three, data is filtered by simple control techniques, such as minimum and maximum limits, measurement gradients, and the like. Level three uses these data in its retroactive loop of the control system. This retroactive loop process helps correct prediction errors of the hydraulic model included in the retroactive process (kalman filter).

Supervisory control and data acquisition (SCADA) :

Field devices grouped into local stations, are linked to a supervisory control and data acquisition system (SCADA) in order to ensure remote supervision, transmission and implementation of set-point control measures, and management of alarms. The MED system is designed to be linked to many types of supervisory software

Rainfall forecasting system :

Setting optimal flow control set points implies that it is possible to find, within a fixed time horizon, a series of instructions as a function of rainfall forecasts for the watershed. These rain forecasts can be obtained with the use of a radar system continuously calibrated with rain gauge data. The MED system was designed to work in parallel with the radar rainfall forecasting software, CALAMAR.

Optimal control system :

Essentially, this module is responsible for the simulation of the sewer network and the selection of the optimal flow control strategy in order to maximize the use of the retention and treatment capacities within the combined sewer system, including the wastewater treatment plant. Many simulation and decision support tools and techniques can be used. Although they must be robust enough to still perform satisfactorily within a noisy environment and under downgraded conditions, such as missing data and communication or other equipment failures. MED-SOM, used for the design of the CSO strategy, coupled to specific modules embedded in the database management system has the ability to operate a real time control system under such adverse conditions.

Data flow :

Monitoring data are transferred from level one to level three through different communications media Validated data are transferred directly to level three MED database. They are read by the control program which computes control set points for the entire prediction horizon. Set points are stored in the database and synchronized to current data. They are then transferred back to the local stations linked to flow regulators. Synchronization is ensured by the communication system and by the supervisor. In order to speed up data transfer for our applications, new communication protocols with error detection had to be developed.

Asseau-BPR has developed this coherent RTC approach to CSO control planning and operation over the last 5 years. The design tools have been extensively used in projects (QUC, Laval, Ile-de-France, Paris, Cleveland). Most components of the RTC system have been tested on some applications, and are presently being implemented in the city of Laval, Quebec, and in the Quebec Urban Community.

CONCLUSION

We presented some of the characteristics of real-time control projects that lead to the development of new tools and approach to real time control design and operation *Based on a large experience of CSO long term planning for a large gap of sewer networks from small ones to large complex ones using* this novel integrated RTC system, called MED, is composed of many elements that can be used for the design of CSO control plans, including different types of operational modes, such as static control, local reactive control, and global predictive real-time control. From extensive experience is CSO long term planning for a large group of sewer networks from small ones to large complex ones using this novel integrated RTC, MED was developed. It is composed of many elements that can be used for development of CSO control plans, including different types of operational modes, such as static control, local reactive control, and global predictive real-time control. Hence, the operating performances have a better chance to converge towards design performance than with systems *designed with modeling tools which can not represent real time control benefits in on a convenient way.* A central database system, MED database, acts as the central link for the design and operating components.

Among others, the most salient advantages of this integrated MED system and approach are :

- It can be adapted to any CSO control applications, whatever the advancement of the project.
- It contains all the components to design CSO control long term plans, including real time control operation
- *MED is calibrated on your preferred modeling tool leaving your staff in control of the modeling results; all optimization functions are exposed and no black box syndrom can be associated to MED*

- All components for operating real time control systems have been developed and offer the most up-to-date RTC techniques and performance. They can also be configured to many types of existing or preferred technology.
- All components are coherent with one another.
- Some of the components can be used independently, such as the monitoring data management module.
- The MED system is continuously being maintained and improved to offer the best performance.

WET WEATHER MODELING FOR A LARGE WASTEWATER COLLECTION SYSTEM

Randy Price, City of Los Angeles
Fernando Gonzalez, City of Los Angeles

ABSTRACT

The City of Los Angeles has a large and complex wastewater collection system serving 3.5 million people in about 1684 square kilometers of service area. The network consists of 10,500 kilometers of sewers varying in size from 20 to 380 centimeters in diameter. Of those sewers, 1,046 kilometers are primary sewers (larger then 46 cm in diameter) discharging to the major outfall system (large sewers carrying flow to the treatment plants). Over 50 percent of the primary sewers are 50 years or older with some of them in poor structural condition due to age and corrosion. The major outfall system is about 306 kilometers long serving four treatment plants. The outfall system has pumping plants, large and complex diversion structures and an off line storage site for wet weather conditions. Besides the City, the collection system and treatment plants serve about 23 contract agencies, which are incorporated and non-incorporated areas in Los Angeles County.

This paper describes the existing wastewater collection system and the modeling of the system with hydraulic modeling software called MOUSE in both dry and wet weather seasons. The paper includes wet weather case studies where MOUSE was utilized as a tool in the decision making process.

INTRODUCTION

The City of Los Angeles has a large and complex wastewater collection system serving 3.5 million people in about 1684 square kilometers of service area that includes 25 contract agencies incorporated and non-incorporated areas in Los Angeles County. The network consists of 10,500 kilometers of sewers varying in size from 20 to 380 centimeters in diameter. Of those sewers, 1,046 kilometers are primary sewers (larger then 46 cm in diameter) discharging to the major outfall system (large sewers carrying flow to the treatment plants). The major outfall system is about 306 kilometers long serving four treatment plants.

The outfall system has pumping plants, large and complex diversion structures and an off line storage site for wet weather conditions. The complexity of the outfall network makes the task of predicting the system's behavior very difficult. Sewer management under these conditions has been based on trial-and-error and observation of past experiences. Over 50 percent of the primary sewers are 50 years or older with some of them in poor structural condition due to age and corrosion. In addition, increases in population in the service area and increasing infiltration and inflow are contributing to need of optimizing sewer flow management. Furthermore, potential natural disasters and other unpredictable phenomena increase the uncertainty about the collection system.

The Bureau of Engineering staff has developed a series of hydraulic models of multiple alternative responses in case of severe damage to the collection system or the treatment process. Moreover, to meet the planning and operation needs of the system, a dry weather dynamic flow model of the outfall system was developed using the MOUSE (Model of Urban Sewer Systems). Arc/Info GIS was used extensively to develop the model and to effectively display the results. Nevertheless, addressing wet weather issues, capacity problems, and wet weather design concerns is crucial to effectively provide valuable wastewater collection management. The modeling of such scenarios can save the Bureau of Engineering and the City of Los Angeles time and money.

This paper briefly describes the existing collection system with some of the known problems, the wet weather model development procedures, and model results obtained in solving and understanding the known problems.

METHODOLOGY

The MOUSE model was developed in two major phases, the Metro Model and the Valley Model. The Metro model is the model south of the Santa Monica mountains in the metropolitan area, and the Valley model is north of the Santa Monica mountains in the San Fernando Valley. Since most of the City's ongoing planning projects are in the metro area, this model was developed first. Figure 1 describes the various components of the model fabrication and the steps that were involved in building input files for MOUSE.

MODEL FABRICATION

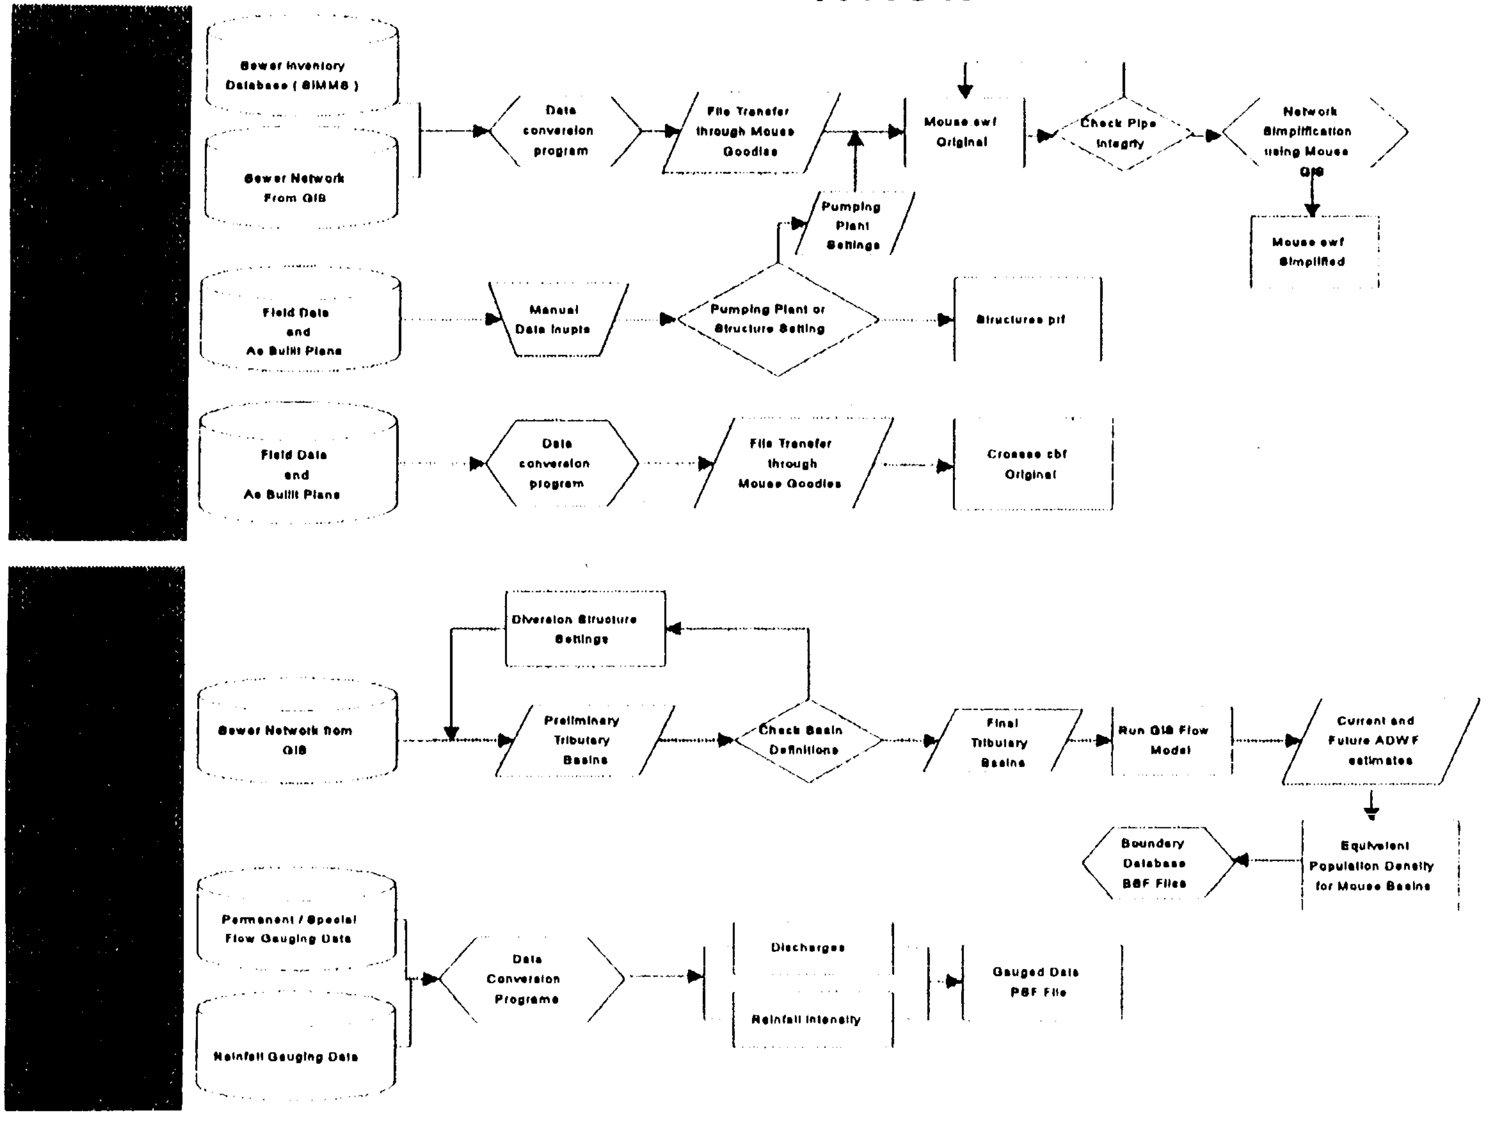

Figure 1

R0025300

The Physical Network Fabrication
The physical network fabrication process was customized by the City so that incorporating pipes, nodes, pumping plants, special control structures, and treatment plants could be accomplished efficiently. Overcoming the size and complexity of the City's sewer outfall network and the lack of readily available information regarding the sewer network, special cross-sections, treatment plants, pumping plants, and control structures was a major challenge. For effective utilization of the electronic sewer inventory data, the City developed efficient data manipulation and conversion procedures using database programs.

Dimensions of pipes, invert and top elevations, were taken from the inventory component of the City of Los Angeles Sewer Information and Maintenance Management System (SIMMS). Geographical information, such as coordinates, were taken from the GIS primary sewer network coverage. Overflow weir crests, pump wet wells and special control structures were taken from the City's *As-Built* records. Field measurements were used to verify current settings records.

The original Sewer Working File (SWF) is composed of 1,516 nodes, 2 pumping stations, 14 weir functions, and 1,561 pipes ranging in diameter from 76-cm to 381-cm for a total length of 263,195 meters. The network was checked for continuity, consistency, and missing information utilizing the MOUSE control of pipe data files and the profile drawing tool.

MOUSE GIS network editor was used for further processing and network simplification. The criteria used for simplification was: a flow direction change >30°, a slope change >0.1%, a diameter change >5%, flow capacity change >5%, or an invert elevation change >0.05 meters. The average simplification rate was 41% for pipes and 42% for nodes. The final simplified network consisted of 568 nodes and 670 pipes, 2 pumping stations, and 14 weir functions.

Through the years, as the needs for conveyance, constructability, and hydraulic efficiency have changed, different hydraulic cross-sections were designed and built into the City's sewers. In total 74 special cross-sections had to be defined and input in the database to describe the City's sewer network. These 74 shapes were variations of 4 fundamental cross-sections. They are Oval, designed in 1890, Elliptical, designed in 1905, Semi-Elliptical, designed in 1915, and Burns-McDonnell, designed in 1929. Several special programs were written to define height-to-width data for input into the model.

The pumps in the model are represented by cut-in/cut-out levels and H-Q performance curves. These data were obtained from pumping plant capacity test and technical data from the pumping plants electronically recorded flow data. Pumping plants are specified to operate at 885 L/S at 28 meters Total Design Head (TDH) and secondary operating points of 570 L/S at 35 meters TDH.

The City's outfall sewer system contains 54 major diversion structures. To simulate the operation and the correct flow split, the model includes 34 flow regulation functions and 14 weir functions. In 14 cases other diversion structures had fixed settings, and were modeled by setting the corresponding elevation in the control node. The last 14 structures required the creation of special "short pipes" to mimic special flow conditions such as underflow in special cross-section pipes.

Catchment Data
Catchment basins were defined using ArcInfo tools. Defining the sewer basins was an iterative process. First, major inlet points to the outfall system were identified using GIS. Then, using these outlets as center points, an upstream trace was performed on the sewer networks, buffers around the sewers were drawn, and polygons were generated. These polygons define the tributary area to the centers. However, from field research on flow splits and catchment areas, many basins were redefined and merged. Later, during the calibration process some sewer lines were extended for proper modeling of the network, requiring subdivision of the upstream basins. GIS provides the flexibility to redefine the affected basins with very little difficulty.

Dry-Weather Generation Model

A wastewater flow model was developed in GIS to assist the engineers in planning, analysis, and collection system management activities. The model is based on basic sanitary engineering concepts and runs on ArcInfo GIS software. The model has four major wastewater components, residential flows, employment flows, ground water infiltration, and industrial flows.

The wastewater model first defines catchment areas and overlays them with the Census coverage. This overlay process provides residential and employment population in each basin. These population numbers are then converted to wastewater flows using standard residential and employment flow generation rates. Next, the model estimates groundwater infiltration for the catchment area by overlaying the catchment basins with Infiltration/Inflow (I/I) basins. The I/I basin boundary and the infiltration rates were determined from an earlier I/I study. Finally, the model determines the industrial component from industrial discharge permit data. The summation of all these components yields the total estimated Average Dry Weather Flow (ADWF) for the tributary basins. The model generates the flows for the current year and for future years based on projected numbers. The results for the GIS based wastewater model provide the information necessary to define the catchments in the MOUSE HD model.

The MOUSE HD model defines diurnal variations of flows using the "Dry Weather Flow" option from the Boundary Data Overview. This option allows a single unit sewage flow rate and a single diurnal variation to generate sanitary curves for each tributary basin. A statistical analysis of calibrated historical data from 33 ultrasonic flow monitors defined the diurnal wastewater flow variation. Further processing of the results from the ArcInfo flow model were required to calculate equivalent catchment data. An equivalent population density was defined for each catchment basin. This number was obtained by dividing the total 24-hour flow generation by the unit wastewater flow rate. Catchments whose area was bigger than 1,000 hectares were adjusted by proportionally increasing the equivalent population density.

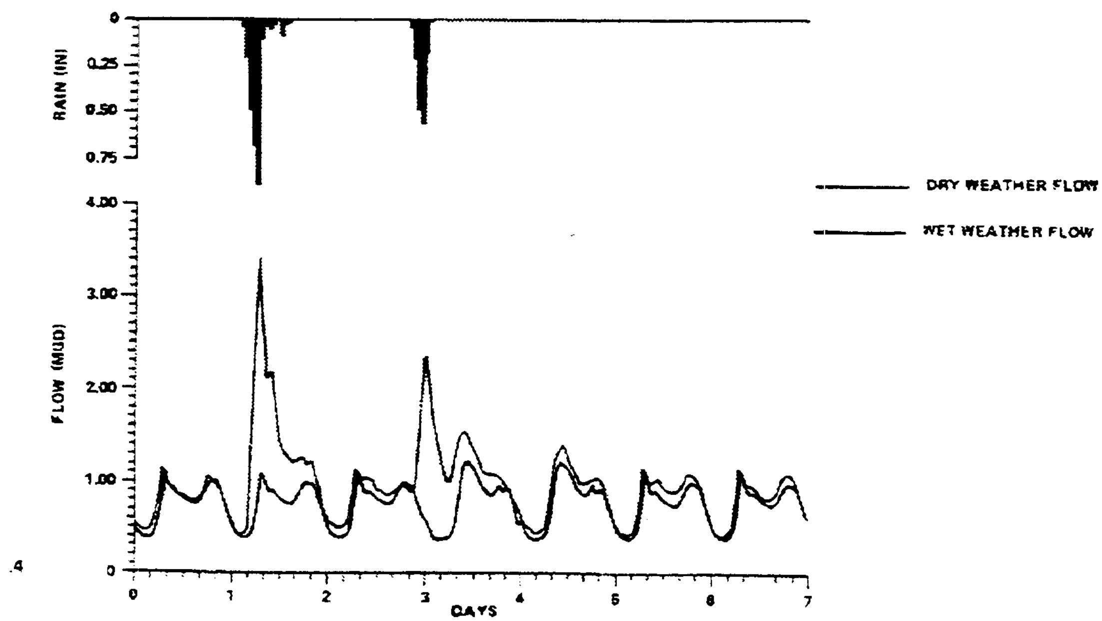

Figure 2

Wet Weather Generation Model

As part of a system wide I/I reduction study, rainfall data was collected from eighteen continuously recording rainfall recording stations. The results of the analysis indicated that Rainfall Dependent Infiltration/Inflow (RDI/I) can equal or exceed peak dry weather flow rates; groundwater and surface flow from storms contribute to infiltration; inflow comes almost exclusively from storm water. Studies of the Infiltration/Inflow in the Los Angeles

R0025302

watershed determined that approximately 10 to 20 percent of the total RDI/I is inflow and 80 to 90 percent is infiltration. Figure 2 shows a typical normal dry weather base flow and wet weather flow hydrograph.

The volume of storm water entering the sanitary sewer system is related to the age and condition of pipes and maintenance holes, and the number of direct connections from illegal lawn and roof drains. These are combined into a runoff factor "R," which is expressed as a percentage of the total volume of rainfall that could potentially enter the sewage collection system. Values for all 206 drainage basins previously identified were developed using a geographic analysis by using isohyets contours, sewer age data, maintenance records, and information from the I/I study for the City of Los Angeles.

The wet weather inflow hydrographs were generated using MOUSE Surface Runoff Models. From the choices available, Surface Runoff model "A" with level of catchment description 1 was chosen because no detail description of the catchment area is used. Rain water is reduced for a value of the initial loss plus a lumped hydrological reduction. The actual hydrological losses and the runoff process itself are left out of the computation. The total catchment surface which contributes to runoff as impervious area is determined by the "R" factor previously defined.

Model Verification

To calibrate a large model takes a long time and it is very difficult to maintain the overview with a model of this complexity. Therefore, the approach taken was to verify the ability of the hydraulic model and flow generation model to replicate the observed behavior of the actual system on both dry weather scenarios and wet weather scenarios for 9 sub-models.

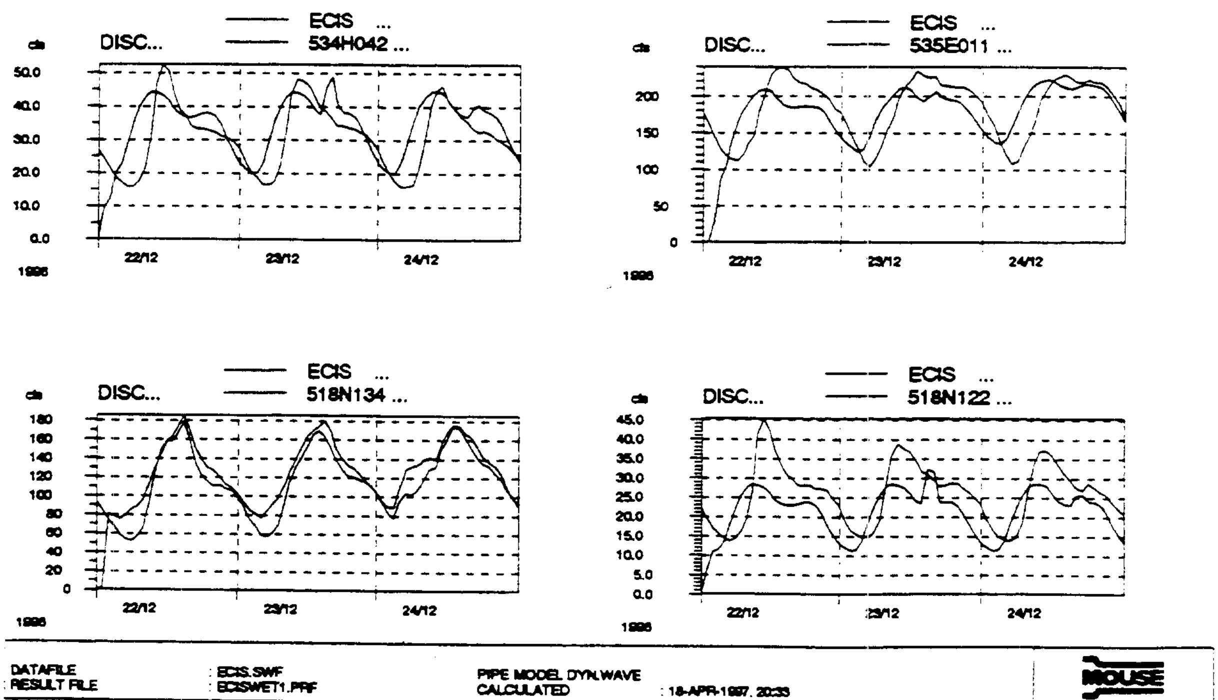

Figure 3

Dry Weather Behavior

The Manning's *n* friction factor and the predicted nodal inflow were calibrated to match the actual dry weather flow levels. Friction factors were changed to accommodate for silt and debris deposits, especially in older pipes, as well as other unknown phenomena. Such *n* values were within a much larger range than those specified in text books based on pipe material only. The modeled flows and levels were then compared to gauged flow rates and levels from 33 permanent ADS ultrasonic flow monitoring stations. The goodness-of-fit standard was set at 80 percent of absolute variation.

Wet Weather Behavior

The rainfall event selected for wet weather calibration was a gauged front loaded 2-year return frequency event. This storm event was gauged between December 22-24, 1996 at the City's rainfall monitoring stations, and was the biggest storm event during the 1996-1997 rain season. The rain data was processed by the MOUSE Runoff Model "A" to generate flows for input directly to MOUSE HD.

The routed flow rates and levels from the model were compared with the gauged flow rates and levels recorded at 32 permanent ultrasonic ADS flow monitoring stations. The goodness-of-fit standard was set at 80 percent of absolute variation. Figure 3 shows the calibration results of the same 4 major outfalls described above.

Case Studies

The wet weather preparedness and operation planning group of the Bureau of Sanitation defined eight (8) different emergency scenarios and conditions to be studied for the 1997-98 rainy season in Southern California. Peak wet weather flow conditions were run for each scenario defined. The peak wet weather was based on the synthetic 10-year back-loaded intensity-duration-frequency (IDF) curve.

Rain Event

Based on recommendations in Technical Memorandum 6B of the Advanced Planning Report, the 10-year return frequency back-loaded synthetic IDF storm was selected for analysis. Results from these runs provided the baseline level of preparedness in the event of heavy rainfall. It provided a high (90 percent) level of preparedness against system overflows and conveyed all but one of the historic storms that occurred over the past 40 years of record. The one exception was a 100-year storm in the San Fernando Valley in February 1980.

Nevertheless, the 10-year IDF storm is conservative. It assumes the unlikely event of uniform storm intensities and durations from the 10-year event throughout the city. The February 1980 event is an example of variances in the storm pattern. This storm approached the 100-year return frequency in the northern parts of Los Angeles, but it was bellow the 10-year return frequency in the downtown and West Los Angeles areas.

The Intensity-Duration-Frequency (IDF) method allows direct comparison of the effects of differing storm return frequencies while eliminating the storm duration and intensity variables. An IDF storm has a synthetic, variable intensity hyetograph, which contains the rainfall intensity for the desired storm return frequency for all durations. For the 10-year return storm the peak hour intensity and volume are the intensity and volume associated with the 1-hour intensity and volume for a 10-year storm.

Simulation Results

To better understand the dynamic simulation results, the wastewater collection system was divided into 27 different segments. Each segment defined a portion of a major outfall sewer network. A profile was then defined for each segment and the Hydraulic Grade Line (HGL) studied carefully. Surcharge and potential spills were identified throughout the network. Other areas of interest considered are the pumping plants, the treatment plants, and selected diversion structures. Under this scenario, the two upstream treatment plants are on-line. No collapses are considered in the simulation and diversion structures are set to their "normal" operating position. A summary of findings from the dynamic simulation can be seen in Figure 4.

Potential Spills

Sewer spills are represented as circles in Figure 4 and described in the following list.

AVORS	Along Burbank Blvd between Sepulveda and Tyrone
EVRS	Upstream of the Tujunga Wash Siphon
LCSFVRS	Upstream of the WHIS junction
NOS	Along Mission Rd between Glendale Blvd and Eagle Rock Blvd
NOS	Upstream of 41st and VanNess

R0025304

COLLECTION SYSTEMS ENGINEERING DIVISION
HYDRAULIC MODEL SIMULATION RESULTS

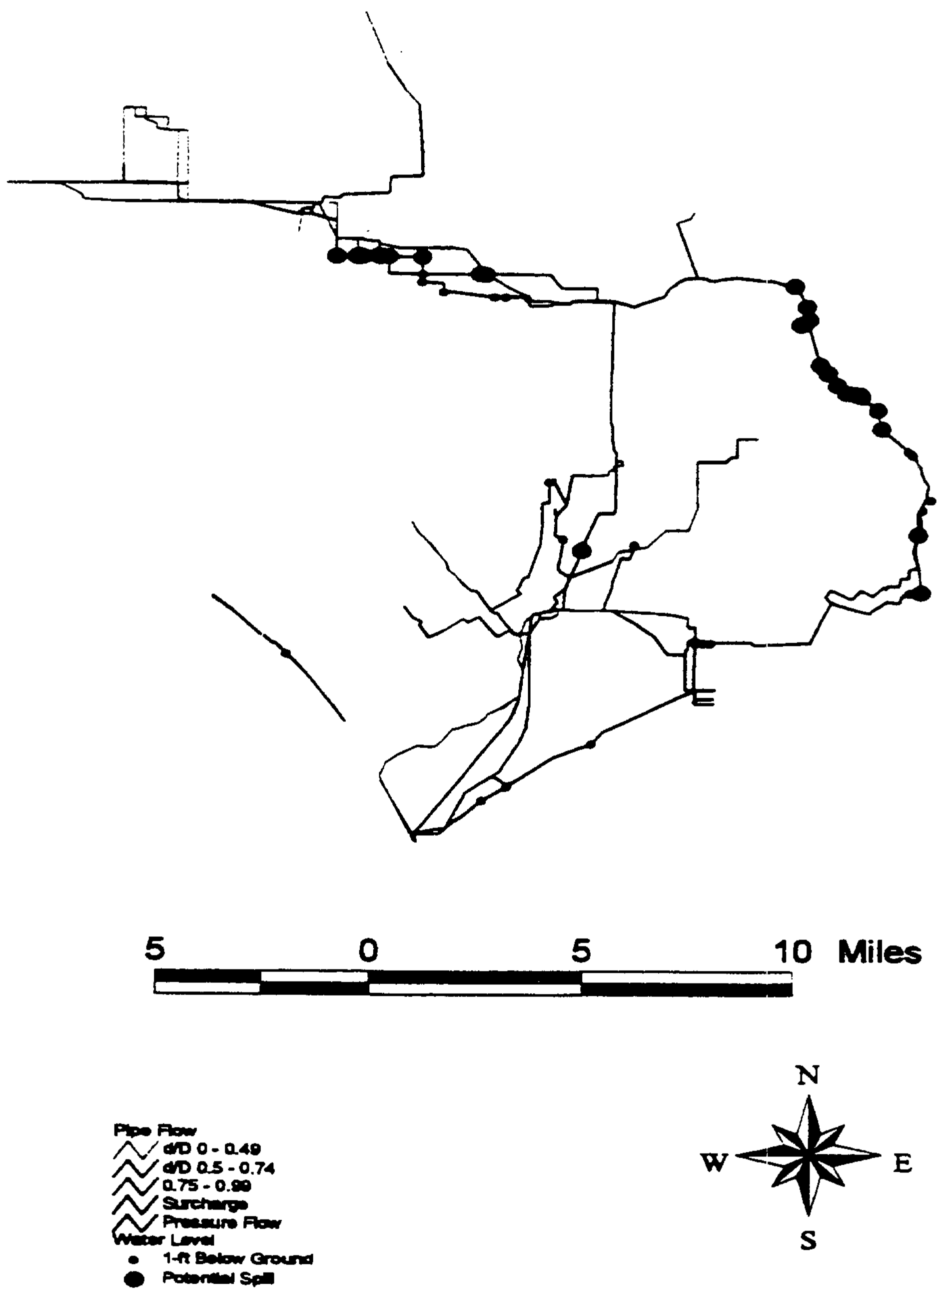

Figure 4

Sewer Line Surcharges
The following lines present potential surcharge conditions:

VORS	Along Acama between the Hollywood Fwy and Forman Ave
NOS	Along Magnolia between Kester and Woodman
NOS	Along LA River between Universal and Griffith Park
NOS	Upstream of the LA River siphon at Ventura Fwy
NOS	Upstream of the LAG inlet
NOS	between Glendale Blvd and the 23rd St junction
NOS	Upstream of the 41st and Van Ness Diversion
SB MAZE	Along Vernon, Crenshaw, and MLK
COS	Between LAX and Imperial Ave
LCIS	Upstream of NORS diversion structure #2

A typical sewer profile with the hydraulic grade line can be seen in Figure 5. A longitudinal profile of the sewer line along Mission Rd. between Glendale Blvd. and Glendale Blvd. and Eagle Rock Blvd. is displayed. The hatched area represents the space between the pipe and the ground surface. Maintenance holes are labeled along the alignment. The water surface, represented as pressure line, has been plotted. Surcharge conditions, along the entire line, are identified where the water level line is higher than the pipe soffit. Spill conditions, at nodes 468K029, 468K046, and 468P001, are represented where the water line is higher than the ground elevation.

Concluding Remarks
For a large collection system with limited staff resources, the response to an overtaxed system during rainfall events can be critical. The use of wet weather simulation gives engineering staff the necessary tools to plan for contingencies and allocate staff during actual storm events. The hot spots in the City are highlighted so the response can be coordinated with the various maintenance yards and on-call staff can be shifted to the necessary areas.

Many challenges were encountered in the development of the Model of the City of Los Angeles Outfall Sewer System. The model network fabrication was a major task because of the size and complexity of the collection system. However, effective data transfers, using existing electronic databases and GIS tools, were the keys to overcoming this challenge. The results have confirmed the validity of using fully hydrodynamic models for the simulation of large urban sewage networks. The model has successfully simulated flows within the City's large and complex system that includes many pipe interconnections, pumping plants, large catchment basins, special hydraulic structures, and reverse flow conditions. With the successful development of the model, MOUSE will become an integral part of the planning and design activities for the City's wastewater facilities.

The City's primary planning strategy will incorporate GIS and MOUSE linked together in a comprehensive scheme which allows increasing sophistication in the modeling procedures. The MOUSE model will be integrated into overall wastewater management from planning and design flows to operational procedures, and can accommodate both a system-wide approach or localized special studies. With GIS, continuous gauging programs, and sophisticated dynamic model calibration can be continuously refined, and models will play an increasing role in optimizing the life of facilities, thus saving City's precious dollars and infrastructure investment.

ABSTRACT

The central zone of the Ile-de-France Region includes some 8 million inhabitants, nearly 200 municipalities, 4 Departments, including the city of Paris, and parts of 4 other Departments, covering an area of 1900 km^2 (750 sq.mi.).

The study's goal is to design a plan that enables to meet, in the year 2015, the dry and wet weather water quality objectives of the Seine and the Marne Rivers. Hence, the study includes all sources of water pollution: urban and industrial wastewater, dry weather overflows, CSOs, SSOs, and stormwater.

In order to obtain a streamlined approach, a watershed approach was retained taking into consideration all sources of pollution and ensuring to meet the water body quality objectives. The approach consisted in defining the maximum load capacity of receiving water bodies, during dry weather and various rainfall events. Four very distinct scenarios were developed.

Comparison of the four scenarios is based on their environmental performance, the nuisance created by the construction and operation of the facilities in these densely urbanized and sometimes historic areas, and their operating and construction costs. We used a multi-criteria analysis to sort out the best scheme and developed its implementation schedule according to the financial capabilities.

KEYWORDS

Watershed analysis, CSO Control plan, Wastewater, Treatment, Stormwater, River analysis.

INTRODUCTION

The central zone of the Ile-de-France Region, namely the Greater Paris agglomeration, includes some 8 million inhabitants, nearly 200 municipalities, 4 Departments and parts of 4 others, and covers an area of 1900 km^2 (750 sq.mi.). In this territory, two levels of government, municipalities and Departments, and the Paris Agglomeration Wastewater Commission (SIAAP) are directly involved in the management of wastewater and stormwater networks. The French Government, the Ile-de-France Region, and the Seine-Normandie Water Agency all help finance the construction of waterworks. The SIAAP is more specifically responsible for the interception of wastewater and its treatment.

In 1992, the SIAAP prepared a wastewater management long-term plan. The plan relied on highly centralized wastewater treatment solutions, which received a strong opposition from the public. It also proposed the construction of very large infrastructures for the control of CSOs. In 1995, the French Minister of Environment requested the preparation of a wastewater study, which would take into consideration diverging views on the orientation of the wastewater treatment scheme. The goal of the study was to meet, within a time span of the year 2015, the dry and wet weather water quality objectives of the Seine River and the Marne River, along with requirements from Northern Sea Water Quality Treaty. Hence, the study included all sources of water pollution: urban and industrial wastewater, dry weather overflows, CSOs, SSOs, and stormwater.

In March 1996, Asseau-BPR, in collaboration with two other French engineering firms, was commisioned to conduct the study of the central area of the Ile-de-France Region dry and wet weather wastewater management plan under a watershed approach.

Approach

Asseau-BPR devised a watershed approach taking into consideration all sources of pollution and ensuring the satisfaction of the water quality objectives.

First, it consisted in defining the maximum load that the receiving water bodies could assimilate, during dry weather and during various rainfall events.

Having fixed these maximum allowable loads that can meet water quality criteria, it was possible to design scenarios that reduced loads accordingly. Four scenarios were designed. They reflected to various degrees the views of the proponents of more centralized and more decentralized wastewater treatment system. All four scenarios were equivalent in meeting dry and wet weather water quality criteria.

Comparison of the four scenarios is based on their environmental performance, the nuisance created by the construction and operation of the facilities in these densely urbanized, and sometimes historic areas, and their operating and construction costs. A multi-criteria analysis was used to sort out the best scheme and develop its implementation schedule, and the cost.

Review of the existing situation

Given that they are located in a densely populated area where combined sewer systems are predominant, the Seine and the Marne are highly utilized by sewer overflows, particularly during rainfall events. In fact, there are nearly 240 stormwater outfalls in the Seine and the Marne (SSO,CSO, stormwater outfalls). Moreover, some municipal and industrial sectors are still not connected to the sanitation network and the wastewater is poured without treatment into those rivers, during wet or dry weather. All that results in a water quality deficiency on the Seine and Marne, which restrains the use of the area and impact on aquatic life.

The wastewater treatment system is served by 4 main treatment plants : the downstream Seine plant (Achères, 2 100 000 m^3/d), the upstream Seine plant (Valenton, 300 000 m^3/d), the downstream Marne plant (Noisy, 18 000 m^3/d) and the Bonneuil plant (50 000 m^3/d). Another station is presently under construction, the center Seine de Colombes with a planned capacity of 240 000 m^3/d.

In addition to these plants are three pre-treatment plants ensuring the effluent grit and sand removal (the Clichy plant, the Briche basin, and the Ile Martinet pump station). These plants' effluent flows through the great SIAAP interceptor, which is one of the 5 interceptors that flows to Achères WWTP.

The network's average flow during dry weather is evaluated at nearly 2.8 Mm^3/d, and will reach nearly 2.9 Mm^3/d in year the 2015. In addition to the wastewater (sanitary and industrial) representing nearly 61% of total supply, this volume includes a significant quantity of infiltration and inflow.

R0025310

Although the water quality of the Seine and the Marne is average good to passable during dry weather, in accordance with the water quality objectives, the situation is quite different during rainfall events. Take for instance the rainfall events of the summers of 1994 and 1995, which caused significant water quality deterioration and a considerable quantity of fish kills.

The Marne has high ammonia content in dry weather, greater than 0.5 mg/l, due to upstream overflows. The Seine deteriorates along its course and its quality is strongly affected downstream of the main treatment plant's effluent discharge (Achères). The contents of dissolved oxygen reaches 2 mg/l downstream of Achères, while the concentration in BOD_5 becomes superior to 10 mg/l and the concentration of NH_4^+ is greater than 2 mg/l all along the Seine downstream of this same treatment plant. During rainfall historical events (July 1994 and July 1995) the dissolved oxygen content of the Seine fell to 0 mg/l after violent rainstorms, occurring several dozens of kilometers downstream of Paris. Moreover, we have observed considerable fish kills following violent rainstorm events.

Water quality criteria

The receiving water body's quality objectives are the local priority. France's agreements in regards with the Northern Sea Treaty quality criteria are:

- 5 mg/l of dissolved oxygen during dry weather, and 4 mg/l for 24 hour duration, 2 mg/l for 6 hour duration, and 1 mg/l in any time duration during wet weather;
- 0.5 mg/l of ammonia, 50 mg/l of nitrate, 11 mg/l of total nitrogen, and 0.5 mg/l of phosphate at any time.

Evaluation of required interventions

We first assembled all information to forecast dry weather sewage production and wet weather generation in the year 2015, and assessed the sewer system and wastewater treatment plant conditions and efficiency. We developed a hydrologic and hydraulic water and sewershed model, to assess wet weather flows, CSOs, and stormwater flows. The models were calibrated against data from large historic rainfall events (July 1994 and July 1995). Thus, overflow hydrographs of each CSO site have been obtained. These hydrographs are associated to overflow pollutograms used for receiving water quality impact modeling.

Representative overflow pollutographs of different collectors and interceptors of Paris and its suburbs were built from a water quality wet weather database. These representative pollutograhs are separated in a maximum of 15 water quality classes. These classes are associated to the overflow sites, which the network's characteristics (watershed and planned water quality behavior) are the nearest to the measures sites definition used to generate them. The overflow hydrographs are analyzed and separated in phases of rise and drop of water level to allow the association of the different quality classes. These pollutographs have easily been built, thanks to the use of the MED software, developed by Asseau-BPR.

Dry weather

A first level of intervention has been applied on all scenarios:
- Correction of connections/junctions in sectors non-attached to the network;
- Reduction of infiltration and inflow by 300 000 m^3/d;
- For all WWTP, addition of nitrification and phosphorous removal facilities.

Wet weather – Evaluation of volumes and pollution loads to control

From a first evaluation of volumes and pollution capacities, poured into the receiving water body during historical events and reference homogeneous rainfall, it has appeared that a small number of important overflows represented more than 80 % of the organic mass overflow during rainfall events. Therefore, it was chosen to prioritize the efforts in controlling pollution in these overflow sites. It has been shown that the control of 80 % of organic loading overflows, for a 6-month return period rainfall, enabled the achievement of water quality objectives. Thus, it has been chosen to completely control the overflows on the main CSO sites (42 out of 240 sites) for bi-annual rainfall. The choice of a 6 month return period to size CSO control facilities is backed up by the possible load control obtained for small return period rainfall events: 60 % for 1 year rainfall, 48 % for 2 year rainfall, 38 % for 5 year rainfall and 29 % for 10 year rainfall.

Intervention scenarios

To allow the control of these wastewater volumes, and to meet the receiving water body quality criteria, 4 intervention scenarios were developed. Each of the four scenarios (see table 1) were designed for structural improvements, including combinations of best management practices (in-line/off line retention, centralized/satellite high rate treatment, water transfers from one basin to another, etc) and for evaluating the potential of implementing global integrated predictive real time control. For this, we used a software we developed in-house (MED-SOM).

The scenarios apply for both dry and wet weather. They reflected to various degrees the views of the proponents of more centralized and more decentralized wastewater treatment systems. All four scenarios were equivalent in meeting dry and wet weather water quality criteria.

Table 1. **Summary of the main infrastructures proposed for CSO control during rainfall events**

Scenario A	*Scenario B*	*Scenario C*	*Scenario D*
16 detention tanks **892 000 m^3**	**16 detention tanks** **878 000 m^3**	**15 detention tanks** **847 000 m^3**	**14 detention tanks** **840 000 m^3**
3 detention tunnels **(19.6 km; 751 000 m^3)**	**2 detention tunnels** **(10.1 km; 543 000 m^3)**	**4 detention tunnels** **(20.6 km; 801 000 m^3)**	**4 detention tunnels** **(16.6 km; 675 000 m^3)**
1 high rate treatment plant **(2.5 m^3/s)**	**7 high rate treatment plant** **(8.5 m^3/s)**	**1 high rate treatment plant** **(2.5 m^3/s)**	**1 high rate treatment plant** **(2.5 m^3/s)**
7 WWTP **Capacity** **Dry w. : 34 m^3/s** **Wet w. : 107 m^3/s**	**7 WWTP** **Capacity** **Dry w. : 33 m^3/s** **Wet w. : 105 m^3/s**	**9 WWTP** **Capacity** **Dry w. : 34 m^3/s** **Wet w. : 96 m^3/s**	**9 WWTP** **Capacity** **Dry w. : 34 m^3/s** **Wet w. : 105 m^3/s**

To these infrastructures are added, for all scenarios, the connection of all non-connected sectors to the sanitation network, the separation of some areas and the doubling of certain collectors. Note that the existing wastewater treatment plants are included in the compilation.

Thus, the scenarios are analyzed and compared between them, in order to determine strengths and weaknesses and to identify the best scenario. For this analysis, 3 rainfall events are used: homogeneous rainfall of 6 month and 10 year return periods and the 2nd July 1995 historical rainfall event.

Hydraulic analysis of scenarios - Dynamic management

When trying to maximize wastewater treatment and flow interception, dynamic flow control represents an additional solution to all the proposed interventions. The influence of dynamic flow control of the great SIAAP interceptors, compared to a static flow regulation, has therefore been evaluated. This analysis has been made from the MED-SOM model, developed by Asseau-BPR, allowing the simulation and optimization of the wastewater treatment system management.

The four intervention scenarios were the objects of a MED-SOM modeling for two reference homogeneous rainfalls (6 month and 10 year return period), and the July 2nd 1995 historical rainfall event. The simulations have also been done in the static management mode with help of the CAREDAS model. The comparison of the results allows seeing the advantages of the dynamic management.

Table 2 compares, for each scenario, the overflow results in accordance with the management mode applied. Alone the networks' downstream zone of the Ile-de-France Region's central zone is included in this evaluation, which corresponds to about half of the studied zone's whole overflow.

Table 2. **Results of the downstream section of the zone of study**

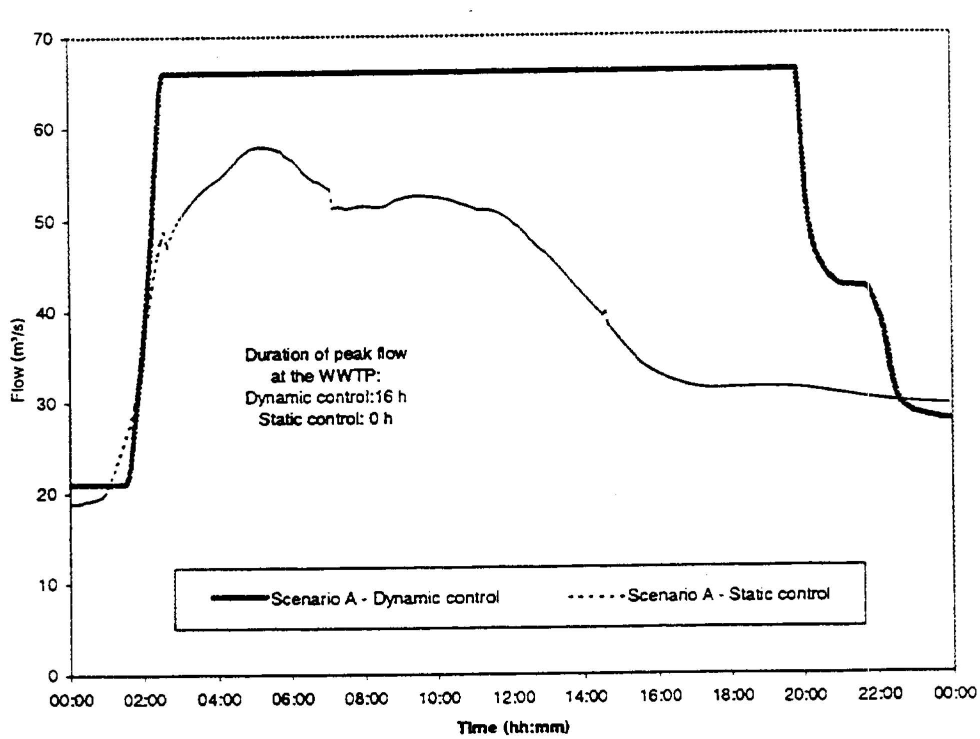
Rain	Scenario	Overflow volume (Mm^3)		
		Static	Dynamic	Situation
				1 826
1/6 months	A	46	0	
	B	67	0	
	C	0	0	
	D	0	0	
				4 596
1/10 years	A	2 207	1 787	
	B	2 316	2 247	
	C	2 240	1 694	
	D	2 081	1 332	
				4 195
02-July-95	A	1 400	1 016	
	B	1 932	1 403	
	C	1 831	1 367	
	D	1 846	1 332	

So it appears that for the 6 month rain period, the scenarios allow a 100 % elimination of overflows (a little less for the static). For the 10 years rain, the dynamic management allows in average, a 62 % reduction of overflowed volumes whereas the gain obtained with the static management is 52 %. However, the dynamic control influence is greater in a real rainfall event dynamic management allows for a 70 %

reduction in overflows for the 2nd July 1995 rainfall event, while the reduction with the static management mode is 58 %.

The performance comparison, in the situation of either a real time or static control, shows that it is very interesting to integrate, within each scenario, certain advanced solution possibilities calling for real time control. In the situation of the actual rainfall event of the 2nd July 1995, the real time control actually allows performance 30 % to 25 % better than a scenario considering only static control. This increased performance is obtained by the optimal use of WWT plants capacity during an important period, as shown on graphics comparing the flows at the Achères' wastewater treatment plant in static or real time control for the 2nd July rainfall event for scenario A (diagram 1). Thus, static control allows full capacity use of the station during 16 hours for this event.

Figure 1. **Scenario A – Inflow to Achères WWTP for the 2nd July 1995 rainfall event.**



Receiving water body impacts (environmental performances of scenarios)

The receiving water body quality impact evaluation is performed with the PROSE model, developed by CERGRENE in the context of the Piren-Seine project. This model evaluates the variation in water quality of the Seine and the Marne. The pollution associated to the hydrographs simulated to each SSO is included as data for the PROSE model.

Dry weather

The simulation results demonstrate that the developed dry weather scenarios allow for the improvement of the receiving water body quality. The dissolved oxygen, the NH_4 and the PO_4 are the parameters showing the most noticeable gains. The downstream sites are the most favorably influenced by the proposed facilities.

- DO: all scenarios allow, the reach of quality criteria.
- NH_4: strong improvement but objectives are not achieved everywhere because of high ammonia concentration upstream in the Marne River.
- NO_3: respect the quality target everywhere, however a significant rise downstream of Achères due to the high level of nitrogen load in the effluent.
- PO_4: the four scenarios cause a significant concentration reduction compared to the reference situation, without however conforming to prescribed criteria.

Wet weather

In average for the 4 scenarios, the planned interventions allow to reduce organic loads in receiving water body by 80 % for the 6-month rainfall, 45 % for the 10 years rainfall and 65 % for the 2nd July 1995 rainfall event.

Table 3. **Evaluation of the overflow reduction for different scenarios.**

		Overflow reduction percentage compared to the reference situation				
Rain	**Scenario**	**Volume**	**SS**	**BOD**	**COD**	**NH4**
6 months	A	55.3	70.5	79.9	72.8	63
	B	54.8	70.0	80.1	730	63
	C	54.5	69.7	79.8	72.7	63
	D	54.5	69.7	79.8	72.7	63
10 years	A	28.0	40.2	45.8	38.4	31.6
	B	25.7	39.0	43.8	36.9	25.2
	C	27.5	39.6	46.1	38.6	30.6
	D	29.2	41.9	48.6	41.4	28.5
2 July 95	A	42.5	54.6	67.0	59.0	46.3
	B	39.1	52.8	64.7	55.6	36.6
	C	38.6	51.8	64.4	55.6	42.1
	D	38.9	52.2	65.1	55.7	38.4

Wet weather impact on water quality was simulated with the PROSE software, developed by the École des Mines de Paris School, respecting the following summer conditions:

- The overflows generated by 6 month and 10 year return period rainfall, and the 2nd July 1995 rainfall event, on low reference conditions, of once in 5 year return period;

- The overflows generated by the 2nd July 1995 rainfall event on low water conditions prevailing on the 2nd July 1995.

The pollutant load reduction results in the Seine's and the Marne's sharp water quality improvement. The quality objectives are reached for the 6-month return period rainfall event and the 2nd July 1995 historical event. However, a 10 year return period homogeneous rainfall and the 2nd July 1995 rainfall event, associated with a low flow situation (5 years return frequency), always leads to anoxic conditions. Moreover, we have demonstrated that the conjunction of low frequency rainfall and severe low water flow was very unlikely. For example, these past 18 years, there was only one important event combining low water conditions and rain susceptible to cause more critical effects than the 2nd July 1995 historical event.

The scenarios' multi-criteria analysis

The four scenarios A, B, C and D represent contrasting development alternatives. The proposed developments allow the achievement of the receiving water body quality objectives during dry weather. During wet weather, the differences between the scenarios are more pronounced, particularly in nitrogen polluted inflows.

The costs and nuisances associated to each scenario are also contrasted and depend on many factors, more or less favorable to one or another of the scenarios.

To classify the scenarios and to single out the most effective one, it is necessary to proceed to a multi-objective analysis, allowing the classification of the scenarios by relative performance according to different criteria. The criteria considered in this analysis are: environmental performance, progressive implementation capacity, operating nuisances, implementation constraints, construction nuisances, operation costs, and investment costs. These analysis criteria are only technical and we give them a score between of 2 to 5 relative to each other.

For each studied criteria mentioned earlier we have obtained a classification. The final results are shown in table 4.

Table 4. **Multi-table analysis of the four intervention scenarios**

	Before balancing				**Balancing**	**After balancing**			
Analysis criteria	**A**	**B**	**C**	**D**		**A**	**B**	**C**	**D**
Environmental performance	3	2	5	4	25 %	0.75	0.5	1.25	1
Functioning flexibility	2	3	4	5	15 %	0.3	0.45	0.6	0.75
Progressive implementation	5	4	3	2	10 %	0.5	0.4	0.3	0.2
Exploitation nuisances	4	2	5	3	15 %	0.6	0.3	0.75	0.45
Implementing constraints	5	3	4	2	10 %	0.5	0.3	0.4	0.2
Construction nuisances	5	4	3	2	5 %	0.25	0.2	0.15	0.1
Exploitation costs	5	3	4	2	10 %	0.5	0.3	0.4	0.2
Investment costs	5	4	3	2	10 %	0.5	0.4	0.3	0.2
Total (X/5)						**3.9**	**2.85**	**4.15**	**3.1**
Total (%)						**78**	**57**	**83**	**62**

Resulting from this multi-objective analysis, scenario C appears to be the most efficient of all four scenarios.

CONCLUSION

The sewer system of the central zone of the Ile-de-France Region services a population of 8 million inhabitants over a territory of approximately 1900 km^2. In its present state, water quality of the Seine and Marne Rivers is severely impaired by effluents from existing WWTP, SSOs, CSOs, and stormwater, during dry and wet weather.

Asseau-BPR has been mandated to conduct a planning study to meet dry and wet weather water quality criteria in a horizon of the year 2015. A watershed approach was performed, where water quality in the two main rivers draining these watersheds became the main design criterion, both for dry and wet weather. We present here the main result of this study, which was finalized in a time of 1.5 years.

Four scenarios were developed. They include the construction of some 1.4 Mm^3 to more than 1.6 Mm^3 of new retention capacity and 2.5 m^3/s to 8.5 m^3/s of high rate treatment plant capacity. The existing 5 wastewater treatment plants are to be upgraded to include more wet weather capacity and nitrogen and phosphorous removal. Depending on the level of wastewater treatment decentralization, two more treatment plants are also included.

All of these four scenarios help meet water quality criteria during dry weather and wet weather, for events such as the historical rainfall event of July 2nd 1995, which has a return period of 5 to 10 years.

USE OF THE WATERSHED MANAGEMENT APPROACH TO REDUCE THE IMPACT OF COMBINED SEWER OVERFLOWS AND TO ADDRESS STORM WATER PHASE II "DONUT HOLES"

Daniel Rourke, Water Pollution Prevention Program Manager - City & County of San Francisco *
Geoff Brosseau, Environmental Consultant

*** City & County of San Francisco, PUC-BERM, 3801 3rd Street, Suite 600, San Francisco, CA 94124**

ABSTRACT

The City and County of San Francisco operates and maintains the City's combined sewer system and wastewater treatment plants. The combined system collects and stores for treatment, both sanitary and industrial wastewater, as well as storm water runoff. To meet stricter effluent limits for discharge to San Francisco Bay and the Pacific Ocean, the City's Bureau of Environmental Regulation and Management (BERM) operates the Water Pollution Prevention Program (WPPP)—which is targeting categories of discharges, such as industrial, commercial, and residential, to reduce their loading of heavy metals and other pollutants of concern to the City's system and ultimately the Bay and Ocean. The City recently completed a 20-year, $1.4 billion dollar Master Plan for Wastewater Management that significantly reduced the number of combined sewer overflows (CSOs) that occur during wet weather. The goal of the new Storm Water Pollution Prevention Program (Storm Water Program) is to reduce the potential impact of the few remaining overflows by minimizing the amount of pollutants that enter the combined sewer system from outside sources during wet weather.

The City implemented the Storm Water Program as a pilot effort in one drainage basin (i.e., watershed) starting in 1995 to test its efficacy and appropriateness for the City as a whole. The WPPP chose to focus the program on a watershed of concern to the City and its efforts to: 1) protect its citizens and the environment, and 2) remain in compliance with environmental regulations. As a result, the Storm Water Program was implemented in the Lower Army and Lower Selby sub-basins of the Islais Creek watershed. The combined size of these two sub-basins was small enough to allow for the implementation of a comprehensive storm water pollution prevention program while being large enough to represent a significant effort in the watershed. The Lower Army and Lower Selby sub-basins are the closest sub-basins in the watershed to Islais Creek, and are a representative sample of the whole watershed's land uses including industrial, commercial, residential, and transportation.

The Water Pollution Prevention Program used a watershed management approach, and linked the Storm Water Program to: 1) the requirements of its NPDES permits, 2) USEPA's Combined Sewer Overflow Control Policy, and 3) upcoming Phase II requirements. San Francisco's combined sewer system presented an interesting opportunity to use the watershed management approach, which is associated more with nonpoint source pollution, in a "point source" situation. San Francisco's well defined major basins, sub-basins, and drainage districts facilitated the use of data on wet weather hydrology and the combined sewer system's hydraulics to understand flows and drainage patterns, and their impact on CSOs. Integrating traditional storm water management techniques and the watershed management approach into the City's existing water quality control programs not only helped it to reduce the potential impacts of combined sewer overflows, but will also facilitate San Francisco's efforts to comply with Phase II storm water regulations well ahead of schedule.

INTRODUCTION

The City and County of San Francisco operates and maintains the City's combined sewer system and wastewater treatment plants. The combined system collects and stores for treatment, both sanitary and industrial wastewater, as well as storm water runoff. To meet stricter effluent limits for discharge to San Francisco Bay and the Pacific Ocean, the City's Bureau of Environmental Regulation and Management (BERM) operates the Water Pollution Prevention Program (WPPP)—which is targeting categories of discharges, such as industrial, commercial, and residential, to reduce their loading of heavy metals and other pollutants of concern to the City's system and ultimately the Bay and Ocean. The City recently completed a 20-year, $1.4 billion dollar Master Plan for Wastewater Management that significantly reduced the number of combined sewer overflows (CSOs) that occur during wet weather. The goal of the new Storm Water Pollution Prevention Program (Storm Water Program) is to reduce the potential impact of these few remaining overflows by minimizing the amount of pollutants that enter the combined sewer system from outside sources during wet weather. The City implemented the Storm Water Program as a pilot effort in one drainage basin (i.e., watershed) starting in 1995 to test its efficacy and appropriateness for the City as a whole.

METHODOLOGY

Framework

The City developed a Program Plan that describes the framework for the pilot Storm Water Program. The Program Plan is a living document designed to grow in length and detail as the Storm Water Program evolves and becomes more defined. The first phase of the pilot program was designed to identify, scope out, and develop the elements of a comprehensive, long-term watershed management effort. The first phase work set the stage for further program implementation in subsequent phases. The City chose to use information on watershed management planning provided in the "(g) Guidance" (USEPA, 1993) to develop the framework for their pilot Storm Water Program. The "(g) Guidance" includes a table (Table 4-11. Watershed Management: A Step-by-Step Guide) adapted from Livingston and McCarron (1992) that describes the general steps for developing a watershed management plan. The steps include:

- conducting inventories and creating maps of watershed characteristics,
- identification of pollutant sources,
- identification of expected changes in land use and infrastructure,
- setting resource management goals and pollutant reduction targets,
- selecting management practices, and
- developing the watershed management plan.

The City adapted these steps to their situation in developing the Program Plan.

Program Approach

San Francisco used this watershed management approach, and linked the Storm Water Program to: 1) the requirements in the City's NPDES permits, 2) USEPA's Combined Sewer Overflow Control Policy, and 3) efforts of other Bay Area storm water programs. The watershed management approach is being used more and more in storm water programs to create effective and efficient urban runoff management programs. This approach attempts to ensure that the right things are done, in the right places, at the right times. San Francisco's combined sewer system presents an interesting opportunity to use the watershed management approach, which is associated more with nonpoint source pollution, in a "point source" situation. San Francisco's well defined major basins, sub-basins, and drainage districts facilitated the use of data on wet weather hydrology and the combined sewer system's hydraulics to understand flows and drainage patterns, and their impact on CSOs. The following steps were used in developing and conducting the Storm Water Program.

1. Characterize watershed and identify problems - As a result of previous work, BERM staff had identified heavy metals (particularly copper and mercury), PAHs, PCBs, dioxin, and selected pesticides as the pollutants of concern for San Francisco. However, it was important to review and verify this list on a regular basis. Of this list, some pollutants are more likely than others to be "storm water" pollutants, that is pollutants that enter the combined sewer system via runoff. In addition, the list of problem pollutants can change because of stricter regulations or permit limits, changing treatment capabilities, or new monitoring information.

In addition to identifying the problem pollutants, Water Pollution Prevention Program staff decided to focus the program on a watershed of concern to the City and its efforts to protect its citizens and the environment, and to remain in compliance with environmental regulations. As a result, the Storm Water Program was implemented in the Lower Army and Lower Selby sub-basins of the Islais Creek Watershed.

This watershed is in the southeast portion of the City and drains to San Francisco Bay. It is expected that the combined size of these two sub-basins is small enough to allow for the implementation of a comprehensive storm water pollution prevention program while being large enough to represent a significant effort in the watershed. The Lower Army and Lower Selby sub-basins include the Potrero Hill and Bernal Heights sections of the City, represent the closest sub-basins in the watershed to Islais Creek, and appear to be a representative sample of the whole watershed's land uses including industrial, commercial, residential, and transportation. To implement this part of the approach, the following tasks were undertaken:

- Delineate and map on a geographic information system (GIS) the sub-watershed boundary and sub-basin boundaries.

- Inventory and map on GIS the storm water conveyance, storage, and treatment system including streets, catch basins, open channels, pipes, pump stations, Southeast Wastewater Pollution Control Plant, storage structures, outfalls, and overflow structures. Provide information on size, storage capacity, treatment capacity of the system, and frequency, volume, and duration of overflows. Note the parts of the system, if any, that are not connected to the Southeast Plant.

- Identify and map to the extent possible ongoing and planned infrastructure improvements, their size, storage and/or treatment capacity, and the date they are expected to be operational.

- Inventory and map current land use by sub-basin. Define and map by at least major categories, such as commercial and residential, and consider defining and mapping sub-categories such as single family residential and multi-family.

- Identify and map zoned land use by sub-basin using the same categories and level of detail as used for current land use inventory and mapping.

- Identify and map to the extent possible ongoing and planned significant developments or redevelopments by land use.

- Inventory and map impervious area (e.g., streets, sidewalks, and roofs) and significant areas of open space or bare soil. To the extent possible, note impervious area that is directly connected to the storm water conveyance system.

2. Identify significant storm water sources with the highest potential of influencing the quality of the City's combined sewer overflows - Based on studies conducted by the City and other agencies, there is relatively complete information on the sources of storm water pollutants. However, new information is always being generated and the sources can change because of changing processes, practices, or products. Therefore, it is important to track this information by reviewing literature and networking with staff from other agencies. It is also important to a watershed management effort to identify and involve stakeholders including residents, businesses, and community groups. As a result, the City recognized that this step could be a major one, so the City focused on developing a framework and the tools first, that could be used later to expand or revise the Storm Water Program, as necessary. To implement this part of the approach, the following tasks were undertaken:

- Review the list of storm water pollutants of concern and identify the most likely sources by land use category or sub-category (e.g., category = residential or sub-category = single family). Generate a list of these land use categories and sub-categories. *

- Identify and record contact information on the major stakeholders in the watershed including large businesses, trade associations for business types that have a significant presence in the watershed, large municipal and other government facilities, City departments with responsibilities that may impact/protect storm water quality, commercial business districts, community groups, and neighborhood associations. Use existing data bases such as the City's business tax license, and in-house lists of trade associations, business district contacts, and community and neighborhood groups.

- Gather and review the City's information on wet weather hydrology and the combined sewer system's hydraulics and operations to understand flows and drainage patterns, and their impact on CSOs. Note the climatic/hydraulic conditions, if any, when combined flows do not go to the Southeast Plant but rather to overflow structures. *

- Based on this review, and the information gathered previously on the storm water conveyance system, identify geographic areas that could be significant sources of pollutants to storm water runoff and discharges through combined sewer overflows. *

- For businesses, review USEPA's list of industries subject to the Phase I storm water regulations and confirm or modify the categorization based on the specific information for the Islais Creek watershed. *

* These tasks will result in a list of potentially significant sources of storm water pollutants of concern. Sources will be on this list because:
  - the land use category or sub-category has been identified as a potentially significant source of storm water pollutants by studies conducted by the City or others, or

  - the geographic area is a potentially significant source because of the design and operation of the storm water conveyance system, or

  - the business type has been identified as a potentially significant source of storm water pollutants by studies or permit programs (e.g., State Industrial General Permit).

The relative contribution of problem pollutants can be estimated by using source and monitoring data. Although these calculations often have large margins of error because of incomplete or inconsistent data, it is still important to go through the exercise, especially when new data becomes available, to confirm the relative importance of the sources. It is also important when focusing on sources to compare their contribution with other sources (e.g., commercial vs. residential) to keep the programs focused on the most significant problems. To implement this part of the approach, the following tasks were undertaken:

- Review studies and reports conducted by the City or others to determine the priority of these potential sources for each of the storm water pollutants of concern. These studies and reports included:
  - for businesses - source identification and outreach programs in the City and elsewhere, inspection and permitting information from the Department of Public Health and BERM, commercial/industrial watershed-based efforts in other jurisdictions, and the USEPA Multi-Sector Permit (1995);

  - for residential - source identification studies and outreach programs in the City and elsewhere;

  - for transportation - reports and studies from the Federal Highway Administration, Caltrans, storm water programs, and others.

3. Identify practical storm water pollution prevention strategies that would reduce the amount of pollutants entering the City's combined sewer system - The strategy for dealing with storm water pollutants is fairly generic but the mix of program elements can change depending on factors such as, land uses, relative contribution of problem pollutants, number and size of businesses in the watershed and their general awareness of environmental regulations. Program strategies may include ordinance revisions, modified discharge permits to include storm water criteria, inspections, monitoring, interdepartmental coordination, workshops, on-site visits, outreach materials, advisory committees, feedback mechanisms, and incentives. The City decided to develop a watershed management approach for dealing with all the major storm water pollutant dischargers in the watershed that is based on the success of their current programs and incorporates the appropriate program elements. To implement this part of the approach, the following task were undertaken:

- Using the prioritization of sources by storm water pollutant of concern, a strategy was developed for each pollutant. The strategies vary depending on the predominant source(s).

- For residential sources, the strategy focuses on outreach including potentially: mailings, speakers bureau for neighborhood meetings, displays at community events, and citizen's advisory committee(s).

- For businesses, the strategy starts with outreach as well, including potentially: establishment of advisory committees, workshops, on-site visits, distribution of outreach materials (such as a general storm water pollution prevention guide), and follow-up. The strategy also includes permitting via the City's Class II permit including a qualifying checklist and storm water pollution prevention plan provisions.

- For transportation sources, there are two categories—public (roads, bridges, and parking) and private (driveways and parking).
  1. For the public transportation areas, the strategy differs based on which agency (City or State) has jurisdiction. As it has in the past, BERM will work with other City departments to develop and implement a strategy for "City streets." The strategy includes enhanced street cleaning, catch basin cleanouts, and special programs for bridges and parking lots. For State-owned transportation areas, the City is working with Caltrans' ongoing storm water pollution prevention program.

  2. Significant sources on private parking areas and driveways are dealt with through either the business or residential elements.

4. Develop storm water technical outreach materials to be distributed to targeted storm water sources - Like the strategies for dealing with storm water pollutants, the best management practices (BMPs) are also fairly generic. Technical outreach materials (e.g., general storm water education booklets, specific BMPs, checklists) have been developed for the vast majority of polluting activities and target audiences. BERM has developed many of these materials and used these existing materials to develop new materials for San Francisco. This approach allows BERM to concentrate on verifying, modifying, and fine tuning existing information for San Francisco and a combined sewer system. To implement this part of the approach, the following tasks were undertaken:

- Develop a generic outreach piece suitable for multiple audiences that explains the overall Storm Water Program—its goals, approach, elements, roles of different stakeholders in the watershed, and City contact information.

- Develop a generic storm water pollution prevention outreach piece suitable for businesses. Develop a companion storm water pollution prevention checklist for distribution to business sources that are not likely to be getting more specific outreach and/or permitting information.

- For specific sources, review existing City as well as other agency outreach materials for appropriateness to the Storm Water Pollution Prevention Program. Modify existing or develop new outreach materials for specific sources. The specific technical outreach materials will likely include: general information on storm water pollution, source-specific information on storm water pollutants and pollution prevention practices, and checklists to be used either in self-audits or for on-site visits by the City.

- For the permitting portion of the business strategy, review the existing Class II permit provisions for storm water for appropriateness for specific business types. Modify existing or develop supplemental provisions, as necessary, to ensure the effectiveness of the permit in preventing storm water pollution. Use the State's Industrial Storm Water BMP Handbook (SWQTF, 1993), Industrial General Permit (State of California, 1992), and USEPA Multi-Sector Permit as guidance to activities of concern and BMPs.

5. **Develop a GIS data base containing the targeted storm water sources** - Water Pollution Prevention Program staff used the existing GIS data base work at BERM and integrated it with the GIS efforts elsewhere in the City. The GIS data base assisted in tracking storm water pollutant sources and facility audits, as well as in program implementation and evaluation. Use of GIS is integral to watershed and storm water management and the City's early work with GIS greatly facilitated implementation of the Storm Water Program.

6. **Conduct educational storm water pollution prevention audits** - For business and government facilities, having determined the pollutants of concern, their sources, the area of focus (i.e., parts of the sub-basin(s)), and the pollution prevention strategy, tools, and BMPs; the City conducted pollution prevention audits or other educational outreach to the target sources. To implement this part of the approach, the following tasks were undertaken:

- Conduct pollution prevention audits including an identification of storm water sources, determination of their significance, and assessment of BMP or pollution prevention practice implementation. Use checklists and outreach materials developed under previous tasks to facilitate the audits and educate the facility owner/operator. Non-storm water discharges entering the storm water conveyance system will be reduced using pollution prevention practices. Non-storm water discharges entering receiving waters directly will be eliminated as soon as possible after discovery.

- Provide feedback to owners/operators at the end of visits and through periodic mailings.

- Develop a follow-up strategy based on threat to water quality, implementation of pollution prevention practices, and when appropriate, compliance with permit conditions.

7. **Evaluate the effectiveness of the storm water pollution prevention program** - To evaluate the program's long term success, ways of measuring results must be incorporated into the program design. The sooner that the types of data necessary to measure success are identified and data collection started, the quicker the feedback and the sooner corrections can be made to increase the program's effectiveness. The City developed an evaluation methodology as an integral part of the Program Plan for the Storm Water Program.

RESULTS

To illustrate implementation of the City and County of San Francisco's pilot Storm Water Program we will focus our discussion of results on the pollution prevention audits conducted as part of the business strategy. Audits including identifying sources of storm water pollution, determining the significance of these sources, and assessing the use of best management practices were conducted of selected businesses. The choice of businesses was based on a compilation of databases including Standard Industrial Classification (SIC) Codes identified in the Phase I storm water regulations, the City's pretreatment database, and the City's hazardous materials program database.

The compilation effort produced a list of 172 businesses located in the project drainage area. The business locations were fixed on the City's geographic information system and maps were produced. A drive-by survey was conducted to verify the businesses' locations. During the drive-by survey, businesses that were found but not listed were added to the audit list, and those businesses that were not found but listed were excluded. The final candidate audit list consisted of 145 business facilities.

A checklist of potential outside activities (e.g., vehicle maintenance, outside storage) was prepared and the businesses were audited. For businesses with storm water exposure, comprehensive audits were performed including site sketches and comments. For those that had no activity or storage exposed to storm water, only facility information was recorded. Audit information was entered in an Access database directly from the checklists. The audit results can be summarized as follows:

1. Among the 145 businesses audited, 45 (31%) of them had an activity or storage exposed to storm water, and 100 (69%) had no exposure.

2. The most common activities at businesses with storm water exposure are:
   - Outdoor loading/unloading — 40% of facilities
   - Outdoor storage — 36%
   - Vehicle/equipment washing — 33%
   - Vehicle/equipment fueling — 31%
   - Vehicle/equipment maintenance — 31%
   - Outdoor process equipment — 7%

3. Among the 45 businesses with exposure to storm water, only five had outdoor process equipment. The possibility of storm water pollution from outdoor processing may be relatively low.

4. Some potential outside activities such as building/grounds maintenance, building repair/construction, and over-water activities were found to be unlikely sources of storm water pollution in the project drainage basins because no businesses were found conducting these activities.

5. The incidence of storm water pollution in the project drainage area is more likely linked to the improper handling of leaks and spills, and inadequate protection for vehicle/equipment service and outdoor unloading/loading areas.

6. Dry weather flows were found at 21 facilities, which constitutes 47% of the businesses exposed to storm water or 14% of businesses audited. The majority of the dry weather flow was from washing/cleaning.

7. None of the on-site storm drains were labeled and few were inspected by facility staff. Some drains were clogged with debris or were heavily contaminated by oil/grease.

8. Of all businesses in the drainage area, the most common Standard Industrial Classification codes in the drainage basin are: Group 75 (automotive repair, services, and parking) (11%), Groups 50 and 51 (whole sale trade) (10% and 8% respectively), Group 27 (printing, publishing, and allied industries) (8%), Group 17 (construction) (7%), Group 41 (local and suburban transit) (7%), Group 52 (building materials, hardware, garden supply) (7%), and Group 73 (business services) (7%).

9. A review of the number of facilities with exposure to storm water runoff out of the total number of facilities in the drainage area shows that certain SIC codes appear more likely to have activities exposed to storm water runoff (see Table 1). The likely SIC codes include: Group 43 (United States Postal Services) (100%), Group 41 (local and suburban transit) (83%), Group 55 (auto dealers and gas stations) (71%), Group 52 (building materials, hardware, garden supply) (42%), Group 75 (automotive repair, services, and parking) (37%), Group 17 (construction) (27%), and Group 73 (business services) (27%).

10. The data showing which facilities are more likely to have activities exposed to storm water runoff can be extrapolated to the rest of the City to determine the magnitude of expanding this pilot effort City-wide.

Table 1. List of Standard Industrial Classification Codes with Likely Exposure to Storm Water Runoff

SIC Group	Description	Number of Facilities*	Percentage
43	United States Postal Services	1 / 1	100
41	Local and suburban transit and interurban highway passenger transportation	10 / 12	83
55	Automotive dealers and gasoline service stations	5 / 7	71
87	Engineering, accounting, research, management, and related services	1 / 2	50
52	Building materials, hardware, garden supply, and mobile home dealer	5 / 12	42
75	Automotive repair, services, and parking	7 / 19	37
17	Construction-special trade contractors	3 / 11	27
73	Business services	3 / 11	27
20	Food and kindred products	1 / 4	25
42	Motor freight transportation and warehousing	1 / 4	25
76	Miscellaneous repair services	1 / 4	25
51	Whole sale trade-non-durable goods	3 / 14	21
50	Whole sale trade-durable goods	3 / 17	18

* Based on number of facilities with exposure to storm water runoff out of total number of facilities in drainage area of same SIC code.

DISCUSSION

The development and implementation of a pilot Storm Water Program in one portion of the City starting in 1995 will greatly facilitate San Francisco's response to the coming Phase II regulations.

Phase I - Although San Francisco's total population is high enough for the City to be subject to the 1990 Phase I federal storm water regulations (i.e., > 100,000), the regulations allow a municipality with both separate and combined sewers to petition USEPA to reduce its listed population to account for storm water discharged to combined sewers and treated in a POTW. The reduction method is based on the proportional length of each sewer type. Since the vast majority of San Francisco is served by combined sewers, the length of separate sewers is insufficient to trigger the Phase I regulations.

Phase II - The approach in USEPA's proposed rule (1998) is that all municipal separate storm sewer systems within a Census-designated urbanized area (e.g., San Francisco) would be regulated under Phase II, regardless of whether or not a particular municipality had combined sewer portions of its system. This approach would require the City to meet storm water regulations in the "storm water" portions of the city (the so-called "donut holes") and the nine minimum CSO controls in the combined sewer sections. San Francisco's proactiveness and Phase II's long timelines (final rule - 3/1/99, applications due 3 years, 90 days later = 5/31/02) mean that these regulations will act more as a "backstop" than as a "driver" to the City's Storm Water Program.

Certain industrial activities (identified by SIC code), including construction sites of 5 acres or more, are covered by State of California's General Storm Water Permits. San Francisco's existing Water Pollution Prevention Program and pilot Storm Water Program are very consistent with the Phase I and II requirements.

Table 2. Comparison of Storm Water Management Program Elements

Element	Phase I	Phase II	General Permits	San Francisco
Program Management	X	X		X
New (Re-) Development/Construction	X	X	X	X
Illicit Discharges	X	X		X
Industrial/Commercial	X		X	X
Public Agencies	X	X		X
Public Education	X	X		X
Program Evaluation/ Monitoring	X	X		X

The permitting process for San Francisco will likely be similar to other Storm Water Management Programs (SWMPs) where a plan is developed and submitted with an application. It is expected that the NPDES permit language will be mostly boilerplate and refer to the plan which can be updated without affecting the permit language.

Since the City currently holds three NPDES permits (one each for its two POTWs and one for Bayside CSOs), the City and the Regional Water Quality Control Board (Regional Board) will explore the possibility of merging requirements into one or two permits. However, this effort may be constrained by the differing legal statutes behind the requirements (i.e., CSO, storm water). In addition, the Regional Board is starting to consider developing a General Permit for municipal storm water. The City and Regional Board will decide at the time of the application which permitting approach to use (e.g., General Permit, individual permit, "merged" permit).

Since San Francisco is served by both combined sewers and separate sewers, the application will clearly indicate which geographic areas of the City are served by separated systems including the Port of San Francisco, parts of Golden Gate Park, and presumably new portions of Bayside that are being redeveloped—China Basin, Mission Bay, Candlestick Point, Hunter's Point, Treasure Island). Because the industrial storm water regulations are written to hold the "owner/operator" responsible, the City's application will also include information on how the City has decided to handle private industrial/commercial facilities on City property served by separated systems.

The City will use several guides in developing its permit application including USEPA and State guidance, as well as the current plans of neighboring Storm Water Management Programs (e.g., Alameda, San Mateo). The application will cover the following elements of SWMPs, which are consistent with both Phase I and II requirements, as well as the elements of the City's pilot Storm Water Program.

- Program Management
- New (Re-) Development/Construction
- Illicit Discharges
- Industrial/Commercial
- Public Agencies
- Public Education
- Program Evaluation/ Monitoring

CONCLUSIONS

Integrating traditional storm water management techniques and the watershed management approach into the City's existing water quality control programs not only helped it to reduce the potential impacts of combined sewer overflows, but will also facilitate San Francisco's efforts to comply with Phase II storm water regulations well ahead of schedule.

ABSTRACT

In July, 1997, the Massachusetts Water Resources Authority (MWRA) completed facilities planning for controlling combined sewer overflows (CSOs) in the greater Boston area in accordance with a federal court schedule. The CSO control plan was developed using the demonstration approach described in the national CSO policy issued by the U.S. Environmental Protection Agency (EPA) in April, 1994. Under the demonstration approach, MWRA confirmed through the facilities planning process that the recommended plan complied with water quality standards. Both technology-based and water quality-based evaluations were performed. The MWRA CSO control plan was developed using the demonstration approach because sufficient data on CSO and non-CSO sources of pollution and corresponding water quality impacts were available and were considered in determining appropriate controls on a site-specific basis. This paper presents the process followed to document compliance with the criteria for a successful demonstration under the EPA CSO control policy.

KEY WORDS

technology-based evaluations, cost/performance, water quality standards, hours of violation, project optimization

INTRODUCTION

EPA, following extensive input from numerous state, municipal, and environmental stakeholder organizations, published its new national CSO Control Policy in April, 1994. The policy implements a national strategy to achieve cost-effective CSO controls that meet appropriate health and environmental objectives. It provides for flexibility in developing long-term CSO control plans and allows CSO controls to be tailored to address site-specific impacts of CSOs. The policy requires that nine minimum control technologies be implemented and establishes a planning process for developing long-term CSO control plans by evaluating a range of CSO control alternatives and demonstrating compliance with water quality standards to protect designated uses.

According to EPA's CSO policy, plans for long-term CSO control and compliance with water quality-based requirements of the Clean Water Act can be developed by using either a "presumption" or "demonstration" approach. Under the ***presumption approach,*** compliance with water quality standards is presumed, if one of three performance criteria is met: i) overflows are reduced to no more than an average of four events per year on an annual average basis, ii) no less than 85 percent by volume of the combined sewerage collected on a system-wide annual average basis is eliminated or captured for treatment, or iii) no less than the mass of pollutants causing water quality impairment for the volume reductions in number ii is eliminated or reduced.

Under the ***demonstration approach,*** compliance with water quality standards is confirmed through the CSO control planning process. This approach was intended to provide flexibility in developing a long-term CSO control plan, particularly where water quality standards are not met due to non-CSO sources of pollution. While not necessarily satisfying the performance criteria of the presumption approach, the plan can be shown to be adequate to meet water quality standards. The demonstration approach depends on a detailed assessment of receiving waters and the impacts of CSO discharges and other sources of wet weather pollutants on water quality.

R0025329

Under the definition of a successful demonstration, a long-term control plan must meet the following criteria:

i The planned control program is adequate to meet water quality standards and protect designated uses, unless standards or uses cannot be met as a result of natural background conditions or pollution sources other than CSOs;

ii The CSO discharges remaining after implementation of the planned control program will not preclude the attainment of water quality standards or designated uses, or contribute to their impairment. Where standards and uses are not met in part because of natural background conditions or pollution sources other than CSOs, a total maximum daily load (TMDL) allocation should be used to apportion pollutant loads, including a waste load allocation and a load allocation or other means;

iii The planned control program will provide the maximum pollution reduction benefits reasonably attainable; and

iv The planned control program is designed to allow cost effective expansion or cost effective retrofitting if additional controls are subsequently determined to be necessary to meet water quality standards or designated uses.

MWRA developed its CSO control plan using the demonstration approach because detailed information on CSO and non-CSO sources of pollutant loads and resulting water quality impacts was collected and could be evaluated in determining appropriate controls based on site-specific conditions. The MWRA successfully demonstrated that its recommended CSO control plan fulfilled each one of the required criteria.

METHODOLOGY

Because CSOs are considered to be point sources of pollution, both technology-based and water quality-based requirements of the Clean Water Act apply in their control to meet water quality standards and protect designated uses. The development of the MWRA's CSO control plan included evaluation of a full range of CSO control technologies, as well as detailed water quality assessments of CSO impacts on specific receiving water segments. MWRA's approach followed the planning requirements of EPA's CSO policy, confirming compliance with state water quality standards.

MWRA's long-term control plan recommends CSO controls for Boston, Cambridge, Somerville, and Chelsea. CSOs from the large sewerage system serving these communities impact Boston Harbor and its major tributaries, including the Charles River. Due to the size and complexity of the system, as well as the diversity of the affected waterbodies, the plan was organized to address 14 distinct receiving water segments.

Technology-Based Evaluations

Technology evaluations were conducted for each outfall and/or group of hydraulically-related outfalls. The alternatives evaluation process involved several screening steps to ensure that detailed evaluations were only performed for feasible alternatives. One method for comparing alternative technologies involved cost/performance curves. Cost/performance curves were developed based on annual model simulations. Two sets of curves were developed, with percent reductions based on CSO load reductions and on total load (CSO plus non-CSO pollutant load) reduction in the impacted receiving water. Curves generated for individual project alternatives showed cost versus CSO load removed as a percent of baseline CSO load, and curves for the receiving waters showed cost versus total load removed as a percent of baseline total load. Parameters analyzed included fecal coliform bacteria, total suspended solids (TSS), and biochemical oxygen demand (BOD) pollutant loads from CSO, stormwater, and upstream or boundary sources, if applicable. This approach was effective in assessing the relative benefit of varying levels of CSO control on the receiving water in terms of all pollutant sources.

Feasible alternatives were also compared using a rating and ranking methodology to identify a preferred alternative on a receiving-water-wide basis. Each alternative was assigned ratings for specific criteria under the categories of water quality impacts, cost, and siting. The ratings under each category were summed and a rank order was established. The rank orders of all the categories were then summed to obtain an overall rank order for the alternatives.

Water Quality-Based Evaluations

EPA's demonstration approach also requires that the recommended CSO control plan be proven adequate to comply with water quality standards by demonstrating that each of four criteria is met. Receiving water quality models were developed and applied to compare the performance of varying levels of CSO control to baseline conditions in the receiving waters. Comparisons were facilitated using pollutant isopleths for a 2-dimensional model of Boston Harbor, and using pollutant concentration profiles for 1-dimensional models of the Charles River and Mystic River. Tabular presentations were used to compare predicted hours of violations of the state water quality standards for swimming and boating. Hours of violation were compared for baseline conditions, baseline conditions for non-CSO pollutant sources only (stormwater, dry weather, boundary conditions), the recommended plan, and the recommended plan considering CSO sources only. A combination of project-specific and system-wide cost performance curves were used to demonstrate that the MWRA's CSO control plan provides the maximum pollution reduction benefits reasonably attainable and complies with EPA's national CSO control policy using the demonstration approach.

The percent annual compliance for the bacteria standard for swimming (200 colonies per 100 milliliters) was calculated to estimate the impact that the remaining untreated CSO discharges would have on water quality. The magnitude of each of the untreated discharges was quantified based on discharge volume from each outfall in the receiving water segment for those storm events in the typical year that cause overflows. Hours of violation associated with untreated discharges were conservatively assigned based on the hours of violation associated with the 1-year, 24-hour storm, since none of the untreated CSO outfalls discharge during the 3-month, 24-hour storm except in one of the 14 receiving water segments (Fort Point Channel).

RESULTS

MWRA's demonstration approach included the results of both technology-based and water quality-based evaluations performed for all receiving water segments. This section presents an example of the technology-based evaluations, followed by the results that show how the overall performance of the recommended plan complies with demonstration approach criteria.

Example of Technology-based Evaluation

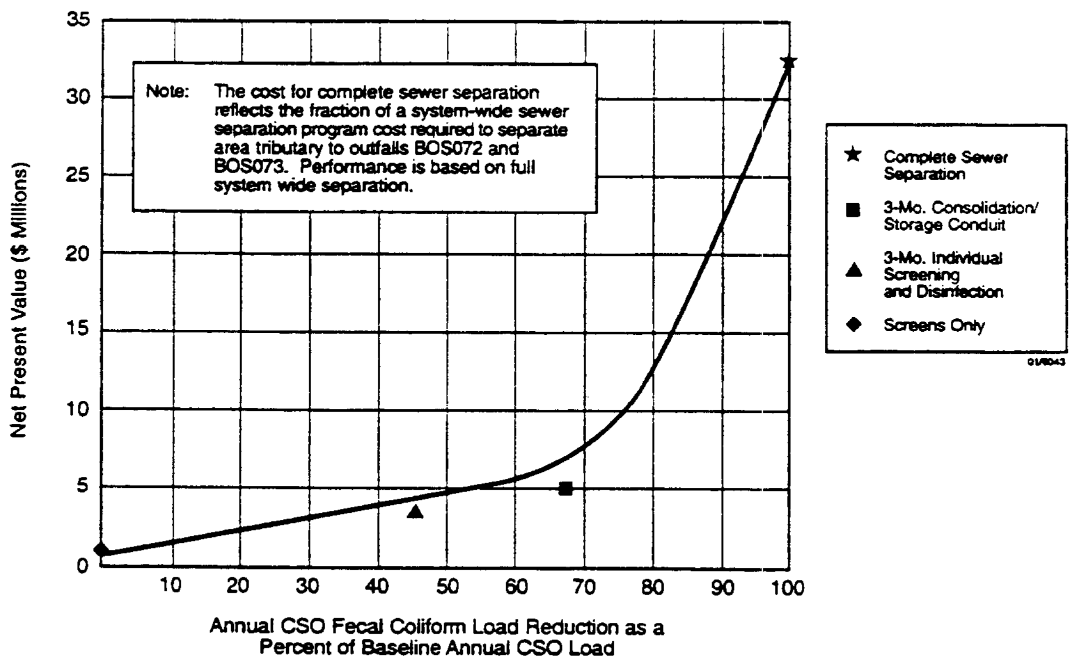
The technology-based evaluations demonstrated that the preferred alternatives represented the best available technology (BAT) economically achievable for each outfall. The results of the evaluations performed to select controls for two adjacent outfalls (BOS072 and BOS073) discharging to the Fort Point Channel receiving water segment are used to illustrate the evaluation process.

Fort Point Channel is a narrow, shallow embayment at the upper part of Boston's Inner Harbor. It is classified as Class SB-fishable/swimmable with restricted shellfishing. No shellfish resources have actually been identified within the channel and sensitive areas that support critical uses, such as swimming, are not located along the channel. Land uses in the vicinity of the channel are a mix of industrial, seafood handling, transportation, and parking. Seven untreated CSOs discharge to Fort Point Channel. No upstream sources or boundary conditions were identified for this receiving water segment. CSOs are the predominant source of fecal coliform bacteria, BOD, and nutrients for the 1-year, 24-hour storm and on an annual basis.

Using preliminary model simulations and system knowledge, four control technologies were initially eliminated from further consideration for outfalls BOS072 and BOS073: CSO relocation, local sewer separation, interceptor relief, individual or consolidated storage tanks, or primary treatment facilities. Following further screening based on cost, performance, construction risks, water quality, and social and environmental impacts, four alternatives were carried forward for detailed evaluations. These included: area-wide sewer separation, a consolidation/storage conduit sized for the 3-month, 24-hour storm, individual screening and disinfection facilities, and individual floatables control. Alternatives for outfalls BOS072 and BOS073 were grouped with alternatives for other CSO outfalls in the receiving water segment to facilitate assessment of overall water quality impacts. The range of controls evaluated for the receiving water generally reflected the range of controls for each outfall. Selection of a preferred alternative was based on the results of the cost/performance evaluations and the rating and ranking methodology.

Figure 1 shows the comparison of annual fecal coliform bacteria load reduction as a percent of baseline annual CSO load for BOS072 and BOS073. The "knee of the curve" indicates that the most cost-effective alternative for controlling fecal coliform bacteria was consolidation/storage of the 3-month, 24-hour storm. Curves for TSS and BOD yielded the same result. Curves showing the percent pollutant removal compared to baseline total receiving water loads from all sources also supported consolidated storage as the appropriate level of control. While complete sewer separation would eliminate CSO discharges in Fort Point Channel, the resulting increase in stormwater loads would cause a decrease in the removal of fecal coliform bacteria compared to consolidation/storage and a net increase in total TSS and BOD loads.

FIGURE 1. NET PRESENT VALUE VS ANNUAL CSO FECAL COLIFORM REDUCTION FOR BOS072 & BOS073



The rating and ranking method was also used to identify a preferred alternative for Fort Point Channel. This method included rating water quality impacts and costs for each alternative. Siting impacts were not rated. Table 1 shows the cost and water quality impact rank orders for the Fort Point Channel alternatives, including CSO controls for outfalls BOS072 and BOS073. The number 1 denotes the highest rank. While there was only minor differentiation among alternatives, the alternative that included the consolidation/storage conduit for outfalls BOS072 and BOS073 had the highest overall rank. Since both the cost/performance and ranking

TABLE 1. SUMMARY OF ALTERNATIVE EVALUATION RANKINGS FOR THE FORT POINT CHANNEL

CSO Control Alternative	Cost Rank	Performance/ Water Quality Impact Rank	Sum of Rankings
Complete Sewer Separation	3	1	4
Control of 3-Month Storm (storage/detention/ treatment) Storage/Consolidation Conduit BOS072, BOS073	2	1	3
Control of 3-Month Storm (screening/disinfection) Individual Screening/Disinfection BOS072, BOS073	2	2	4
Floatables Control	1	3	4

methodologies supported the consolidation/storage conduit for outfalls BOS072 and BOS073, this was the preferred alternative selected. Facilities planning efforts then involved further evaluations of alternatives for siting and construction of the conduit, as well as comparisons of costs, construction risks, and environmental impacts.

Optimization of the Preferred Alternative

The preferred alternative for outfalls BOS072 and BOS073 was construction of a 1,500-foot-long, 10-foot-diameter consolidation/storage conduit. While the original intent of the storage conduit was to capture the 3-month, 24-hour storm, siting issues related to locating tunnel shafts resulted in the conduit being of sufficient size to capture and store the volume of combined sewage generated from all but two storms in a typical rainfall year. Stored flows would be pumped back to the interceptor system once wet weather flows in the system subsided. Flows in excess of the conduit storage capacity would receive floatables control and continue to discharge from the outfalls to Fort Point Channel.

The feasibility of optimizing the preferred alternative to provide a higher level of CSO control was investigated. Optimization would involve providing either a larger storage volume, or combining the storage conduit with another CSO technology such as disinfection. The cost-effectiveness, performance, and receiving water benefits for three incrementally higher levels of control were evaluated. The benefit of removing more pollutants from the waterbody was assessed based on cost-effectiveness, i.e., the unit cost to remove the increment of pollution, and on the relationship between providing incrementally higher levels of control and attaining designated uses.

Table 2 presents the cost and performance of existing baseline conditions, the preferred alternative, and the three higher levels of control evaluated. Based on the net present value per annual pollutant load removed, the preferred alternative is the most cost-effective level of CSO control in terms of achieving control of fecal coliform bacteria, TSS, and BOD, followed by the 11-foot-diameter, 1,500-foot storage conduit. The higher level of control would cause a 7 percent increase in net present value cost for an additional 5 percent reduction in annual pollutant load, showing that the increased cost would be proportional to increased performance.

Model results indicated that under the recommended plan, the bacteria standard for boating is violated during the 3-month, 24-hour storm near outfalls BOS072 and BOS073. The standard for swimming is violated in the remainder of the channel. These violations are due to stormwater discharges, since only treated CSO flow from another outfall is discharged into the channel for this size storm. The model also showed that even total elimination of CSO discharges from the outfalls would not result in attainment of the boating standard during the 1-year storm. Since even total elimination of CSO discharges would not change the level of uses attained in the Fort Point Channel during wet weather due to stormwater, incrementally increasing the project cost to

TABLE 2. COST EFFECTIVENESS OF INCREMENTALLY HIGHER LEVELS OF CSO CONTROL FOR OUTFALLS BOS072 AND BOS073

Alternative	Annual Activation Frequency		Percent Reduction in Annual Pollutant Load			Capital Cost ($ millions)	Net Present Value per Annual Pollutant Load Removed		
	BOS072	BOS073	Fecal Coliform	BOD	TSS		Fecal Coliform ($/count x 10^9)	BOD ($/lb)	TSS ($/lb)
Baseline conditions	10	19	--	--	--	--	--	--	--
10-ft diameter, 1,500-ft long storage conduit	2	2	80	80	80	$13.5	$85	$2,670	$1,490
10-ft diameter, 1,500-ft. long storage conduit with disinfection	2	2	96.7	93	93	$18.4	$97	$3,175	$1,769
11-ft. diameter, 1,500-ft. long storage conduit	2	2	85	85	85	$14.3	$86	$2,685	$1,496
12-ft. diameter, 1,895-ft. long storage conduit	0	0	100	100	100	$17.2	$88	$2,752	$1,534

achieve a proportional incremental increase in CSO control was not recommended. It was noted, however, that the concept of incrementally increasing the size of the storage conduit should be re-evaluated based on more detailed, site-specific information to be developed during design.

Results of Water Quality-Based Evaluations

Results of the water quality assessments performed under the demonstration approach show that MWRA's recommended CSO control plan fulfills the criteria set by EPA for a successful demonstration.

Criterion i: The planned control program is adequate to meet WQS and protect designated uses, unless WQS or uses cannot be met as a result of natural background conditions or pollution sources other than CSOs

The recommended CSO control plan complies with state water quality standards and protects designated uses in all 14 receiving water segments, either by elimination or relocation of CSOs, or by meeting the requirements for the state's water quality classifications of Class B(CSO) or Class SB(CSO) for minimally impacted waters, or by using a variance designation until more water quality information is available.

Performance of CSO control alternatives was evaluated in terms of receiving water impacts. Based on the existing designated uses and associated water quality parameters identified for each receiving water segment, a number of measures were identified to quantify the impact of the CSO control alternatives on water quality. Typical output from the receiving water models used in evaluation of CSO control alternatives included the duration of violation of fecal coliform bacteria standards, predicted fecal coliform bacteria density (broken down by source), and fecal coliform bacteria density isopleths. The modeling analyses focused on fecal coliform bacteria as the parameter of concern, since designated uses to be protected are shellfishing, swimming, and boating. The results of fecal coliform bacteria evaluations were summarized by major basin to demonstrate compliance with EPA criteria for a successful demonstration.

The results of Boston Harbor receiving water model analyses for fecal coliform bacteria under 3-month, 24-hour design storm conditions for baseline conditions - all sources, baseline conditions - non-CSO sources only, and the recommended plan - all sources showed that under baseline conditions, the swimming and boating bacteria standards are violated in several areas of the harbor. However, when baseline conditions - non-CSO sources only and the recommended plan results were compared, the fecal coliform bacteria densities were virtually the same. This means that following implementation of the recommended plan, remaining violations will be predominantly due to impacts from non-CSO sources.

In the Charles River, violations of both the swimming and boating bacteria standards occurred under all conditions, and as in Boston Harbor, the model showed that following implementation of the recommended CSO control plan, remaining violations will be predominantly due to non-CSO impacts. Of particular interest in the Charles River were the dry weather fecal coliform bacteria concentrations that violate the swimming standard all the time. During wet weather, stormwater and upstream sources contribute a major percentage of fecal coliform bacteria to the river basin, while CSOs are not a significant source. The recommended CSO control plan meets *Criterion i* for the Charles River, since significant pollution sources from the upstream Charles River watershed prevent water quality standards from being met even during dry weather. Because efforts are on-going to identify and control non-CSO sources, the regulatory option for a short-term variance from water quality standards for CSO discharges into the Charles River was deemed to be appropriate until more information on the non-CSO sources is available.

> *Criterion ii: The CSO discharges remaining after implementation of the planned control program will not preclude the attainment of WQS or the receiving waters' designated uses or contribute to their impairment. Where WQS and designated uses are not met in part because of natural background conditions or pollution sources other than CSOs, a total maximum daily load, including a wasteload allocation and a load allocation, or other means should be used to apportion pollutant loads*

Hours of violation of the fecal coliform bacteria standards for swimming and boating from the 3-month, 24-hour storm for baseline conditions and for the recommended plan were calculated. For all receiving water segments, the hours of violation after implementation of the recommended plan due to CSO-only discharges is zero for both the swimming and the boating standards. When the "recommended plan CSO-only" results were compared to the "baseline conditions non-CSO-only" results, it was clear that the violations of the bacteria standards remaining after implementation of the recommended plan will be caused by the impacts of non-CSO sources.

Table 3 presents the hours of violation of the bacteria standards for swimming and boating due to the 1-year, 24-hour storm for each of the receiving water segments. Table 3 also presents the annual percent compliance with the swimming standard, assuming each discharge event in the typical rainfall year had the same impact as the 1-year, 24-hour storm. As shown in Table 3, the percent compliance with water quality standards, even using the extreme case based on hours of violation caused by all sources in the 1-year, 24-hour storm, is greater than 95 percent in all receiving water segments. Using hours of violation based on CSO-only for the 1-year, 24-hour storm, the compliance for all segments is greater than 98 percent.

> *Criterion iii: The planned control program will provide the maximum pollution reduction benefits reasonably attainable*

The planning process has resulted in selecting CSO controls that will provide the maximum pollution reduction benefits reasonably attainable for each receiving water segment affected by CSOs. The recommended plan will maximize capture of combined sewage flow and provide treatment at the MWRA Deer Island treatment plant or MWRA CSO treatment facilities for almost all of the total annual combined sewage volume. Implementation of the recommended CSO control plan will reduce the total annual volume of CSO discharges compared to baseline conditions by about 58 percent and will reduce the annual volume of untreated CSO discharges by 95 percent. Of the annual CSO volume remaining after implementation of the recommended plan, 95 percent will be treated at MWRA CSO facilities prior to being discharged. When conveyance to the Deer Island treatment plant is considered, 99.7 percent of the total annual combined sewage volume will be captured and treated under the recommended plan.

As shown by Figure 2, the most significant reductions in CSO volume and pollutant discharges, including BOD, TSS, and fecal coliform bacteria, are predicted to have occurred from 1988 to 1997, which is consistent with

TABLE 3. HOURS OF VIOLATION OF BACTERIA STANDARDS FOR 1-YEAR, 24-HOUR STORM (based on 96-hour simulation)

Receiving Water Segment	Hours of Violation of Swimming/Boating Standards[1] for Fecal Coliform				Annual Compliance % All sources vs CSO only

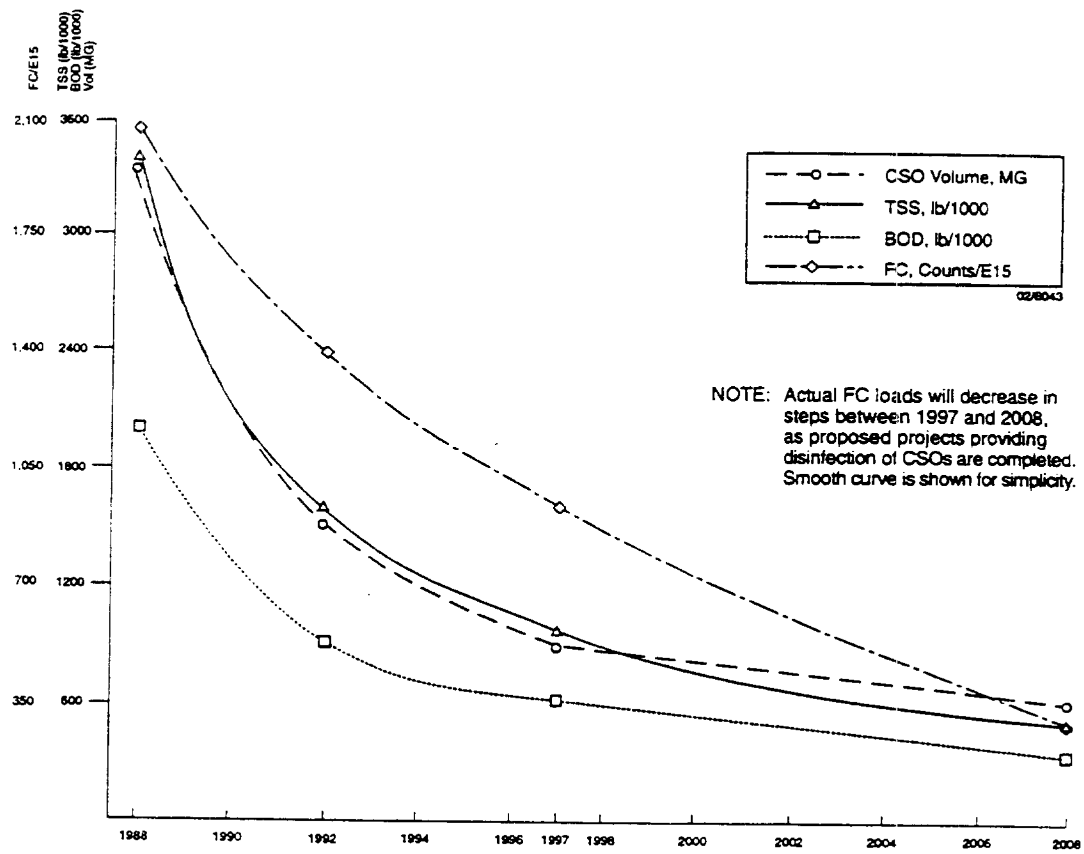
(1) Swimming standard = 200 # / 100 ml; Boating standard = 1000 # / 100 ml.
(2) Includes boundary, stormwater, dry weather, and CSO sources.
(3) Includes Back Bay Fens.
(4) CSO discharges are eliminated.
(5) These segments violate the bacteria standard for swimming all the time if dry weather components are included.
(6) Treated discharges only.

system improvements that were undertaken during that time. The substantial reduction in CSO volumes are primarily related to increases in pumping capacity at the Deer Island treatment plant. Additional reductions associated with the MWRA CSO control plan will occur from 1997 to the year 2008, by which time reductions on the order of 80 to 90 percent will be achieved for CSO discharge volume, BOD, TSS, and fecal coliform bacteria.

With 95 percent of the flow being captured and conveyed to Deer Island for secondary treatment, further reductions in CSO volume or pollutant loads after the year 2008 would have relatively little significance in terms of water quality improvement, and would be even less significant when compared to potential total load reductions to the receiving waters. If further improvements to receiving water quality are to be realized, these improvements must come from the control of non-CSO sources. Higher levels of CSO control beyond those recommended in the CSO control plan would not achieve measurable receiving water benefits.

FIGURE 2. ANNUAL VOLUME AND POLLUTANT LOADS, CSO ONLY



Criterion iv: The planned control program is designed to allow cost effective expansion or cost effective retrofitting if additional controls are subsequently determined to be necessary to meet WQS or designated uses

Given the level of control that the recommended CSO control plan will achieve, additional controls will not likely be justified until substantial reduction in non-CSO sources of pollutants are achieved. Where feasible, the recommended plan would allow for providing higher levels of CSO control if necessary. For example, where hydraulic relief is currently recommended, storage and/or treatment units could be added in the future.

DISCUSSION

MWRA used the demonstration approach because detailed information on the combined sewer system had been gathered and the accuracy of models to evaluate system performance and water quality impacts from CSO and non-CSO sources of pollution had been verified. According to EPA's CSO policy, the demonstration approach was intended to provide flexibility in developing CSO plans, such that a plan could be shown to meet water quality standards while not necessarily satisfying the criteria under the policy's presumption approach. Analyses conducted during facilities planning actually showed that MWRA surpasses the presumption approach requirements, even before the CSO control plan will be fully implemented.

MWRA's CSO control plan meets the first presumption criterion by reducing the activations of untreated CSOs to no more than an average of four events per year on an annual average basis in the typical rainfall year.

The results of system modeling also showed that the percent capture, or the percentage of flow entering the combined sewer system during periods of precipitation which is captured for treatment, steadily improved from 1988 to 2008. In 1992, when initial improvements at the Deer Island treatment plant were near completion, but implementation of major conveyance system improvements and construction of the new Deer Island treatment plant were only beginning, MWRA nearly achieved the 85 percent capture cited in the second criterion under the presumption approach. Under 1997 conditions, assuming full pumping capacity at the Deer Island plant, MWRA exceeds the 85 percent capture criterion. Additional combined sewage capture by the year 2008 will be achieved when, under the recommended CSO control plan, 95 percent of the flows entering the system will be treated at the Deer Island plant to meet secondary effluent limits. The third presumption criterion requires that no less than the mass of pollutants causing water quality impairment for the percent reduction in volume achieved be eliminated or reduced. Since 95 percent of the combined sewage flows will receive secondary treatment, this third criterion will also be met.

Although MWRA meets not one but all of the criteria under EPA's presumption approach, the demonstration approach provided the advantage of tailoring CSO controls to specific conditions in distinctly defined receiving waterbodies. Greater emphasis could be focused on protecting waterbodies that support sensitive uses rather than making across-the-board reductions without considering site-specific water quality and existing designated uses.

CONCLUSIONS

The MWRA's CSO control plan complies with the requirements for a successful demonstration under EPA's national CSO policy, confirming that water quality standards will be met and designated uses protected. Using the demonstration approach involved comprehensive and detailed assessments to accurately characterize receiving waters, CSO and non-CSO sources of pollution, and associated water quality impacts. By developing the plan according to the demonstration approach, CSO controls were selected to address site-specific conditions. The demonstration approach not only resulted in an environmentally sound plan that provides an appropriate level of CSO control, but also a cost-effective plan that acknowledges the need to consider ratepayer interests.

ABSTRACT

The Northeast Ohio Regional Sewer District (NEORSD) is the agency responsible for wastewater treatment in the Cleveland area. Its jurisdiction includes interceptor sewers, three wastewater treatment plants, and combined sewer overflows (CSOs). NEORSD's National Pollutant Discharge Elimination System (NPDES) permit requires development of a CSO control plan.

The Westerly district of NEORSD's service area is tributary to the Westerly Wastewater Treatment Plant (WWTP). It consists of approximately 40 km^2 (10,000 acres), of which 75 percent are served by combined sewers. It is entirely located on the west side of the City of Cleveland. The combined sewer area contains 4 interceptor sewers, 70 static regulators, 8 hydrobrakes, 8 automated regulators, and 26 CSO outfalls. Lake Erie, Cuyahoga River, Rocky River and Big Creek receive CSO discharges from this area during wet weather. When peak wet weather flows exceed the capacity of the Westerly WWTP, the overflows are routed to the adjacent Combined Sewer Overflow Treatment Facility (CSOTF).

NEORSD is undertaking a study that will result in specific recommendations for a long-term wet weather control plan in the Westerly district. This paper focuses on aspects of the study that have been completed and on the results obtained. An extensive monitoring program including more than 100 flowmeters was conducted during the spring of 1997. The separately sewered area, which has over-under sewers, was included in the investigations. Data management utilizes a Geographical Information System (GIS). A detailed HydroWorks™ model of the collection system is fully integrated into the GIS. Monitoring and analysis of the operation of CSOTF was performed.

Based on results of the data collected, several projects have been identified for early implementation. These projects include location and removal of sources of dry weather contamination and prevention of river water inflow into the sewer system. While these projects are underway, a range of long-term alternatives are being evaluated for an overall wet weather plan for the Westerly district.

INTRODUCTION

In accordance with its NPDES permit, the NEORSD must develop a long-term combined sewer overflow control plan (LTCP). Efforts towards this plan were initiated in the early nineties, when the NEORSD conducted a Phase I CSO study of its entire service area. Phase II studies are now being conducted in the service areas tributary to each of the three District wastewater treatment plants. This paper describes the study being conducted in the Westerly district. The study was initiated in late 1996 and is scheduled for completion by the end of 1998. The study area is shown in Figure 1.

The ultimate goal of the Westerly district CSO study is the reduction of the impact of combined sewer overflows in the receiving waters. The study also intends to devise solutions to alleviate basement flooding whenever possible.

A thorough understanding of the Westerly district system is paramount to the development of this study. The *Methodology* section describes the technologies and procedures utilized to attain this understanding and summarizes the methods utilized to analyze and manage the information about the Westerly district. Results of the data collection and analysis efforts are then presented, along with a description of projects

being implemented based on the results. The *Discussion* section contains the approach for evaluating alternatives for CSO control and a summary of public information activities. The paper concludes with the status of the study as of March, 1998, and a summary of its most relevant aspects.

METHODOLOGIES

Flow Monitoring

The general goal of the flow monitoring program was to provide an understanding of flow characteristics in the Westerly collection system. Specifically, the program provided data for calibration of the sewer system hydraulic model, for SSES tasks such as determination of infiltration and inflow (I/I) components within the separate sanitary sewer areas, and to assist in the quantification of study area pollutant loads.

In total, 108 flow monitors and 7 rain gauges were installed within the Westerly district. Primary flow monitoring and rain gauging were conducted from March 3 through June 16, 1997. A subset of monitors (11 total) remained in place until August 27 to further evaluate the performance of the WWTP and CSOTF during larger rain events. The meters recorded flow measurements every 5 minutes throughout the field investigations.

Water Quality Sampling

Sampling of outfalls to study area receiving waters was conducted during both dry and wet weather. During dry weather, field investigations were performed to determine flows and pollutant loads from outfalls in the Westerly drainage area. These investigations included a shoreline reconnaissance survey to locate the outfalls. Flows were measured and samples were taken for any outfalls found flowing during dry weather. Flows were sampled for bacteria and ammonia as indicators of possible contamination from wastewater.

Outfall quality monitoring during wet weather was performed to allow quantification of pollutant concentrations and loads entering the receiving waters. Eight outfalls in the Westerly system were monitored for water quality during five rainfall events. Both automated time-weighted composite and grab samples were collected at each site for analysis. Parameters analyzed included bacteria, BOD, TSS, nutrients and metals. Each sampling site was equipped with an ADS flow meter for measuring depth and velocity and an Isco Model 3700 sampler for collecting water quality samples. During each storm event, the Isco Model 3700 sampler was manually activated and collected a 350 ml sample in a glass vessel every 15 minutes for 6 hours (24 samples).

The eight sampling sites were selected to characterize discharges from outfalls that had large amounts of storm water (i.e., from highway drainage) or from areas with largely separate over-under sewers. An extensive database of quality from outfalls with mostly combined sewers was already available from a previous study (Havens & Emerson, 1994). This approach allowed cost-effective characterization of all of the major types of pollutant loads from the Westerly district.

Receiving Water Assessment

The Westerly district is interesting in that it drains to four different receiving waters. In each case, there are numerous sources of pollution other than CSOs entering upstream (or, in the case of Lake Erie, up-wind). The pollutant loads from the study area (CSO as well as storm water) were estimated and compared to background or upstream pollutant loads.

CSOTF Evaluation

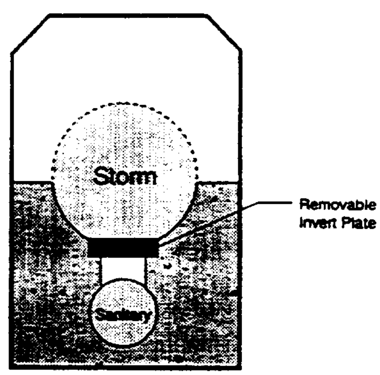
The flow monitoring and sampling program also assessed the effectiveness of CSOTF. CSOTF stores and treats wet weather flows that exceed the Westerly WWTP influent capacity. Six storms were intensively monitored and sampled to provide flow and mass balance information. From this, pollutant removal effectiveness was defined. These results are presented in detail in a separate technical paper (McMasters et al, 1998).

Sewer System Evaluation Survey (SSES) Information

Existing sewer system information was collected from various sources. The NEORSD maintains sewer plans, profiles, and structural drawings for all interceptors and much of the sewer system. Drawings which were not available from this source were obtained from the City of Cleveland, who owns and maintains the local sewers. In 1978, Cuyahoga County produced county-wide aerial maps which were used as base maps by the City of Cleveland to produce area-wide sewer maps showing sewer alignments, types and sizes. Regulator schematic drawings and drainage area boundaries were obtained from the NEORSD Phase I CSO Study. In all, about 1,000 drawings were cataloged and reviewed. This emphasizes the importance of developing data management methods for approaching large area-wide projects.

FIGURE 2

TYPICAL OVER-UNDER SEPARATE SEWERS



OVER-UNDER

A field inspection program was carried out to check and confirm the accuracy of existing information for mapping, determine the condition of the sewers and obtain information necessary for developing the hydraulic model such as flow direction, connectivity, and elevations.

Selected portions of the separate sewered area were evaluated for infiltration/inflow. About half of this separate sewer system has a unique design common in the Greater Cleveland area known as "invert plate sewer" or "over-under sewer." In this configuration the storm sewer is directly above the sanitary sewer. At manholes, a removable cast iron plate which forms the invert allows access to the sanitary sewer. A typical over-under sewer design is shown in Figure 2.

The separate system was inspected in detail. Flow monitoring results were used to rank suspect I/I stretches. Dye testing with televising was used to investigate I/I sources. A total of over 7,700 meters (25,000 feet) of sanitary sewer ranging in diameter from 20.32 to 45.72 cm (8 to 18 inches) in 145 pipe reaches were televised.

Geographical Information System (GIS)

The extensive amount of data generated by this project required effective management. In addition, NEORSD routinely produces presentation-quality maps for its facilities planning projects. Utilizing a GIS to manage data was a natural choice for the needs of the project.

Cuyahoga County planimetric maps based on 1993 aerial photos were translated into ArcView® format and served as the base maps for the GIS. Local sewers were digitized in AutoCAD® and imported into ArcView®. Under the Westerly District Interceptors Inspection and Evaluation Project (Duke et al, 1998), data were collected on the NEORSD interceptor sewers and outfalls. This data was combined with the local sewer data to form a complete physical representation of the Westerly district in the GIS.

Digital databases containing manhole and pipe information were linked to the ArcView® GIS. Other databases include information on the over-under sewers (condition of each manhole plate), locations of flowmeters, and water quality sampling results. Spatial information such as land use, ward boundaries, and neighborhood boundaries were also included in the GIS.

The ArcView® GIS was developed to facilitate data storage for both mapping and hydraulic modeling tasks.

HydroWorks™ Collection System Model

The hydraulic model for Westerly needed to include all interceptors and outfalls, as well as major trunk sewers in the combined system, all over-under sewers (down to 20.32 cm [8-inch] pipes) in the separate system, all hydrobrakes and both static and automated regulators. The HydroWorks™ model was selected because it could simulate this system in a stable and robust manner. HydroWorks'™ capability to simulate automated flow control structures incorporating the PID control process was particularly important. The GIS was used for handling the large volume of collection system data during the model development and as an input and output processor.

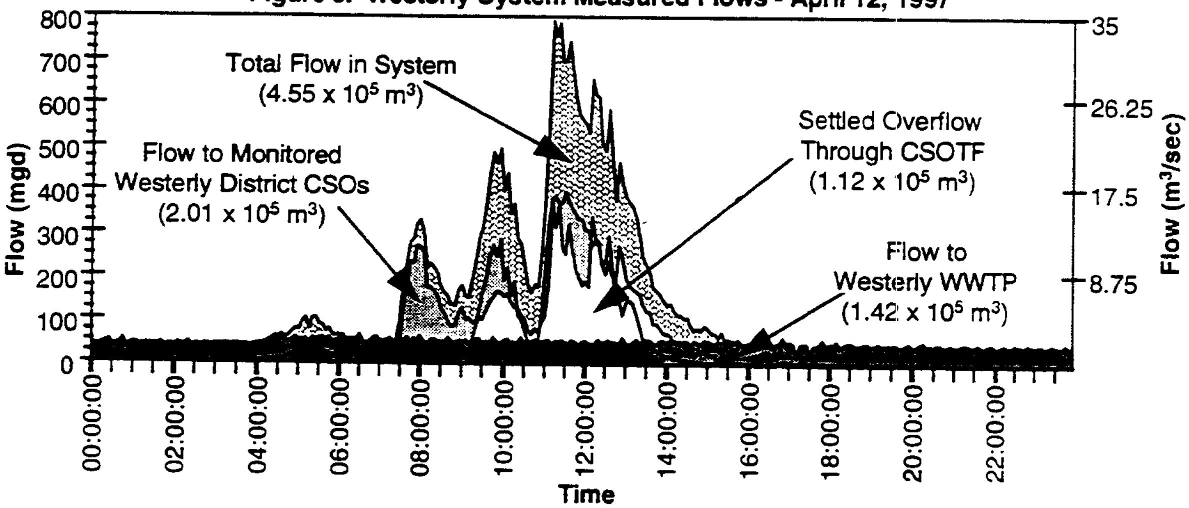
RESULTS

Flow Monitoring

The flow monitoring program successfully monitored over 15 storm events, with the majority of the flow meters being operational for most of the storm events. The data are being used mainly to understand flows in the system and for calibration of the HydroWorks™ collection system model.

The measured flows were analyzed to determine overall volumes in the system for various storm events. One example of this is shown in Figure 3, in which total volumes for the storm of April 12 are estimated. The volume treated at the WWTP, at CSOTF, and the volume overflowing are estimated based on the flow data. This indicates that the treatment facilities in the Westerly system already allow treatment of about 56 percent of the wet weather volume during the one-day period. This does not include storage in the system (autoregulators and hydrobrakes) and in the CSOTF tanks, which results in higher capture.

Figure 3. Westerly System Measured Flows - April 12, 1997



Dry Weather Outfall Sampling Results

The results of the dry weather outfall reconnaissance and sampling are summarized in Table 1. Only a small percentage of the total number of outfalls showed evidence of possible contamination from wastewater. Each of the outfalls was traced upstream by NEORSD staff to determine potential sources of contamination. Letters were written to responsible parties, and the problems are in the process of being corrected. It should be noted that the total pollutant load from these dry weather sources was minimal in comparison to background or upstream loads, and can be neglected during facilities planning.

Table 1. Dry Weather Outfall Investigations

Receiving Water	Outfall Data Summary				
	Outfalls Found	Outfalls Flowing		Outfalls Needing Further Investigation*	
		Number	Percent	Number	Percent
Cuyahoga River	140	19	14	9	6
Lake Erie	37	1	3	1	3
Rocky River	71	24	34	15	21
Total	248	44	18	25	10

** Ammonia ≥1 mg/l and/or fecal coliform ≥ 10,000 MPN/100ml*

Wet Weather Outfall Sampling Results

Concentrations of parameters measured during this project (mainly in storm water) are compared in Table 2 with CSO concentrations previously measured. Results indicate that generally lower concentrations were found in storm water than in CSO. These values are being used to estimate pollutant loads based on the CSO and storm water volumes computed by the hydraulic model.

Table 2. Comparison of Outfall Quality

Parameter (Unit)	Mean Concentration - All Storms and Sites	
	Phase II Project Data (Mainly Storm water)	Phase I Project Data (Mainly CSO)
BOD_5 (mg/l)	12.1	81
TSS (mg/l)	58	444
FC (MPN/100ml)	33,500	855,000
NH_3 (mg/l)	0.8	4.3

Receiving Water Assessment

This assessment indicated that upstream or storm water loads, rather than Westerly district CSO loads, were the dominant factors influencing attainment or non-attainment of water quality standards in the Cuyahoga River, Rocky River and Big Creek. (CSO loadings to Lake Erie were insignificant.) The CSO loadings were either larger or of the same order of magnitude as upstream dry weather loadings (due to large upstream drainage areas). However, control of wet weather sources other than CSO was determined to be equally or more important to water quality conditions.

In consideration of the above finding, rigorous water quality modeling is not being used for the evaluation and selection of CSO control alternatives in the Westerly district. Instead, models are being used to demonstrate that the selected CSO control alternative does not in itself prevent attainment of water quality standards as required by the demonstration approach of the CSO policy. Incremental impacts resulting from the LTCP are being calculated and compared to existing conditions and conditions without CSO overflows (the Ohio Strategy requires that the control option of eliminating all CSOs be considered) using existing models and design storms to evaluate incremental water quality impacts.

I/I Results

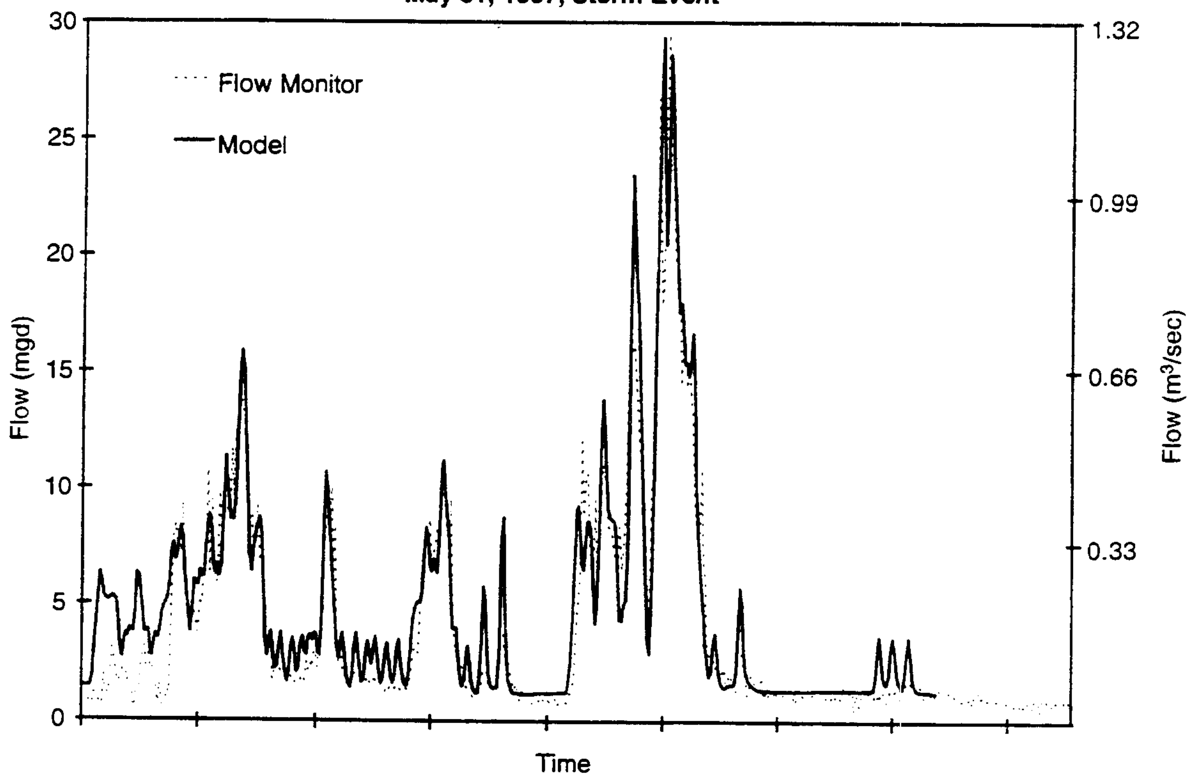
Out of 265 manholes with invert plates, 140 were intact and positioned properly. The remaining 125 plates (47%) were either damaged (45), seated improperly (24), or missing entirely (55). The I/I investigations in these pipe stretches determined that most of the inflow — and contaminated overflows —

are the result of the condition of these invert plates. Investigation of separate sewers which are not invert plate sewers determined that inflow was largely due to private property connections. In order to effectively investigate and televise these sewers, many reaches required extensive sediment cleaning. Since basement flooding had been reported in some of these areas, the cleaning is expected to provide some relief from this condition.

HydroWorks™ Model Calibration

The approach to HydroWorks™ model calibration relies on in-depth knowledge of the collection system. Emphasis is placed on drainage system data which includes pipe attributes and land use characteristics. Calibration was carried out for dry weather and wet weather events. For the initial storm run, model results showed a good comparison against flow monitoring data. One of the calibration curves is shown in Figure 4. It depicts the event of May 31, 1997, which had a total rainfall of 2.2 cm (0.87 in.) over a 36-hour period.

Figure 4. HydroWorks Model Calibration
May 31, 1997, Storm Event



River Inflow

An unexpected finding was made during the course of the sewer system investigations. Three CSO outfalls to the Cuyahoga River were flowing into the collection system. The problem was caused by river levels being higher than the weir levels at regulators upstream of these outfalls.

A fast-track study of the affected outfalls indicated that, although the problem had been observed in a year when Lake Erie (and thus the Cuyahoga River) had reached record levels, it could persist even at lower lake levels. The study determined that transportation, pumping and treatment of the inflowing river water represented a significant cost, and that collection system capacity was being diminished by the river inflow. The cost-effective solution to control the problem would be the installation of "duckbill" valves at two of the problem sites, and the increase of the weir elevation at the regulator upstream of the third site.

Study recommendations were expeditiously adopted, and the river inflow control project is currently in its final design stages. Construction is planned for later this year.

DISCUSSION

At the time of the writing of this paper, the study team has developed a clear understanding of system characteristics. The stage is set for conducting the alternative analysis.

Traditional capital intensive solutions for the control of combined sewer overflows include increasing system storage, conveyance, or treatment capacities. In analyzing possible alternatives for the Westerly district, structures such as tunnels, basins and vortex separators will be assessed. However, special attention will be paid to optimizing the operation of the existing system. The automated regulators that are already a functional part of the system make Westerly especially suited for this type of approach.

A multicriteria approach is being employed for the analysis of potential CSO control solutions. Criteria in the analysis include capital and operational cost, effectiveness, reliability, public acceptance, maintenance complexity, and permitting issues. The weight of each criteria in alternative evaluation is being determined by assessing the importance of each criteria to NEORSD decision makers. A measure of public acceptance of each potential alternative will result from the extensive public participation program that is part of this study.

The public participation program was initiated at the local government level. Council representatives of the wards located in the study area were individually contacted and briefed on the project, as were City of Cleveland public officials engaged in functions related to wastewater. Outreach to the general public was achieved by holding public meetings at a library in the study area. Neighborhood organizations and community groups were invited to attend. In addition, flyers announcing the meetings were posted on bulletin boards throughout the study area, and advertisements appeared in community newspapers. Two of four planned meetings have already taken place, with satisfactory general public attendance. At these meetings, the public was informed of the goals, status and available results of the study, and had opportunity to ask questions and raise concerns. At the upcoming meetings, the public will be invited to comment on proposed alternatives before final recommendations are selected.

CONCLUSIONS

Now in the facilities planning stage, the Westerly study has the database and tools which will allow the development of a cost-effective LTCP. In the process of developing these data and tools, noteworthy findings, early actions, and benefits occurred:

- As a result of the study's field investigation efforts, the City of Cleveland has already received extensive information on problems with manhole invert plates, system blockages, and potential improper connections.

- During the flow monitoring effort an existing flowmeter located at the discharge of CSOTF was revamped and extensively tested, leaving CSOTF with an improved process for measuring and reporting overflows from the facility.

- Water quality investigators meticulously traced every incident of dry weather flow from outfall to source, notified the appropriate parties, and are tracking the source removal process.

- River inflow through the outfalls located in the Westerly district will soon be a problem of the past. Construction of river inflow control facilities will be well underway by the time the Westerly CSO Study Final Report is produced.

- Thanks to the public information program, residents of the study area have a forum where they can bring questions and concerns. Even when their sewer-related problems fall beyond the realm of the NEORSD, residents are educated on how to proceed towards a solution.

- NEORSD planners and engineers are making use of the Westerly District Geographical Information System even as it is still being developed.

If a project's achievement can be measured by how early the community starts reaping its benefits, the Westerly study is a success.

ACKNOWLEDGMENTS

Funding for this project was provided by NEORSD.

APPENDIX

Abbreviation	Term
BOD	Biochemical oxygen demand
cm	Centimeters
CSO	Combined sewer overflow
CSOTF	Combined Sewer Overflow Treatment Facility
FC	Fecal coliform
GIS	Geographical information system
I/I	Infiltration and inflow
km^2	square kilometers
LTCP	Long-term control plan
mg/l	Milligrams per liter
mgd	Million gallons per day
MPN/100 ml	Most probable number per 100 milliliters
NEORSD	Northeast Ohio Regional Sewer District
NH_3	Ammonia
NPDES	National Pollutant Discharge Elimination System
OEPA	Ohio Environmental Protection Agency
PID	Proportional integral differential
SSES	Sewer System Evaluation Survey
TSS	Total suspended solids
USEPA	United States Environmental Protection Agency

ABSTRACT

An approach and a tool developed to optimize long term CSO plans are proposed. The idea consists of investigating a large number of alternative CSO control measures in a global optimization problem and considering the overall CSO control performance. Alternative CSO control measures include the sewer network operating mode, the localization and sizing of the retention facilities, the transport and treatment capacities of the sewer network. The optimization tool, MED-SOM, is linked to an hydraulic/hydrologic model. It simulates the behavior of the network scanning through all possible combinations and permutations of CSO control alternatives in order to find the CSO plan that best suit the environmental objectives at the least possible cost. Preliminary results show that the proposed CSO plan approach can help reduce the cost of CSO control programs by as much as 30% compared to more traditional approaches.

KEY WORDS: Combined Sewer Overflow, long term CSO control plan, conceptual design, optimal control, nonlinear programming, automatic sewer design, sites of intervention.

1.0 INTRODUCTION

The optimization of a CSO plan is generally a complex task. It demands a broad expertise in various fields including hydrology, hydraulics, environment, mathematics, civil and mechanical engineering, and process control. Difficult issues such as the localization and the sizing of retention facilities, the assessment of additional transport and treatment capacities and the choice of a control strategy have to be addressed and answered, ultimately in an optimization process. Therefore, to decrease the potential risk of designing a CSO plan that is not properly optimized in terms of implementation cost and/or CSO reduction, most engineers use hydrologic and hydraulic simulation tools to perform there CSO plan studies. In general, the approach followed consists of finding the CSO sites, according to a prior knowledge of the sewer network behavior, identify control solutions, and simulate the proposed solutions in order to find to most profitable one in term of CSO reduction and construction cost.

This conventional CSO plan approach is simple and has proven to be valuable over the years in many cases of application. However, the conventional approach precludes the study of all combinations and permutations of a large and diverse solution set since each change is evaluated through a trial and error process. Moreover, most hydrologic and hydraulic softwares used do not have the ability to investigate control outside of static or local control. As a consequence, there is no guarantee that the best CSO plan found using the conventional approach is the best CSO plan that could have been proposed.

In the present paper, a new CSO plan approach is presented. Conversely to the conventional approach, the proposed method breaks the barrior of the trial and error method and enables to evaluate the environmental performance and the implementation cost of a large number of CSO control measures. The approach also evaluates the influence of the selected management strategy on the cost of the best CSO plan that complies with the environmental objectives. The use of the CSO plan optimization method and the software MED-SOM, developed by ASSEAU-BPR, is illustrated through various projects. The work plan described below is the one that will be used for the development of the CSO plan of the Westerly District for the Northeast Ohio Regional Sewer District (Cleveland, Oh).

2.0 CSO PLAN OPTIMIZATION WITHOUT THE CONSTRUCTION OF NEW FACILITIES

Different operating control modes have been proposed in the literature for the management of sewer networks (Papageorgiou, 1988; Gonwa and Novotny, 1993; Gelormino and Ricker, 1994). Just changing the mode of operation of a sewer network from static control to dynamic control can readily maximize the use of existing transport, retention, and treatment capacities. Furthermore, it has been shown, in the example of the Quebec Urban Community CSO control project, that these measures are cost effective compared to the construction of new facilities (Lavalle et al., 1996). Using the MED-SOM software, the CSO performance of three control strategies can be evaluated: static control, local control, and global optimal control. We explain below how these control modes operate using MED-SOM.

2.1 Static control

The static sites of control enables to simulate the sewer network behavior associated to fixed flow regulators such as orifices, weirs, gates, and pumps. This flow operation mode is simulated directly by MED-SOM without any other inputs from other commercial hydrologic and/or hydraulic softwares (e.g., SWMM, HydroWorks). In this case, the commercial models are used only to validate and calibrate the simulations done with MED-SOM. In a long term CSO plan, a plan defined with no new facilities and static control permits to assess the minimal acceptable performance.

2.2 Local dynamic control

Local reactive control enables to maintain a prescribed flow or water level downstream of a flow regulator. This type of control is used to minimize the risk of flooding and to maintain hydraulic stability into the network during rainfall events. Conversely to the static control mode, the locally controlled sites can be designed to maintain a constant flow to the wastewater treatment plant without regards to the hydraulic load found into the sewer network.

In MED-SOM, the water level set points are converted at each control period as flow set points using PID (Proportional Integrative, Derivative) algorithms. All flows and water level set points can be time varying, however, the variations must be defined prior to the beginning of simulations. While the behavior of the network is simulated with the commercial models, the local set points can be defined by the designer or computed by MED-SOM. If computed by MED-SOM, the local set points are such that the total overflow volume is minimal for the rainfall event considered. Therefore, with MED-SOM, the design engineer can determine the best performance, in term of CSO reduction, that can be achieved when using local control.

2.3 Global optimal control

Global optimal control consists of finding, at each control period, the flow set points that enables to achieve specified control objectives. Control objectives can be : the minimization of the CSO volumes, the maximization of the use of the wastewater treatment plant capacity, the minimization of dewatering time, and the minimization of operating costs. Moreover, this control strategy enables to meet specific requirements at each control sites. For example, specific pollution sensitivity can be assigned to overflow sites in order to transfer overflows from more sensitive receiving water bodies to areas that can handle more important pollutant loads.

In MED-SOM, the optimization problem that consists in finding the optimal set points, is solved using a CEOLFC (Certainty Equivalent Open Loop Feedback Control) strategy in conjunction with a nonlinear programming algorithm with linear constraints (Methot and Pleau, 1997; Pleau and al., 1996). The choice of such a problem formulation reduces computing times and improves the robustness of the global optimal strategy in real time control. In particular, the robustness problem associated to modeling uncertainties is addressed by correcting the flows and volumes predicted in the optimization loop according to the flows and volumes simulated by an explicit hydraulic model such as SWMM. The operating and control objectives as well as the constraints defined in MED-SOM are summarized in Table 1.

The future rainfall needed to built the optimization problem can be provided in MED-SOM either by a meteorological forecasting model transforming radar images into future rainfall intensities (e.g., CALAMAR) or by extrapolation routines based on past measurements. In particular, the future rainfall intensities can be extrapolated using a bell shape Gauss curve calibrated on past rainfall measurements.

The behavior of the control sites and flow regulators dynamic can be simulated by MED-SOM to reproduce as closely as possible the behavior of the sewer network. The regulators' dynamic is approximated to a first order model with dead times, whereas the sites are controlled by PID algorithms. The architecture of the global optimal scheme is presented in Figure 1.

The simulation results recorded when all the flow regulators are globally and optimally controlled give a good assessment of the best environmental performance that can be achieved without the addition of new facilities. Therefore, if these results do not meet the environmental objectives, one must include the addition or the replacement of facilities within the CSO plan development.

3.0 CSO PLAN OPTIMIZATION WITH THE CONSTRUCTION OF NEW FACILITIES

In the majority of the CSO plan projects, the environmental objectives cannot be fulfil only by modifying the control strategy, and new facilities have to be built or replaced. MED-SOM can be used to simulate and optimize a predefined set of CSO control solutions, from a more conventional approach. The added benefit of using MED-SOM is in evaluating how these facilities can best be operated, according to one of the operating modes described above. Under this approach, the planned CSO control facilities can be set to fixed capacities or have an initial null capacities. If the capacities are assumed to be zero, the overflow volumes recorded at each retention site can be associated to the retention volume that should be built in order to have no overflows.

MED-SOM also enables to perform automatic CSO plan optimizations with basic information such as control site availability. The approach consists of investigating, in a global optimization problem, all the potential combinations and permutations of CSO control facilities, locations, and sizes, and to find the solution set that meets the environmental objectives at a minimal cost. The construction of the optimization problem is made by defining a fictitious sewer network including at each possible site an infinite number of new retention tanks, conduits, or treatment facilities. Each facility has a capacity ranging from 0 to a maximum capacity – usually related to geometry of the water works and land availability. From this complete network, including all possible CSO control solutions and possible operating modes and with an infinite number of potential facilities, the automatic CSO plan optimization routine finds the best CSO plan that optimally fulfills the environmental objectives specified.

3.1 The cost function

The cost function defined in the automatic CSO plan optimization approach is built according to a table relating costs to retention capacities. The table can be defined by the design engineer or it can be automatically built by MED-SOM using the physical description of the sites. The cost function is represented in the optimization problem as a smooth cubic function guaranteeing the convergence of the CSO plan optimization to an optimum. The parameters of the cubic function are computed using a linear regression routine, such that the sum of the squared difference between the costs defined in the table and those predicted by the smooth function is minimal.

3.2 Designing new facilities

The designing mode implemented in MED-SOM is usually used in the planning process to pre-design the new facilities. In order to use this feature, data related to the geography and the geology of the retention sites have to be defined. The results provided by MED-SOM include various retention tank design information such as: the volume of excavation, the width, the length and the height of the storage tanks, the thickness of the base and the roof, the number and the diameter of the columns needed to support the roof, and the depth of the tanks in the ground. The design informations are determined in conjonction to the cost function to assure the lowest CSO plan cost.

3.3 A case study: the Quebec Urban Community CSO plan project

The west side of the sewer network of the Quebec Urban Community (QUC) is composed of three main interceptors merging at a connecting chamber. Downstream from that point, the flows are conveyed through a tunnel to the wastewater treatment plant. The plant has a capacity varying between 110 MGD and 135 MGD depending upon the St-Lawrence River's tide. The actual storage capacity of the network is provided by two tunnels, the *Affluent Tunnel* upstream of the treatment plant (capacity 4 MG) and the *Versant Sud Tunnel* located in the south interceptor (capacity 0,2 MG) (Figure 2).

The objective of the QUC study was to develop a CSO control plan to reduce the total CSO volume below a prescribed value of 80 MG per summer, taking the summer of 1988 as an average year.

The QUC CSO control program will begin by implementing global optimal predictive control in order to benefit from the existing in-line retention capacity provided by the two tunnels cited above, and the wet weather treatment capacity of the wastewater treatment plant. The 4.6 M$ investment for implementing this first phase of the CSO program is very cost effective. It will help eliminate 60% of CSO events and reduce the total CSO volume by 60% during an average year, as shown by simulation with MED-SOM for year 1988 (Lavalle et al., 1996).

The remainder of the QUC CSO control program for this western portion of its sewer network consist of building four additional retention tanks (sites C,D,E,F) totaling 4 MG of retention capacity. These tanks will also be operated under global predictive real time control for improved performance. Using a conventional control approach the estimated retention volume needed was superior than 5 MG. Therefore, a reduction of 25% in volume needed to comply with the environmental objectives was superior than 5 MG.

3.4 A case study: The central region of Ile-de-France

The sewer network modeled within MED-SOM for the CSO plan study of the central region of Ile-de-France is composed of five interceptors located along the Seine River. The objective of the CSO plan was to find a set of CSO control solution which would help maintain acceptable water quality levels in the Seine and Marne Rivers for rainfall events of recurrence higher than 1 in 10 years.

Seven potential retention sites, including tanks and tunnels were identified from a first screening process aimed at locating the land available for the construction of storage facilities. New transport facilities, allowing the transfer of water from one interceptor to another or from an interceptor to an existing or planned treatment station were also considered as potential interventions. After a second screening process, six transport facilities and five wastewater treatment plants (new or to be upgraded), were included in the CSO plan study.

In this study, four sets of solutions designed to handle 80% of wet weather overflows discharged into the Seine and Marne River for a 1 in 6 months rainfall event, operated under static control. We further analyzed these four scenarios applying global predictive real time control and showed we could improve the environmental performance of all four scenarios by some 30%. This improved performance meant that we could then comply with wet weather water quality objectives for a 1 in 10 years event.

3.5 A case study: The Westerly District in Cleveland

Asseau-BPR has designed a methodology for the elaboration and optimization of the CSO plan for the Westerly District of the greater Cleveland area according to the plan described above:

Assess the potential of applying a single type or a combination of static, local control, and global optimal control to the existing system, maximizing in-line storage, and CSOTF and WWTP capacity.

Add transport capacity to the previous scenario if the existing treatment facility capacity is not attained.

Add new retention facilities within the combined sewer network, if needed.

Add treatment capacity at the wastewater treatment plant or on-line treatment at different points within the network.

Evaluate the benefit of interbasin transfers to the East or South WWTP District.

The location and sizing of the global combination of these facilities will be facilitated by the automatic design capabilities of MED-SOM.

4.0 CONCLUSION

A new CSO plan optimization approach has been presented. The approach integrates the sewer network management rules and all the possible scenarios of intervention that can be planned by the design engineer in a single CSO plan optimization study. As a consequence, a large number of scenarios of intervention can be investigated in a very effective manner, with little resources and in a short period of time. Moreover, since the automatic CSO plan approach is based on nonlinear programming, the scenario of intervention chosen by MED-SOM is guaranteed to be optimal with respect to the objectives specified by the operator. And for robustness, MED-SOM works in parallel to a commercial model (e.g., SWMM or HydroWorks, etc.) to assure a good representation of the hydraulics and the hydrology.

This novel optimization approach has been used in various projects with substantial success: in the Quebec Urban Community, we have been able to show a very significant cost effective first step by applying global optimal real time control and the cost of the complete CSO plan has been reduced considerably; in the central region of Ile-de-France, we have been able to increase the environmental performance by applying real time control to all four set of CSO control solutions previously defined for static control. The automatic plan optimization process will be further applied to the Westerly District of the greater Cleveland area.

EXPERIENCES WITH URBAN STREAM QUALITY MANAGEMENT

(The good, the bad, the ugly, and the promising)

Nancy U. Schultz, P.E., CH2M HILL, 75 Erieview Plaza, Suite 100, Cleveland, OH

This presentation will provide a brief review of how our urban streams got into their current predominantly degraded conditions, then summarize activities and results of several recent programs aimed at rehabilitating, or at least protecting, urban streams. As implied by the subtitle, the experiences described in this presentation cover the gamut from successful to futile, with several excursions into interesting. The one thing each of the experiences have in common is that none of the programs and their impacts have proven to be as simple as originally thought.

History provides numerous examples of innovative thinking that oversimplified the problems and consequently contributed to urban stream quality degradation. Roman paved roads with gutters to direct the drainage away from the pathway resulted in simultaneous increases in the flashiness of the drainageway flows, decreases in the vegetative filters bordering the streams, and concentration of the wastes washed off the roads. Thomas Crapper's introduction of the water closet resulted in urban streams becoming the most convenient depository for human wastes. Putting a lid on the drainageways (enclosing the sewers in pipes) protected the public from proximate contact with the noxious contents – and simultaneously removed any remaining habitat in the small urban streams. The River Des Peres in St. Louis, Missouri is a prime example where an urban stream habitat was buried, in that case to clean up the site of the world's fair.

The cholera epidemics of the late 19th century resulted in recognition that the waste carried away in the sewers could still cause problems in downstream water supplies. Chicago's solution to their own pollution of the water supply was direct, expensive, and effective. The sanitary and ship canal diverted the Chicago River away from Lake Michigan and directed the river, and all the sewage from the City, toward the Illinois River. Chicagoans no longer practiced inadvertent re-use of their wastewater, but the Chicago River, the lower Des Plaines River, and the Illinois River became open sewers, subject to low dissolved oxygen, mucky bottoms and noxious algal mats during low flow periods. By the 1920s, Chicago had intercepted the dry weather flows from most of the storm sewers, directing the sewage to a wastewater treatment plant that removed most of the solids and putrecible materials while the urban streams were left with virtually no flow between storm periods. Most inland US cities followed that example and built intercepting sewers and treatment plants in the next few of decades.

The 1972 Clean Water Act started the cities on the path of providing treatment, beyond mere dilution, of their waste waters. However, Clean Water Act strategists continued the trend of oversimplifying the problems. Water quality standards included numeric criteria allowing simple judgement of compliance or non-compliance. Those "simple to judge" criteria resulted in most area wide water quality management plans focusing on the measurable criteria and the recognized point sources. This focus on the simple criteria and the easily recognized sources of pollution resulted in billions of dollars of expenditure. Some streams, like the Cuyahoga River, improved dramatically. Nevertheless, many of our urban streams – like the Cuyahoga -- still fall far short of the quality implied by the Clean Water Act objective of fishable, swimable waters.

Recognition of the remaining problems with our urban waterways has resulted in a number of urban stream protection and rehabilitation efforts. The presentation will summarize several examples. Each will be categorized as good, bad, ugly or promising based on the author's opinion. Recognize, however, that this opinion is based on current understanding of the probable consequences of the programs. History has demonstrated that at no time has the then current understanding proved adequate in the light of hindsight.

Urban stream programs to be summarized will include programs aimed at both dry weather and wet weather problems, such as:

- Chicago's progression from deep tunnels to side stream aeration and suburban stormwater management
- St. Louis Meramec River greenway planning and River Des Peres rehabilitation in
- Stormwater quality management in Santa Clara Valley, California
- Drainage management in Edmonton, Canada
- Watershed management in Montgomery, Alabama
- Watershed management in Atlanta, Georgia

THE URBAN STREAM USE DESIGNATION: A STEP TOWARDS IMPROVED MANAGEMENT

Lester A. Stumpe, P.E., Northeast Ohio Regional Sewer District

ABSTRACT

Urban streams, by definition, have been dramatically altered in ways that have profound impacts on their function and character. Some impacts, like pollutant sources, are directly regulated. However, a host of land use changes are less easily controlled. These include loss of habitat at a wide range of geographic scales, changes of the hydrologic cycle, and direct impacts on streams as a result of engineered structures. In turn these influences trigger a cascade of consequences that further exacerbate stream health. A wide range of constraints in urban areas influences control and restoration efforts. Given these circumstances it is not surprising that urban streams typically do not meet the full range of water quality standards. At the same time, the current usage and/or the potential value of urban waters to a large adjacent population is good reason to seriously consider upgrading the quality of urban streams. These seemingly opposing forces are at the center of the current debate about regulatory use designations for urban waters.

Issues surrounding urban water quality standards and the concept of special urban use designations are explored in the context of facilities planning and ongoing watershed restoration efforts. Specifically, this paper discusses the feasibility of meeting Ohio's bacteria standards for the protection of recreational uses and biological criteria for the protection of aquatic life. It is argued that the unique characteristic of urban problems and the constraints on restoration work in urban area make attainment of existing standards impractical. The development of special urban use designations is suggested as a vehicle for setting reasonable goals in urban areas.
This paper is prepared to prompt discussion at an interactive session at the WEF conference "Advances in Urban Wet Weather Pollution Reduction". Additional data and graphics will be used in the actual presentation.

INTRODUCTION & THESIS

Water quality standards, as a form of a goal statement, should generate a creative discomfort zone that motivates measurable progress to close the gap between the present state and some more desirable state. Time-honored principals of effective goal statements are that they motivate in the intended direction, that progress towards goals can be measured and, finally, that stated goals are achievable. The thesis of this paper is that current standards, as applied to urban streams, are in some cases not achievable and may actually frustrate progress toward restoration.

Urban streams have been severely altered in ways that are, to some extent, irreversible. Still, urban streams can be a substantial community resource if the complex maze of urban constraints can be negotiated. Part of the solution lies in exploring alternative targets for urban streams that benefit urban communities while protecting the larger ecosystem. Without the driving force of realistic targets, restoration of urban watersheds is likely to be a slow and frustrating process.

Given the intractable nature of the urban stream restoration problem, it is appropriate to consider creation of specific urban use designations in place of the current rigid deterministic approach. Thoughtfully constructed, urban use designations could be part of a reinforcement process that helps urban communities to realistically assess the value of urban streams and motivates them to undertake restoration efforts. Elements of the reinforcement cycle would include: The state of the environment ⮝ community understanding of the problem ⮝ water quality goal setting ⮝ corrective actions that address root problems ⮝ state of the environment.

METHODOLOGY - THE MILL CREEK CASE STUDY

Mill Creek drains 11 communities before joining the Cuyahoga River, which in turn is a tributary to Lake Erie. Mill Creek has a drainage area of 60.6 square kilometers (23.4 square miles) with a length of 20 kilometers (12.2 miles). The average stream gradient is 1%. A unique feature of the water course is the 18 meter (60 ft.) waterfall that effectively divides the upper and lower portions of the stream and provides a virtually absolute barrier to fish migration.

Land use in the watershed is primarily urban, zoned for single and multiple family dwellings. A portion, located mostly along main streets, is zoned for retail business, commercial office or industry. Open space is limited to parks, cemeteries, golf courses and a racetrack. Detailed sewer modeling studies identified that the imperviousness for the drainage area is in the range of 35 to 40%.

The drainage system for the area includes separate sewer and combined sewers. A large capital program to construct storage tunnels, interceptors and connecting local sewers to control point source pollutants is currently underway. As a part of the facilities planning process for these facilities, the Northeast Ohio Regional Sewer District (NEORSD) embarked upon an extensive program to study the water quality issues of Mill Creek.

RESULTS/DISCUSSION — AQUATIC USE STANDARDS

- **OHIO'S AQUATIC USE STANDARDS**

Ohio is fortunate to have a mature water quality management program that includes a focus on the end uses of water bodies. In particular, the Ohio Environmental Protection Agency (Ohio EPA) is nationally recognized for having a model program which sets targets for the biological functions of streams.

In brief, the program establishes criteria for benthic macro-invertebrate populations (utilizing the ICI index) and the fish community (utilizing the IBI index) based upon the characteristics of a particular water body. Reference scores, which are specific to eco-regions within the state, form the basis for expected criteria scores. Ohio EPA has developed its Qualitative Habitat Evaluation Index (QHEI) as a tool in helping it to evaluate the habitat characteristics of a particular stream segment. An underlying premise is that there is a strong correlation between QHEI habitat scores and expected IBI scores where the influences of sources of pollution have been eliminated. Mill Creek has been assigned a use designation of Warm Water Habitat, which is Ohio's most common aquatic life use, and the lowest designation that Ohio identifies meeting as the fishable goals of the CWA.

A question that is explored in this paper is whether biological criteria, derived from relatively un-impacted reference streams, should be used as a standard for streams that have predominately urban watersheds. A similar alternative question is whether the QHEI assessment process is adequately sensitive to urban stresses that would preclude the development of a balanced biological community.

- **MILL CREEK STUDY DATA**

Results of habitat evaluations conducted during the study show that the QHEI scores are at the top of the good to fair range. Yet the results of the Mill Creek water quality study show that the benthic community was depressed, as measured by ICI scores. The fish community scored in the very poor range on the IBI scale. These results could indicate that point sources are having a major impact on the aquatic life. However, the depth of data collected in Mill Creek suggested that while water quality is impaired, it is not degraded to a degree that would explain the low biological scores. As a result, the Mill Creek study began to focus on a wide range of other possible contributing influences. This included a geomorphic assessment of the stability of Mill Creek's stream channels. The study team concluded that low fish scores and depressed benthic scores are the result of a complex mix of factors typical of urban watersheds. Control of pollution sources is expected to improve water quality for aquatic life, however habitat loss and hydrologic changes are expected to preclude attainment of aquatic use criteria. A review of the literature on the subject suggests that streams dominated by urban land uses typically are not able to maintain biological integrity. The literature has consistently shown that decreased biological function correlates well with increased levels of imperviousness.

- **DISCUSSION**

Looking at root problem causes — A key to setting realistic expectations for urban streams is to understand the chain of events triggered by the urbanization process. One chain of events starts with the alteration of the hydrologic cycle caused by an increase in the amount of impervious surfaces. Altered hydrology (higher high flows, and lower low flows) can have its own direct effect on the biology of a stream. For example, low flows result in fewer pools and riffles for fish during critical periods. Higher stream flows translate to higher stream velocities, which may stress certain fish species. A secondary impact of the increased frequency of higher flows is the disruption of the stream's natural dynamic equilibrium. In response higher flows channels typically change by widening or down cutting. The resulting bank sediment loads can cause significant stresses to a streams aquatic life. Additionally, the new sediment load can be the trigger for additional channel changes further down stream. Because of ongoing efforts to protect infrastructure by locking the channel into place with various engineered solutions, the channel is prohibited from achieving a natural dynamic equilibrium. A similar analysis can be done for primary actions related to the destruction of habitat and engineered changes within the stream corridor.

The above analysis points to the fact that urban stressors are plentiful and their interactions are complex. Further, many of these stressors are typically not subject to regulation under the Clean Water Act. At least not in a practical and direct fashion. Accordingly, most regulatory requirements continue to be focused on sources of pollutants (typically point sources). This focus can be counter productive if attention is directed from more fundamental root causes of stream impairments.

Urban environments present multiple constraints — Urban stream restoration efforts, including riparian corridor creation, channel re-engineering and soils bio-engineering in combination with hydrologic stormwater management, hold some promise for the restoration of streams. However, these techniques are far from a panacea. In urban settings it is difficult to apply these techniques at the intensity needed to restore streams to levels that can support the diversity of natural occurring ecosystems.

For example, meaningful corridor restoration is likely to involve substantial land use changes. Further, and not surprisingly, the amount of corridor restoration needed is related to the degree of biological integrity that is desired. Creation of a 15 to 25 foot corridor may help substantially in stabilizing stream channels. However, a more comprehensive goal of biological integrity may involve development of corridors 100 to 300 feet in width. In addition to the high cost of land in urban corridors, there are social issues related to individual impacts upon existing landowners.

Re-engineering of channel morphology is often severely constrained by the practical cost of moving extremely expensive infrastructure to achieve desired channel patterns and form. Additionally, stable channels need to be designed to transport rather large channel forming flows and their sediment loads. Channel dimensions and features for these high flows are not likely to match dimensions that are ideal for supporting desired aquatic life forms under conditions of dramatically lessened base flows (a direct result of urbanization).

Theoretically, intensive stormwater management can mitigate some of these problems. For example, storage and controlled discharge can manage peak flows. Infiltration techniques, if broadly enough applied, can lessen peak flows and help restore base flows. But the application of all of these techniques may require allocation of significant land areas and in fact substantially impact upon land use.

Starting with Community Values — These practical impediments are not a reason to given up on urban stream. Urban stream management is in fact an area where interest is growing rapidly. At NEORSD, we promote urban stream restoration believing that we can be part of community efforts to revitalize and, in certain cases, may yield a return in hard economic terms. (For instance a major urban neighborhood redevelopment project is marketing heavily its connection to Mill Creek as an asset.) The key is working with the community to establish goals that make sense at the community levels.

Our experience with watershed planning at the community level shows that urban flooding concerns are often the top priority. A second tier of concerns might include degraded stream esthetics, lack of recreational access, or stream safety. The community does place some value on knowing that a stream is healthy, but in urban areas there is not generally a strong expectation that streams be returned to a near natural biological state. The message from our public is that they support stream enhancements at reasonable costs, where they address understandable problems and where it makes economic sense.

The general public seems willing to accept a varied range of biological integrity for urban streams. However, Ohio's use designation process recognizes few permanent intermediate points between a culverted stream, which is not listed as a water of the State, and the use designation of Warm Water Habitat that is seen as meeting the goals of the Clean Water Act for fishable waters. It is logical to suggest that there should in fact be a range of choices for urban streams, or even a reasonably easy process for community creation of a "designer" use designation.

Minimum biological standards — A strong case can be made for the development of some minimum biological standard. However, minimum standards need to be tailored to account for specific situations. One important argument in favor of biologic criteria is that the biological community serves as a continuos sentinel of chemical water quality conditions. For example, a poor biological metric score, where a good score is expected, could be indicative of a toxic spill. Another argument for biological criteria is that when they are being met, they may constitute proof of ecosystem health not with standing some marginal problem with chemical criteria. In both cases, the key is tying a particular metric score to a reasonable expectation. Because the metric scores that constitute the current standard are derived from sites not predominately impacted by urban conditions, it is reasonable to question if they constitute an achievable goal for altered urban areas.

Unfortunately, the selection of an appropriate reference site is not an easy matter. The ideal sites would seem to be fully urbanized watersheds where point source and nonpoint source controls have been fully implemented. While degraded biological communities are common in urban areas, many of these streams have yet to benefit from the full implementation of technology based controls. Additionally, the degree of urbanization of a watershed should logically be a factor in setting minimum goals. Still another difficulty is recognizing the impact of a range of different geological conditions. For example, the stability of streams can be expected to be influenced by valley profile and soil types the degree of hydrologic disturbance, etc. Fortunately, it may be possible to account for a range of geological variables through by use of stream classification schemes. Classification schemes group the responses of stream to multiple variables into a limited number of stream types. Specifically, it may be possible to develop minimum biological metric that explicitly account for habitat, and stream type.

Beyond minimum standards — Some urban area will want to consider restoration beyond a minimum level. But what levels of restoration are achievable? What are the costs? Which restoration techniques and which best management practices work for specific circumstances? State environmental protection agencies have the expertise and data gathering capabilities to help answer some of these questions for communities who can be motivated to go beyond the minimum. Additionally, these data sets would be valuable to communities who are considering urbanization. At the current time we do not have a full range of tools to help urbanizing communities understand the impact of their land use plans on streams. Additionally, where urbanization is chosen we need tools to help communities quantitatively understand what measures can be taken to mitigate the impacts. For example, what is the value to a stream of establishing a given corridor width for a certain percentage of the stream.

Finally, cause-effects data would be valuable for future comprehensive watershed trading. One of the constraints on tailoring use designations to urban areas is the need to consider the impacts on a larger ecosystem scale. For example urban water quality may be significantly impacting a down stream resource. It is likely that these situations will have to be handled on a case by case basis. Also, because the cost of environmental protection can be very substantial it may be appropriate to call upon the market place to help make decisions about how and where such protection can most efficiently be provided. For this type of market driven watershed trading to occur it would be desirable to have better data on the impacts of urbanization and the most cost effective restoration techniques.

In summary, biological indices can be valuable in tracking progress of urban stream restoration efforts. While urban biological metrics are typically low, improvements can be made through the application of evolving stream restoration techniques. Depending upon the degree of urbanization and the constraints that exist, major aquatic life improvements may be quite expensive. The key to choosing an appropriate stream target is to involve the community in the goal setting process. However, the current states of engineering and science do not allow for a deterministic approach to stream restoration. Progress is generally made through incremental approaches and these typically involve learning from errors and building upon the successes of previous efforts. Logical scientific reasoning and practical aspects of dealing with urban constraints suggest against regulatory standards based upon reference reaches with little urban impacts. A case can be made for the development of minimum bio-criteria based upon urban reference streams. Additionally, a database on the restorative effects of stream restoration practices would be valuable to communities who are considering voluntary efforts to restore streams, or are in the process of making land use decisions.

RESULTS/DISCUSSION — RECREATIONAL USE STANDARDS

- **RECREATIONAL USE DESIGNATIONS AND CRITERIA**

Use designations for recreational use in Ohio are based on the physical depth of the water body and the type of use anticipated. The "Primary Contact" use designation is assigned to any water body of sufficient size to allow for the possibility of full body contact. Ohio's bacterial criteria for recreational use, as is common in other states, are based on the concept of indicator organisms. Fecal coliform and E. coli are assumed to correlate with the presence of pathogens which can be transmitted to, and cause illness in, individuals which come into contact with the contaminated water. Ohio's recreational use criteria are shown in Table 1.

- **MILL CREEK STUDY DATA**

Extensive quality and quantity modeling was undertaken to assist in sizing a system of storage tunnels and conveyance interceptors for combined and separate sanitary sewers in the Mill Creek drainage area. Using source data in combination with conveyance models and water quality models, facilities planning studies develop tools to show the positive impact of the controls. Current condition continuous model runs show that during events that produces significant run off bacteria concentrations will rise very quickly to levels in the range of 500,000 bacteria counts per 100 milliliters. Generally with in a period of 24 hours, the stream will have flush out high bacteria concentration and return to typical back ground levels. Model runs show that the $180 million capital improvements program will substantially reduce the peak bacterial concentrations to levels in the range of the 50,000 counts per 100 milliliter. However, the duration of stream bacteria concentrations which exceed the standard level of 2000 counts per 100 milliliter does not change substantially. These results reflect the fact that the bacteria concentration of stormwater is expected to remain high even after reasonable measures to repair the area sewer infrastructure.

- **DISCUSSION**

Urban environments are severely altered— As discussed in the preceding section, even after a very expensive program of capital improvements, Mill Creek is not expected to comply with recreational use standards. Similar situations are common for urban areas across the country. To understand this problem, it is useful to begin the discussion of appropriate goals/standards for recreational use by analyzing the factors of urbanization, which contribute to the bacteria problem.

By definition, urbanization creates a density of population that will characteristically be served by a system of sewers. Older sewer systems where characteristically designed with relief points (i.e. combines and separate sanitary sewer overflow points). With large expenditures these sources of pollution can be controlled to an extent that they are no longer a dominant factor. Still, this leaves a large underground wastewater sewer net work which represent a potential source of contamination. Theoretically, collection systems could be designed and maintained for zero discharge of pollutants. However, in practice every manhole and every pipe joint (including those of private laterals) is a likely source of pollution during some part of its life cycle.

The other major source of pollution is the direct run off of bacteria from land surfaces. In pre-development conditions the largest fraction of this load would not make its way to streams. Through the process of filtration either (e.g. through soils or through the forest litter) much of the bacteria load would be filtered out. However, in the urban environment, it is only a very short path (typically across pavement) for surface bacteria to be washed into a storm sewer inlet for a subsequent quick ride to a stream.

Typical standards may not consider the special circumstances of urban dominated streams —
The construction of Ohio's recreational use standards is typical of the approach use by other states (i.e. setting a requirement for the geometric mean of five samples in thirty days and allowing a percentage of points to exceed a second higher limit point). Standards constructed in this manner should be able to pick up long term sources of contamination and yet not record an undue number of positives. In beach situations, for which standards were probably first constructed, there is also generally a large body of water that dampens contaminant variability. However, as discussed earlier, urban dominated streams characteristically experience a quick rise in bacteria concentrations in connection with rain events. The fall of bacteria concentrations in urban dominated steams is also relatively quick when compared with bacteria decrease for event contamination at beaches. Given this variability it seems unlikely that current standards are the best possible tools for protecting public health or measuring progress.

Looking at results of stream modeling before or after implementation of controls it is fairly easy to determine wet weather periods when recreational contract should be discouraged. However, whether water quality standard calculations will identify bacteria concentrations as a problem depends on the chance matching of sampling times with periods that correspond with rain events.

Restoration efforts are constrained — In urban area limited space, cost, individual property rights, and other environmental goals team up to present tremendous obstacles to wet weather bacteria controls. Irrespective of water quality standards it is the hope of most urban area to substantially upgrade their underground infrastructure. But cost practicality, translated to political reality, dictates that current collection systems will not be replaced in mass to eliminate the multitude of potential sources that a collection system represents. Implementation of large regional stormwater storage and treatment facilities is constrained by both space considerations and cost. Further, tunnel storage and treatment as practical necessity where land is not available, may not be compatible with attempts to restore base flows for aquatic life uses. Given these constraints, and the ubiquitous nature of bacterial sources, it is not surprising that many water quality managers in urban areas are rather blunt in stating that safe bacteriological levels are not possible to achieve during wet weather flows for urban streams.

Using positive goal setting as a model — Viewed outside the framework of a regulatory/enforcement model it is fairly obvious that many recreational use standards funk the test of having positive motivational aspects for officials who are charged with achieving them. Standards are imposed externally, at levels that are seen as unattainable. The real community concerns of cost are discounted by the Clean Water Act. And measurement of progress in controlling pollution is often frustrated by the construction of the standard itself.

In fact, urban communities do want safer waters. But given the constraints many would rather aim for more realistic targets. Most urban areas seem to accept the proposition that for the foreseeable future urban streams will have higher then safe bacteria levels following rain events. A logical management option is to discourage contact recreation of urban streams following rain events. In fact this management approach may be prudent for at least two other reasons. First, even with the most sophisticated controls imaginable in place, urban streams will always have a high potential to be contaminated. And second, the hydraulics and unique structures typical of urban streams create multiple safety hazards during high stream flows.

Suggested guidelines — Given the difficulty of controlling wet weather bacteria contamination in urban stream, a better approach may be to focus on management of contact recreation. The following ideas are offered as practical regulatory approach for urban dominated streams.

Establish a use designation, with appropriate criteria, that are specific to dry weather periods. Other requirements, as presented below, could be tied to this use designation; however, the key concept is to tailor programs to community concerns:

- Dry weather monitoring frequency appropriate for the task of quickly finding and correcting dry weather discharge problems.
- Development of tools to help refine the predictability of periods when urban streams are not safe for contact recreation. This would likely include wet weather studies and modeling.
- Development of programs to educate the public about limits of the use designation (i.e. when stream are not safe for recreational contact).

- Implementation of technology based best management practices evaluated against specific targets such as increasing the number of safe contact recreation day's and/ or to decrease the peak concentrations of water borne disease indicators.

URBAN USE DESIGNATIONS — STARTING A CONTINUOUS IMPROVEMENT CYCLE

The Clean Water Act is rightfully recognized as one of this countries best piece of environmental legislation. Fairly inflexible standards have, in fact, worked to bring about improvements that were long overdue. For instance, the CWA was successful in combining incentives with the requirement for a uniform level of secondary treatment at municipal waste treatment facilities. More recently, progress has been advanced by consistent water quality standards. Progress continues to be made in using the science of ecosystem assessment to define water quality problems and to identify needed reductions of pollution sources. However, it is also clear that these improvements are in areas in which the CWA has clear regulatory authority. Further, progress has been achieved by setting goals at reasonable levels. Restoration of urban dominated streams present unique challenges which do not appear to have yielded well to the top down standards approach. A viable model for restoration may start with acceptance that the Clean Water Act is not the best approach to control land use decisions related to urbanization.

The suggested starting point for an alternative approach to restoration is a fundamental evaluation of the problems and cause of urban stream impairments. With this information in hand the community can be involved in setting goals to drive corrective actions that will strike at root problems. Goals should be achievable, measurable and be in line with community values. This model de-emphasizes the focus on defining the end point, in favor of efforts to promote continuous improvement. The reinforcing aspects can be represented by a causal-loop with the following elements: state of the environment ^ community understanding of the problem ^ water quality goal setting ^ corrective actions that address root problems ^ state of the environment.

To continue to focus on standard setting at the state level to provide direction to the restoration of urban streams may actually frustrate a more productive continuous improvement model. Consider how externally imposed standard can impact the various elements of the proposed reinforcement loop. For example, current standards do little to provide the basic incentive for an urban community to look fundamentally at the full range of causes for impairment of urban stream. Instead, standards have focused our attention on pollution abatement. Too often a meaningful goal setting process is never started, because externally imposed standards are already set at unachievable levels. We are required to proceed with expensive controls designed to achieve compliance with pollution reduction standards. But could this money have been better spent on selected restoration technologies that deal more fundamentally with the root problems and produce results that are more valued by the community? The answer to this last question affects the likely hood that the community will feel positive about its expenditures and will be willing to become critically involved in discussions about the next step of an improvement process.

In contrast, the development of a specific urban use designation could actually be the catalyst for community work to fundamentally define the root problems that are at the heart of urban stream impairments. If flexibility is allowed in setting goals the community can respond with ideas that are efficient in increasing the value of the resource. In fact these corrective actions may start to target the root causes of urban stream with measures such as habitat protection or restoration. With the support of data from state environment agencies, communities might have access to information that could affect choices about stream restoration or land use. Minimum standard could still be set as needed to protect down stream resources or to provide needed leverage against particular sources of pollution. Ownership in a goal, set at the local level, is likely to encourage the concept of individual stream stewardship and individual action at the homeowner level. Whether dramatic changes occur quickly should not the appropriate measure of success for the model. A more important measure is whether the community is engage in a process of discussion about protection and use of the resource.

CONCLUSION

Urban streams and their immediately adjacent corridors have typically suffered a range of virtually irreversible direct impacts. (For example, all first order tributaries of a stream may in fact be storm sewers.) Given these dramatic changes it is unrealistic to expect urban streams to achieve standards that are attainable in less impacted areas. Further, the numerous physical and practical constraints in urban areas limit what can practically be accomplished through stream restoration techniques. Large gaps between the requirements of standards and what is practically achievable in an urban setting can actually result in a counter productive situation.

Too frequently urban water quality is treated as an all or nothing proposition (e.g. either an urban stream is treated as a sewer that is not a regulated water body or it is expected to be upgraded to meet full fishable and swimmable criteria.) Minimum standards are appropriate. However, these standards should in fact be minimum standards and should recognize that in some cases irreversible changes have taken place, which are not regulated by the Clean Water Act.

Given the intractable nature of many urban water quality problems it is appropriate to rethink both the targets set by standards and more fundamentally the role of standards. Urban use designations offers a way to solve problems by focusing special attention on the particular problem causes and constraints of an urban areas.

The elements which have been suggested are characteristically described as the watershed approach (i.e. addressing root problem causes and real world solution constraint, involvement of stakeholders in goal setting, setting priorities to coordination action on the restoration and/or protection of end uses, and principals of adaptive management to take advantage of opportunities). Watershed approach is being accepted as the preferred process for dealing with complex and intractable water quality problems. Few watershed texts would suggest the current process of holding stakeholders to unrealistic externally imposed standards as a way of pressuring stakeholders for progress.

Table 1 RECREATIONAL WATER QUALITY CRITERIA			
Water Quality Criteria:	**Secondary Contact** **Wading**	**Primary Contact** **Full Body Immersion**	**Bathing Waters** **Bathhouse/ Lifeguard**
Fecal Coliform	BACTERIAL COLONIES/100 ML SAMPLE		
Geometric mean of at least 5 samples within 30 days:	No Criteria	**< 1000**	< 200
Maximum for 10% or more of samples within 30 days:	< 5000	**< 2000**	< 400
E. Coli	BACTERIAL COLONIES/100 ML SAMPLE		
Geometric mean of at least 5 samples within 30 days:	No Criteria	**< 126**	< 126
Maximum for 10% or more of samples within 30 days:	< 576	**< 235**	< 235

Assessing the Condition and Status of Aquatic Life Designated Uses in Urban and Suburban Watersheds Using Biological Assessments

Chris O. Yoder and Robert J. Miltner
Ohio EPA., Division of Surface Water
Ecological Assessment Unit
1685 Westbelt Drive
Columbus, Ohio 43228

Ohio EPA employs biological, chemical, and physical monitoring and assessment techniques in biological surveys in order to meet three major objectives: 1) determine the extent to which use designations assigned in the Ohio Water Quality Standards (WQS) are either attained or not attained; 2) determine if use designations assigned to a given water body are appropriate and attainable; and 3) determine if any changes in key ambient biological, chemical, or physical indicators have taken place over time, particularly before and after the implementation of point source pollution controls or best management practices for nonpoint sources. Biological criteria are one of the principal assessment tools by which the status of water bodies is determined in Ohio. The results of biological monitoring in selected urban Ohio watersheds shows a tendency towards lower biological index scores with an increasing degree of urbanization and allied stressors, becoming more severe as other impact types such as combined sewer overflows (CSOs) and industrial sources coincide. Out of 110 sampling sites examined statewide, only 23% exhibited good, very good, or exceptional biological index scores. Of the sites classified as being impacted by urban sources, only two sites (4.5%) attained the applicable biological criteria. Poor or very poor scores occurred at the majority of the urban impacted sites (85%). More than 40% of sites affected by suburban development were impaired with many reflecting the impact of housing and commercial land uses. The results demonstrate the degree of degradation which exists in most small urban Ohio watersheds and the difficulties involved in dealing with these multiple and diffuse sources of stress. In the Cuyahoga River basin, which contains older and extensively urbanized subbasins, aquatic life use impairment occurred in the vicinity of 10-20% urban land use. These results contrasted somewhat from a similar analysis of small streams in the Columbus metropolitan area where full attainment of uses was observed at higher proportions of urban land use. In both areas the utility of biological criteria to serve as a reliable and consistent vector for urban land use indicators was demonstrated. Well designed biological surveys using standardized methods and calibrated indicators can contribute essential information to urban watershed management. Because the resident biota respond to and integrate all of the various factors that affect a watershed, their condition is the cumulative result of all significant stressors within watersheds. It is important that ambient monitoring not only be done as part of the overall urban nonpoint source management process, but that it is done correctly in terms of timing, methods, and design.

WATER QUALITY CONCERNS AND REGULATORY CONTROLS FOR NONSTORM WATER DISCHARGES TO STORM DRAINS[1]

L. Donald Duke and Molly M. Kihara[2]

ABSTRACT: Nonstorm water discharges to municipal separate storm sewer systems (MS4s) are notable for spatial and temporal variability in volume, pollutant type, pollutant concentration, and activity of origin. The objective of this paper was to determine whether current technical knowledge and existing U.S. policy support an improved regulatory approach. The proposed policy would use type of discharge as a regulatory basis, merging the concepts of allowability of *de minimis* discharges and type-based statewide consistent rules. Specific research objectives were to comprehensively identify discharge types, characterize their prevalence in California, analyze relevant local and regional regulatory guidelines, and systematically evaluate opinions of experts about potential water quality impacts. Results demonstrate nonstorm water discharges were widespread in at least one sector, industrial facilities subject to a state permit; one discharge for every four facilities was reported in 1995, even though the permit explicitly prohibits such discharges. Clear consensus exists for minimal water quality concern for some discharge types when considering both municipal guidelines and experts' opinions. In particular, condensate from a wide range of equipment and discharges from fire fighting equipment testing were found to be of low concern. Discharge types with consensus high concern were largely limited to discharges prohibited under other regulations, such as wastewater and hazardous waste management controls. Some discharge types where no consensus was identified, such as landscape irrigation, nevertheless generated concern for water quality impacts and appear to be relatively widespread. Available information supports technical feasibility of the proposed policy because at least some discharge types show strong consensus for de minimis impacts among regulatory guidelines and opinions of technical experts.
(KEY TERMS: storm water management; nonpoint source pollution; separate storm sewers; watershed management; urban runoff.)

INTRODUCTION

The Federal Water Pollution Control Act (commonly referred to as the Clean Water Act, or CWA) has evolved from 1972 to the present, incrementally addressing additional categories of discharges, including nonpoint sources and developing different bases for pollutant control. In 1972, Congress established the National Pollutant Discharge Elimination System (NPDES) permit program and mandated the imposition of uniform, technology based limits on industrial and wastewater treatment plant discharges. The Water Quality Act (WQA) of 1987 amended the CWA, imposing water quality based requirements on discharges of toxic pollutants, and adding the control of pollutants in storm water runoff as a national goal.

The WQA explicitly defined storm water discharges as point sources, therefore subject to NPDES regulations. Subsequent regulations required NPDES permits be held by municipal agencies operating municipal separate storm sewer systems (MS4s) serving 100,000 or more people. MS4s are widely found in the western United States, where sharp seasonal precipitation patterns have led flood control agencies to construct systems to convey large peak runoff volumes directly to receiving waters. MS4s discharge all flows directly to receiving waters, even small volume low flows including nonstorm water discharges during dry seasons. This approach is less often applied in the eastern United States, where urban runoff more commonly is conveyed in combined systems, so that low flows are routed through publicly owned treatment works along with sanitary and industrial discharges, and large storm flows may

R0025375

bypass treatment facilities. The WQA storm water provisions require operators of MS4s to control pollutants upstream of input to the MS4, an approach that avoids the prohibitive costs of centralized treatment for seasonal high volumes of urban runoff.

By regulation, municipal NPDES storm water permits must "effectively prohibit" nonstorm water discharges into the MS4 (40 CFR 122.42), and MS4 operators must implement and enforce illicit discharge elimination programs (USEPA, 1990). The policy is driven by the observation that nonstorm water discharges contribute a potentially significant fraction of pollutants discharged by MS4s to surface waters in certain urban watersheds (Line *et al.*, 1996).

The observation is supported by a limited number of watershed-specific studies. Montoya (1987) determined nearly half the annual MS4 flow volume in Sacramento, California could not be attributed to precipitation. Pitt and McLean (1986) concluded dry weather flows accounted for more than half of annual mass loadings of certain chemical parameters from two catchments in Toronto, Ontario, during 1984. A study of Santa Monica Bay, California, identified significant contributions of metals and other pollutants from dry season discharges (Lau *et al.*, 1994). These results are highly dependent on land uses and other factors in the watersheds. USEPA, in proposing its Phase II NPDES storm water regulations, concluded that nonstorm water discharges contribute a wide range of pollutants such as pathogens, metals, nutrients, oil and grease, and phenols to MS4s across the U.S. (USEPA, 1995). That study's conclusions are based on diverse evidence from inspections, end-of-pipe observations, investigation of sediments in storm sewers, citizen reports, dye testing, dry weather sampling, and fecal coliform tests.

Existing evidence is not sufficiently systematic or well defined to support general conclusions about water quality impacts from nonstorm water discharges to MS4s (Duke *et al.*, 1997). Reliable anecdotal evidence, such as a detailed study of nonstorm water discharges from industrial facilities of the Lawrence Livermore National Laboratory (Mathews and Welsh, 1995), supports the premise that at least some discharges are unlikely to cause water quality problems. However, water conveyed in MS4s is highly variable in frequency, volume, and pollutant concentrations. Therefore, it is difficult to characterize chemical composition of specific discharges or classes of discharges, and to estimate their contributions to pollutant loadings to ultimate receiving waters. Constituent concentration data from sampling and analysis of individual, facility specific nonstorm water discharges to MS4s are not generally found in the primary literature.

Research Objectives

The overall goal was to evaluate water quality implications of types of nonstorm water discharges to MS4s using formal data, indirect evidence in the form of regulatory data, and informal knowledge of experienced practitioners. The purpose was to assess feasibility of a statewide policy to allow selected discharges based on discharge type, incorporating the concept of *de minimis* discharges to be consistent with federal requirements for effective prohibition of nonstorm water discharges to MS4s. The research included three specific objectives. The first was to evaluate current U.S. policy structure to assess the conceptual feasibility of the proposed policy, and use results of the data analysis to assess its technical feasibility. The second was to characterize existing information about types of such discharges widely found in the U.S., in particular in California. The third was to evaluate the current state of knowledge about water quality impacts of such discharges by type.

METHODOLOGY

First, the existing U.S. policy and regulatory structure was evaluated to determine the basis for the proposed new policy. The research then constructed a basic characterization of nonstorm water discharges currently found in California, using the literature to develop a comprehensive list of discharge types and using data collected by state agencies to estimate relative predominance of discharges from one sector – industrial facilities. The authors then evaluated two forms of qualitative information about the current understanding of water quality impacts of nonstorm water discharges, categorically by discharge type. The information evaluated included guidelines now in place for a number of large municipal agencies in California and opinions of a sample of experts from regulatory agencies, the regulated community, and other professionals with expertise in water quality of discharges to MS4s.

Discharge Types

By reviewing the academic literature, descriptive reports by federal and state environmental agencies, and current regulatory guidelines promulgated by federal, state, and local agencies (USEPA, 1990, 1991, 1995; CSWRCB, 1995, 1997), 110 discharge types were identified. The discharge types were organized

R0025376

into 20 categories, but otherwise were accepted largely as found in the literature.

Industrial Discharges

The research evaluated nonstorm water discharges in annual reports submitted by industrial facilities covered under the statewide NPDES General Permit for Discharges of Storm Water Associated with Industrial Activities, or General Industrial Permit (California State Water Resources Control Board, 1997). The analysis established, for one sector of storm water dischargers, whether individual discharges are widespread and which discharge types are most common. To the authors' knowledge, no comparable information is available for discharges from other sectors. This does not imply the industrial sector is necessarily the most important in terms of volume, frequency, or pollutants conveyed in nonstorm water discharges.

The present research summarized that information for five of the nine California administrative regions known as Regional Water Quality Control Board jurisdictions, or RWQCBs. The five RWQCBs selected include some of the most heavily developed urban areas in the state, and are sufficiently geographically distributed to capture potential regional diversity. RWQCB information was acquired under a statewide review project, as described in Duke *et al.* (1997).

Municipal Agency Guidelines

The research next evaluated guidelines from five agencies with storm water pollution control responsibility for large municipalities in California. Guidelines evaluated included regulations or policies targeted at discharge types, and intended to categorically prohibit, allow, or allow under certain conditions discharges of those types to each agency's MS4. The five selected municipalities were known to be among the most active in the state in developing and implementing storm water pollution controls under their municipal NPDES storm water permits. Description of the procedures for evaluating agency guidelines and text descriptions of some of the key agency policies appear in Duke *et al.* (1997), and are not repeated here.

Preferences reflected in existing guidelines may be interpreted as evidence of concern by those agencies with potential water quality impacts of nonstorm water discharges. Those concerns may be considered to reflect current professional judgment about those discharge types which categorically are expected to be detrimental to receiving water quality.

Broad Based Survey of California Experts

A questionnaire was administered to professionals in California with expertise in storm water quality. The purpose of the survey was to characterize current understanding of concerns with potential water quality impacts of discharges by discharge type, and determine whether current opinions approach consensus for any discharge types. Results were compared with agency guidelines evaluated as described above. If local agency guidelines were consistent with one another within discharge types, and also emphasized controls consistent with water quality concerns of experts statewide by discharge type, we might suggest current understanding of water quality impacts is sufficient to support statewide policies. For discharge types where agreement was strong, results support selection of those types as candidates for statewide policies.

Details of the structured survey mechanism are available in Duke *et al.* (1997), and are summarized here. The questionnaire asked participants to indicate, on a simple numerical scale, their degree of concern with each of the 110 discharge types. "Concern" for water quality impacts was defined to include issues of "volume, concentration, and types of pollutants" for each discharge type, as in USEPA's definition of *de minimis* water quality problems (USEPA, 1991). Responses were expected to capture a range of opinions depending on the respondents' depth and type of experience; on their professional interests, such as differing views held by regulators and the regulated community; and on regional factors. The questionnaire instructed respondents to base their answers on concerns for their own MS4, so the responses may depend on the relative prevalence of each discharge type in their region; on characteristics of regional receiving waters, such as susceptibility to certain types of pollutants; and on characteristics of other discharges in the region, with consideration of cumulative impacts of certain pollutants.

The responses were not specific about causes for concerns because the compound question allowed multiple possible reasons for a given score. Further, the results should not be interpreted as type based scores to rank discharge types from greatest to least concern statewide because responses were designed to reflect concerns of a given region rather than opinions about discharge types' importance on a statewide scale. This survey design supported the assessment of statewide consensus by seeking any diversity of opinions on the basis of regional experiences.

For similar reasons, survey respondents were not selected with an intent to be a representative sample of all stakeholders or of any specified group, but

R0025377

rather as a convenience sample of persons with recognized expertise in the field. The sample was developed from participants in the California Storm Water Quality Task Force (SWQTF), a public interest group with advisory status to the California State Water Resources Control Board. SWQTF attendance is voluntary, so no formal membership rolls are maintained, but consistent attendees consist largely of high level staff of municipal agencies operating MS4s that hold municipal NPDES permits for storm water discharges. Other attendees represent regulated industrial firms and their trade associations, public interest groups with broad-based environmental concerns, and public agencies with responsibilities for storm water regulatory development and enforcement. SWQTF attendees were an appropriate source for opinions about water quality impacts of discharges to MS4s by virtue of long experience, responsibility for decisions about storm water pollutants, and a history of active and thoughtful involvement in related policies. Since the purpose was to identify areas of consensus, the convenience sample was considered adequate if it included respondents representing many of California's diverse regions and various professional interests.

The questionnaire was presented at a regularly scheduled meeting of the SWQTF on March 8, 1996. Questionnaires were completed and returned by 32 respondents, with composition as follows: 17 municipal agency personnel; eight industrial personnel; three state or federal regulatory agency personnel; and four consultants, with experience working with all three above groups. Geographically, respondents held responsibilities within four regions of intensive urban development in California. Seven were from Los Angeles and the immediately surrounding region (total 1995 population about 9.1 million); 13 from other Southern California urban regions, from Orange County in the north to San Diego in the south (about 8.2 million); six from the San Francisco Bay Area (about 5.1 million); and three from the Central Valley, from Sacramento in the north to Bakersfield in the south (about 3.9 million). Three of the respondents had statewide responsibilities. Together, the represented regions contained a population of about 26.3 million persons in 1995, more than 80 percent of the statewide total of about 31.6 million.

In evaluating responses, discharge types were considered to have consensus minimal impact if at least 50 percent of respondents selected "1" (minimal) as their degree of concern, and no more than two respondents selected either "4" (moderately high) or "5" (high). Discharge types were judged to achieve consensus high concern if the sum of respondents selecting scores of 4 and 5 represented at least 50 percent of returned questionnaires. This criterion was less stringent than the consensus minimal concern criterion, on the grounds that moderately high concern might be reason enough to justify protecting receiving waters from the discharge.

In-Depth Survey of Selected Experts

Detailed analysis of experts' opinions, the rationale behind those opinions, and the precise nature of their concerns with water quality by discharge type was beyond the scope of the present research. However, a possible approach for detailed analysis was demonstrated by administering a more in-depth questionnaire addressing a small number of discharge types to a small number of selected experts. Results illustrate the types of rationale used by the experts to arrive at their overall condition; the aspects of discharge types leading to high concern, where present; and the definitiveness or tentativity of the current state of knowledge, represented by respondents' stated confidence in their ability to reach conclusions requested.

Fifteen experts were selected from among regular SWQTF attendees recognized to have long experience with storm water quality, high level responsibility with an agency or corporation, and high respect among their SWQTF peers. Twelve of the 15 responded to the request for information. Four had responsibility in the San Francisco Bay Area; three each in the Central Valley and the greater Los Angeles area; and two in other parts of southern California. The experts were drawn primarily from the ranks of municipal agency personnel, but respondents included two regulatory personnel and one operator of a large industrial facility.

Ten discharge types were included in the questionnaire, selected arbitrarily from the list of 110 used in the overall survey. Some of the discharge types were drawn from those where the overall survey showed consensus, either toward minimal impact or high impact. These were selected to verify consistency of the small group with the larger sample and to identify rationale behind those judgments. Others were chosen from types that did not achieve consensus. These were intended to assess consistency of the rationale behind the varying opinions, and also to identify underlying technical factors in the opinions.

RESULTS AND DISCUSSION

Results are organized as follows. The first section below presents the regulatory and policy foundations for control of pollutants in nonstorm water discharges. The next section assesses the degree to which these discharges are widespread in California, through data about the relative frequency with which industrial facilities reported various discharge types in their annual report under the statewide General Industrial Permit. The following section evaluates the current understanding about water quality concerns by discharge types, including results of the expert opinion survey and analysis of municipal control policies. That section is divided into three subsections according to degree of consensus of the opinion survey. The final section discusses findings of the in-depth survey.

Regulatory Structure, Policy, and Basis for a New Approach

The choice between prohibiting all nonstorm water discharges and allowing certain discharges depending on conditions is an example of the choice between "global" and "local" environmental regulations, a recurring theme in surface water pollution control policies in the U.S. Both have significant advantages.

Global regulation specifies uniform requirements for all discharges of a given type, or emissions from a given activity, within a large jurisdiction. Requirements take no account of local or site-specific conditions. The stated rationale for such global regulations is to facilitate enforcement, as it is unnecessary to work backward from an over polluted body of water to determine which point sources are responsible and which must be abated (EPA v. California ex re. SWRCB, 426 US 200, 204, 1976 in Percival *et al.*, 1992). Requirements of the original CWA were global in nature: NPDES rules for wastewater discharges specified technology-based, numerical effluent limits that were uniform by industrial sector. Outright prohibition of nonstorm water discharges to MS4s in California would be a global environmental control policy.

A local approach has the alternative advantage that regulatory requirements can reflect different needs of specific receiving waters depending on factors such as their sensitivity to pollutants, assimilative capacity, and pre-existing degree of degradation. The local approach can avoid inefficient regulating of pollutants or activities not found to be causing harmful effects in a given locale. Agencies can focus regulatory resources on those pollutants, and polluting activities, found to be responsible for impairment of particular receiving waters. Watershed based regulations and discharge standards based on Total Maximum Daily Load (TMDL) calculations are examples of local policies.

USEPA has interpreted WQA's language specifying "effective prohibition" to require that nonstorm water discharges either be directed to sanitary sewer systems or be individually issued NPDES permits for discharge to MS4s (USEPA, 1990). This interpretation allows, within appropriate limits, discharges to MS4s that do not present water quality problems in receiving waters. This approach could achieve some of the advantages of a local environmental control policy. Allowing some discharges can avoid costly and burdensome requirements on the regulated community by permitting storm drain systems to receive nonstorm water discharges which are not expected to convey pollutants that contribute to water quality problems. These discharges include, for example, certain cooling water that does not contact pollutants on commercial or industrial surfaces before entering a storm drain inlet. Some such discharges historically have been widely practiced.

However, in practice, municipal NPDES storm water permit requirements to effectively prohibit nonstorm water discharges have led many MS4 operators to articulate a policy prohibiting all non-storm water discharges to their systems. This outright prohibition avoids the need to make case-by-case determinations of whether discharges are causing water quality problems, and averts potential conflict with USEPA over such determinations. This approach, while possibly efficient from an enforcement viewpoint, suggests overregulation, because nonstorm water discharges that may not have an adverse effect on receiving water quality need to go through costly and unnecessary treatment and disposal. The approach fails to achieve the potential advantages of local environmental control policies.

At the same time, because enforcement requires expenditure of scarce resources and municipal agencies commonly have many responsibilities and competing priorities, many MS4 operators expend little effort ensuring prohibition even when it is specified in their permits. In these cases, non-storm water discharges to MS4s may be in effect under-regulated if some are causing adverse impacts to water quality. The environment may be better protected if a rational policy identifies discharges that are not causing water quality problems in receiving waters and those that are so that MS4 operators may concentrate on enforcement.

For these reasons, the state of California is considering a statewide or global regulatory guidance policy which may be used by municipal permit writers to readily identify types of non-storm water discharges that may be allowed under conditions of a given watershed. This guidance would be consistent with statutory requirements to effectively prohibit nonstorm water discharges and with regulations allowing

R0025379

local determination of acceptable discharges. The underlying principle of the approach is that certain types of nonstorm water discharges may be acceptable in all or most watersheds, and that others dependent on receiving water conditions may be addressed by local determinations. The approach would help achieve consistency in rulemaking among jurisdictions within the state, increase certainty within the regulated community about compliance requirements, and improve efficiency in surveillance and enforcement by MS4 operators and regulatory agencies.

Support for this approach draws from the concept of *de minimis*, or insignificant, impacts of particular discharges. The *de minimis* concept has had varied regulatory applications, including determining acceptable risk from construction and operation of nuclear power plants, describing risk of food additives under the Delaney Clause, and characterizing Superfund liability settlements made by the USEPA. In 1987, Congress in Section 516 of the WQA directed USEPA to study whether some discharges of pollutants are not significant in terms of volume concentration, and type of pollutant, and to identify the most effective and appropriate methods of regulating such discharges (Public Law 100-4, 1987). The resulting report (USEPA, 1991) defines *de minimis* discharges of pollutants as not significant in terms of volume, concentration, and type of pollutant.

The present research, in characterizing knowledge about discharges by type, explores the feasibility of establishing a global approach to effective prohibition of nonstorm water discharges. The approach would be accomplished by developing comprehensive rules for discharges by type: identifying a wide list of potential discharges and considering whether rules by type are effective to control them. Conceptually, an approach based on discharge types would classify discharges according to their pollutant characteristics and potential impacts on receiving water quality. Regulations may specify that classes of discharges be allowed, prohibited, allowed under certain conditions or with certain associated control measures, or subject to case-by-case determination.

Regulations such as USEPA rules for municipal discharges have moved toward rule making based on type of discharge by identifying a number of specific types of non storm water discharges to MS4s that must be addressed in a program to prevent illicit discharges to the MS4 (USEPA, 1990). The rules implicitly accept certain discharge types as potentially harmful in most conditions and other discharge types as *de minimis*, some of these for a given location or set of conditions. This rulemaking is a rational initial step to achieve the regulatory advantages of a global policy within selected jurisdictions, and for a selected small portion of discharge types.

Nonstorm Water Discharges by Industrial Facilities

A large number of regulated facilities reported nonstorm water discharges in annual reports under the General Industrial Permit during 1995. As Table 1 shows, 2,084 discharges were reported by 7,905 facilities in the five evaluated regions, or approximately 0.26 discharges per reporting facility. The proportion was remarkably similar among regions, ranging only from a high of 0.31 discharges per facility in the Central Valley region to a low of 0.22 in the Santa Ana region. This is a large proportion, considering the terms of the General Industrial Permit specify nonstorm water discharges are not permitted. For similar reasons, it is likely the total number of discharges is underreported and the proportion of discharges in each type is more accurate than the total number of discharges.

The most widely reported discharge type in all five regions was landscape irrigation. This accounted for at least 20 percent of reported discharges in each region, with a high of 29 percent in the Santa Ana region. A total of 495 facilities, or about 6.3 percent of all reporting facilities in the five regions, checked the space on the annual report specifying at least one discharge to storm drains of landscape irrigation water.

Some regional differences were demonstrated. Air conditioner condensate accounted for about 15 percent of reported discharges in the Los Angeles region, and 14 percent of discharges in the San Diego region, but only 8 percent of Central Valley discharges. Similarly, discharges from auxiliary water supply for fire prevention and building sprinkler systems accounted for 19 percent of San Diego region discharges and about 10 percent of facilities in all other regions except the Central Valley, where they were only 2 percent of discharges. Conversely, 14 percent of Central Valley discharges were associated with vehicle washing, a larger number than in the other regions, where they were between 5 percent and 7 percent of reported discharges.

Opinion Survey and Municipal Guidance

This section summarizes responses to the broad-based survey and analyzes type based guidelines of selected municipal storm water agencies. The section is divided into three subsections: discharge types where the survey showed consensus for low water quality concern; those with consensus of high or moderately high water quality concern; and discharge types that did not elicit consensus among survey respondents. Each subsection includes guidance for those discharge types from the five municipal

agencies considered, in particular the implications of existing municipal policies for those discharge types.

Survey respondents volunteered a number of discharge types not previously identified in the literature review. No consensus was available for these discharge types, as they were rated only by those respondents who wrote them into the questionnaire. Many of these were minor alterations to types among the 110 identified, but four were notably different and potentially important: washing homeless areas; groundwater discharge mixed with seepage from natural oil discharges; home auto washing; and septage waste hauler spills.

Consensus Low Water Quality Concern. Table 2 summarizes results for 21 discharge types where the survey results suggested consensus of minimal water quality concern. Seven of eight discharge types in the Condensate category met the minimal concern criterion; the only type not listed was condensate from chemical tanks and pipelines. Similarly, four of five types in the Fire Fighting category, and two of three in the Surface Water category, met the criterion for consensus minimal concern.

In the Ground Water and Surface Water categories, the low concern discharge types were naturally occurring: springs, diverted stream flows, and flows from

Municipal Jurisdictions Considered:

a Alameda County Urban Runoff Clean Water Program (ACURCWP, 1994).

b County of Los Angeles Municipal Permit (RWQCB, 1996; Gary Hildebrand, 1997, Los Angeles County Department of Public Works, Environmental Programs Division, Water Quality Section, Personal Communication to J. Lilien, May 7, 1997).

c Regional Water Quality Control Board, Santa Ana (RWQCB Santa Ana, 1984; RWQCB Santa Ana, 1996).

d County of Sacramento (Larry Walker Associates, 1992; David Brent, 1996, City of Sacramento Department of Utilities, Personal Communication to J. Lilien, November 18, 1996).

e Santa Clara Valley Urban Runoff Pollution Prevention Program (SCVURPPP, 1995; SCVURPPP, 1997).

riparian habitats or wetlands. In the Water Supply category, the discharge types identified as low concern are relatively infrequent and/or of small volume. This might also explain why respondents expressed little concern for water quality for discharge types in the Fire Fighting category. Some of these assumptions were tested for a few discharge types using the detailed survey, with results described below.

Table 2 shows reasonably good agreement among municipal agencies' policies regarding categorical controls for these discharge types. Nine of the 21 low concern discharge types were categorically allowed by at least one of the municipalities. (Two of the nine were allowed under specified conditions, each by two municipalities.) One discharge type, fire fighting discharge from building sprinklers, was allowed by one agency but prohibited by another. The other 12 discharge types were not allowed by any of the five municipal agencies.

Consensus High Water Quality Concern. Table 3 summarizes results for 15 discharge types of high water quality concern under the criterion described above. The distribution of opinions was considerably wider than opinions about minimal concern.

All discharge types classified as sewage or spills (of either hazardous or nonhazardous compounds) attained consensus for high concern. This is not a surprising result, and is perhaps not especially meaningful for statewide policy since alternate regulatory controls prohibit such discharges. A similar rationale might explain the consensus for two of the 26 discharge types in the Process category, wastewater and oily waste separators. On the other hand, no clear consensus was identified for the other 24 Process category discharge types. This is surprising given the nature of some of those discharges, such as bilge and ballast water. The result may suggest that site specific conditions may be so variable that statewide

(1) Prohibited by two municipal agencies: Alameda County Urban Runoff Clean Water Program (ACURCWP, 1994) and Santa Clara Valley Urban Runoff Pollution Prevention Program (SCVURPPP, 1997). No other specific guidance for any of these discharge types from any of the five municipal jurisdictions considered.
(2) Most such discharges are subject to Industrial General NPDES Permit.
(3) Routinely prohibited under other regulations.

R0025383

policies are not supported for these discharges. Alternately, perhaps responding experts were not sufficiently familiar with these discharge types to produce consistent results. This result implies that some California storm water experts may be willing to accept certain process discharges if the specific process activities and chemical composition of the discharge are well known and carefully controlled.

Of the five discharge types in the Transportation category, three achieved consensus for high concern. All three were associated with vehicle maintenance and fueling activities. In the Cleaning category, only three of the 14 discharge types showed consensus, and all were similar to Transportation category activities: one was fuel related; one was washing of trucks and trailers; and the third was equipment washing. This result suggests that nonstorm water discharges associated with transportation activities in general may be widely considered for prohibition at the statewide policy level.

Almost none of the 15 discharge types meeting the criterion for consensus high concern were addressed by municipal storm water guidelines. The only exception was process equipment washing, explicitly prohibited by two municipalities. This does not suggest the five municipalities had no concerns with the other discharge types, but rather they had not identified a need to promulgate controls under storm water regulations. As shown on Table 3, most discharge types of this group were addressed at least peripherally under regulations or controls specified for hazardous wastes, wastewater discharges, or other activities. It is not surprising to find strong consensus on high water quality concern with discharge types long recognized as problems and controlled under a variety of regulations. The converse result, that the surveyed group did not identify other discharge types with high water quality concern in their own jurisdictions, implies no other types by nature were necessarily so great a water quality threat that categorical prohibition was urgently needed, at least in the opinions of these individuals.

Discharge Types With Absence of Clear Consensus. Table 4 lists discharge types where no consensus was achieved among survey respondents. It is not surprising this was the largest group, both because of the restrictive criteria for consensus and the diversity of interests of the survey respondents. Results showed substantial diversity of opinion.

Many discharge types received multiple scores of 4 and 5, while also receiving multiple responses with a score of 1. Four Cleaning category discharge types received more than 10 responses of 4 or 5, and none of the 11 nonconsensus types received fewer than five such scores. Each also received numerous scores of 1: three to five respondents expressed minimal concern with vehicle and pavement washing, and at least 10 respondents expressed minimal concern with washing buildings, windows, and graffiti marked surfaces. A similar diversity, though somewhat less extreme, was evident among the 23 nonconsensus discharge types in the Process category, and all three types in the Mining category, which may be considered process oriented.

This high diversity of opinion may be attributable to a number of factors, as discussed above. The results suggest that current knowledge of these discharge types is not sufficient to support statewide policies, and that additional research is needed on the diversity of characteristics of these discharge types. The nonconsensus discharge types might be considered of high priority for future field research to quantitatively characterize potential pollutants and determine if characteristics are sufficiently uniform to support statewide policies.

The diversity of opinions was further evident in the municipal guidelines. Of the 80 discharge types on Table 4, 22 were categorically prohibited by at least one of the five agencies; 21 were allowed unconditionally by one or more municipalities; and conditional exceptions were found in at least one municipality for 23 discharge types.

A total of 29 different discharge types were either categorically or conditionally allowed by at least one of the five municipalities. Only 12 of these 29 types were allowed by three or more of the five municipalities, a strong piece of evidence for the lack of uniformity in different California agencies' approaches. The most surprising result is that five of the discharge types for which at least one municipality promulgated a categorical prohibition were either categorically or conditionally allowed by at least one other municipality. Further, a large number of discharge types allowed by one or more municipal agencies, presumably because they generated minimal concern for water quality impacts, did not achieve consensus of the surveyed experts for the same minimal concern.

The inconsistency of municipal guidelines demonstrates varying responses by local decision makers to incomplete information about water quality impacts. Many discharge types were allowed in some municipalities without restriction, and prohibited in other municipalities. It is not clear how much of the diversity may be attributed to regional differences, such as varying sensitivity of receiving waters or varying political climate as expressed in a preference to avoid burdensome environmental controls on local businesses. It is not considered likely the pollutant content of the discharges themselves should be strongly different among regions, though variability is expected among individual discharges. The frequency of certain

Municipal Jurisdictions Considered:

a Alameda County Urban Runoff Clean Water Program (ACURCWP, 1994).
b County of Los Angeles Municipal Permit (RWQCB, 1996; Gary Hildebrand, 1997, Los Angeles County Department of Public Works, Environmental Programs Division, Water Quality Section, Personal Communication to J. Lilien, May 7, 1997).
c Regional Water Quality Control Board, Santa Ana (RWQCB Santa Ana, 1984; RWQCB Santa Ana, 1996).
d County of Sacramento (Larry Walker Associates, 1992; David Brent, 1996, City of Sacramento Department of Utilities, Personal Communication to J. Lilien, November 18, 1996).
e Santa Clara Valley Urban Runoff Pollution Prevention Program (SCVURPPP, 1995; SCVURPPP, 1997).

discharge types may vary among regions, as shown above in the evaluation of discharges from industrial facilities, but no evidence suggests municipal agency guidelines vary among regions in a similar pattern to varying frequency of industrial discharges.

The large number of discharge types allowed under specified conditions suggests reasonably wide support for that mechanism. Conditional permitting could achieve the benefits of exempting from prohibition discharges believed to have minimal water quality impact. However, conditional permitting is considerably more costly than type based prohibition or permitting, both to develop permits and to enforce. Further, lack of adequate enforcement may lead to routine violation of conditions and possible water quality impact.

Results of Detailed Questionnaire for Selected Discharge Types

Results of the detailed survey are described in Duke *et al.* (1997) and not repeated in detail here. Table 5 summarizes one aspect of the results, the number of responses of 4 or 5 to each of nine questions for each of the ten discharge types.

Two discharge types were given scores of 4 or 5 by a majority of respondents for the question of "overall concern," intended to be the same question as the broad based survey. Construction equipment washing, a subset of the equipment washing discharge type that achieved consensus high concern in the broad based survey, was so ranked by nine respondents in the detailed survey. Further questions revealed 11 of the 12 respondents would have high concern if the discharge were widespread or "prevalent" in their region. The reasons for the concern were pollutant concentration and types rather than discharge volume for most of the respondents. Fire fighting discharge, which did not elicit consensus on the broader survey, showed the second largest number of respondents with high concern, again attributable to pollutant concentration and types rather than volume.

Nine of the ten selected discharge types, with the notable exception of landscape irrigation, were found by the respondents to be of much less concern if they were subject to on-site controls or Best Management Practices (BMPs). Each respondent was asked to describe the best currently available BMPs with which he or she was familiar for each discharge type; then to describe their degree of concern if those BMPs were fully implemented for each discharge of that type. No more than one respondent expressed moderately high or high concern for any of the nine discharge types if the selected BMPs were rigorously implemented. The availability of BMPs for these

R0025387

discharge types supports the concept of conditional allowability, the mechanism noted above in discussion of municipal guidelines for many of the non-consensus discharge types in Table 4.

The landscape irrigation discharge type elicited high overall concern from only three of the 12 respondents under current conditions, but seven respondents expressed high concern if the discharge type were prevalent. This result is notable because the review of industrial facility reports showed this as the single most common discharge type, being reported by about 7 percent of all industrial facilities filing annual reports for five regions of California in 1995. Further, it is a discharge type that appears resistant to on-site pollution prevention, compared to others, because this is the only discharge type where more than one respondent described high concern even if best available controls were rigorously implemented.

CONCLUSIONS

This research acquired data to assess the conceptual and technical feasibility of an approach for nonstorm water discharges to relieve the regulatory burden of developing and issuing individual permits that would use discharge type as the basis for regulation.

The first objective was to determine the policy basis for such an approach. Currently, compliance with relevant regulations is often inefficient as practiced. Outright prohibition of non-storm water discharges overregulates by prohibiting some discharges that may not affect water quality. "Effective prohibition," specified by WQA, is interpreted by USEPA to allow individual discharges under separate NPDES permits, but such permits are not widely utilized by municipalities operating MS4s because they are administratively complex, burdensome to develop and enforce, require detailed evaluation of individual discharges, and are subject to USEPA overrule of local judgments.

A possible improved approach merges two concepts derived from current instruments: determination of *de minimis* discharges; and consideration of nonstorm water discharges by functional type. The resulting approach would define *de minimis* discharge types which may be globally accepted for discharge to storm drains. Allowing certain such discharges under blanket statewide guidelines can relieve the regulatory burden and avoid the expense of controlling activities with little expected environmental impact. Any policy eventually promulgated should be based on both technical analysis, which may be guided by this paper's preliminary effort, and a full assessment of stakeholders' preferences about costs, regulatory effectiveness, environmental protection, and other factors.

The second objective was to characterize existing information by discharge type. The evaluation produced three major results:

- A large number of discrete types of nonstorm water discharges exist. More than 100 distinct types of discharges were found in the literature, and several more were suggested by survey respondents.
- Nonstorm water discharges appear to be widespread. Approximately one in four industrial facilities in five California regions reported at least one type of discharge during the 1995 reporting year, even though such discharges were required to be eliminated under permit conditions.
- Some discharge types were widespread in industrial facility reports. For example, runoff from landscape irrigation was reported by nearly 500 facilities within five regions of California, more than 6 percent of all reporting facilities.

The third objective was to characterize the current state of knowledge about concerns with potential water quality impacts of nonstorm water discharges by discharge type. An integral part of this objective was to test the strength of consensus among practitioners and responsible agencies – to determine whether current knowledge supports statewide policies for any discharge types. Two forms of information, evaluation of existing municipal guidelines and a consensus oriented survey of statewide experts, addressed this objective, and suggested the following results:

- Clear consensus existed about water quality concern for some discharge types. The limited survey, with a convenience sample of experts, implemented by this research was sufficient to demonstrate some consensus.
- Discharge types that achieved consensus for minimal water quality concern were not uniformly allowable under current municipal guidelines in California.
- Discharge types that achieved consensus for high water quality concern were almost entirely limited to discharge types readily recognized as important sources of water quality degradation. Most of these were prohibited under existing regulations not related to storm water; few were explicitly prohibited by municipal guidelines designed for storm water pollution control.
- Municipal agency control policies in different regions of California were highly inconsistent for specific discharge types, especially among discharge

types that did not achieve consensus in the statewide survey. This suggests the current state of knowledge is not sufficiently definite to support statewide policies for a large number of discharge types.

• Discharge types failing to achieve consensus might be considered the highest priority for additional research. These are the types where feasibility of global policies could be justified or counterindicated by better understanding of potential water quality impacts, such as field data to characterize pollutants originating with these activities and understanding of conditions under which pollutants are found in higher concentrations.

The discharge types were evaluated largely as found in the literature in order to be as completely inclusive as possible in this initial stage of analysis. Critical analysis of discharge types should be a focus of future research. Aggregating and analyzing discharge types according to similarities in pollutants, function, applicable best management practices, and other factors may facilitate implementation of policies based on discharge type.

An in-depth survey requesting opinions on a limited number of discharge types revealed three notable results with policy implications:

• Discharge types for which respondents expressed high concern for water quality impacts generated most of the concern from two factors, type and concentration of pollutants, and relatively little to volume of discharge.

• For nine of the ten selected discharge types, almost none of the respondents expressed high concern if currently available BMPs with which they were familiar were rigorously implemented. The survey did not, however, address whether the respondents believed such BMPs could be effectively enforced or would be rigorously implemented if regulations so specified.

• Landscape irrigation was one discharge type for which opinion suggests high impact if prevalent. This discharge type was the most widely prevalent among industrial facilities. It was also the only discharge type of the ten selected for in-depth opinion polling where a substantial number of respondents believed currently available BMPs would not reduce concerns to minimal if rigorously implemented.

ACKNOWLEDGMENTS

This research was funded in part by California State Water Resources Control Board Contract Number 5-104-140-0 and managed by Dr. Xavier Swamikannu, whose technical assistance is deeply appreciated. We appreciate the efforts of California Storm Water Quality Task Force members for their participation in the opinion surveys and review for accuracy and completeness of the agency report from which many of these results were derived. Important data and other information were provided by numerous California State personnel, in particular Dr. Thomas Mumley (San Francisco Bay Area Regional Water Quality Control Board); Pamela Barksdale (Central Valley Regional Water Quality Control Board); and Bob Whitaker (Santa Ana Regional Water Quality Control Board). Research assistance at UCLA was provided by Jonathan Lilien of the Environmental Science and Engineering Program and Lara Ganse, Thomas Lo, and Patricia Harris of the Environmental Health Sciences Department. Editorial support was provided by Jill M. Barnes.

Abstract

This research evaluated storm water runoff water quality constituent data collected by industrial facilities under California's 1992 General Industrial Storm Water NPDES Permit. Data for 13 constituents were evaluated for a sample of 130 metal plating facilities in Los Angeles County, reported over a 3-year period. Results are intended as a screening level determination of several factors: proportion of facilities detecting the constituents; their concentrations in a single-industry, single-region set of facilities; and possible trends over time. The analysis also tested the limitations of the self-reported data, which report concentration rather than load and may not be representative of facility runoff. Zinc and copper were detected at more than 80% of facility locations; nickel, chromium, lead, and cadmium were detected at more than 25% of locations. Mean concentrations of copper, lead, zinc, suspended solids, and oil and grease at sample facilities testing for the constituents were roughly comparable to mean concentrations reported by US EPA for a similar set of data from a nationwide sample of metal products manufacturing facilities. As a fraction of water quality standards, median concentration at facilities detecting the constituents were relatively high for copper and silver compared to standards for aquatic life, and for cadmium and lead compared to human drinking water standards. Trends over the 3-year period in concentration of pollutants in facility runoff that may result from regulatory pollution prevention requirements were inconclusive. The concentration data show evidence of other confounding influences sufficiently large and systematic to obscure possible trends in pollutant reduction.

1. Introduction

Pollutants in storm water runoff associated with industrial activities are one form of industrial waste discharge of increasing concern in the US. Urban runoff and other non-point sources are believed to be important sources of pollutants in surface waters of the United States [1–3]. Runoff from urban activities has been estimated to account for substantial proportions of the total mass of some pollutants in some receiving waters [4].

The proportion of pollutants in urban runoff originating with industrial activities relative to other non-point sources has been suggested to be substantial in some areas of the US [4,5]. Research under the Nationwide Urban Runoff Program (NURP) in the 1970s and 1980s suggested concentrations of certain pollutants are significantly higher in runoff from industrial areas than from other land uses [6,7]. However, the characteristics of chemical constituents in runoff from industrial facilities, and their impact on receiving waters, are not well understood. Pollutant type, concentration, and long-term load may be expected to vary over time and across locations with factors such as density of urban development, types of industrial activities, seasonality of precipitation, and proportion of receiving waters originating as urban runoff. These variables and others, such as ecological sensitivity of receiving waters, confound assessment of environmental impacts of urban runoff [8]. The same factors obscure the potential impacts of industrial storm water regulations on improving water quality.

Differences in runoff constituent characteristics among different types of industrial activities are poorly understood. The groundbreaking NURP studies sampled only a small number of industrialized areas, limited to industrial parks and urban areas with a large proportion of land zoned for industrial uses, and did not

R0025391

distinguish among different industrial sectors or types of activities [6]. It is not clear that runoff constituent concentrations from industrial activities are sufficiently uniform to be adequately represented by measured discharges from areas zoned for industrial use, which can encompass industrial activities as diverse as metal products manufacturing, lumber and wood processing, concrete products storage and preparation, warehousing, and a wide range of other manufacturing and non-manufacturing activities.

Systematic data for a large number of facilities, disaggregated by type of industry, first became available with US EPA's analyses of self-reported monitoring results for 31 distinct industrial sectors from a nationwide sample [9]. The nationwide US EPA sample encompassed many facilities subject to a wide range of climates, rainfall regimes, state and local level regulations, and other factors. Those results therefore may not reliably predict pollutant concentrations within industry sectors for any given geographic area. The self-reported nature of the data introduces other limitations, as described in the Methodology section below.

Other results in the literature are limited. Line et al. [10] reported runoff concentration data for selected constituents at 20 North Carolina industrial sites encompassing 10 different sectors. Line and colleagues' results are much better controlled for data acquisition and geographic area of facilities than the US EPA data. However, the samples of two facilities per industry category is too small to capture the variability in pollutant-generating activities present within a given industrial sector. Both studies were limited because they evaluated runoff concentration data, an imperfect surrogate for pollutant loads, the factor arguably most useful for identifying impacts on the environment and assessing effectiveness of pollution prevention. To the authors' knowledge, no agency analyses or published research completed to date has systematically evaluated a sample of industrial facilities to characterize annual load of pollutants by sector.

In the US, regulations to reduce pollutants conveyed in runoff from industrial facilities have been promulgated by US EPA under the National Pollutant Discharge Elimination System (NPDES) of the 1972 Federal Water Pollution Control Act (Clean Water Act, or CWA) and the subsequent 1987 Water Quality Act (WQA) [11]. The most recent federal regulation includes specific requirements for each of 29 different sectors, and is known as the NPDES Storm Water Multi-Sector General Permit for Industrial Activities (hereinafter, the Multi-Sector Permit) [12]. States with authority to enforce the CWA have developed state-level regulations largely patterned after US EPA guidelines. California, the jurisdiction of interest for this paper, promulgated a General NPDES Permit for Storm Water Discharges Associated with Industrial Activities (hereinafter, the General Industrial Permit) [13], first effective in 1992 and renewed in 1997. The number of facilities subject to the regulation is known to be large, perhaps in the range of 30,000 to 50,000 in California, but is not well-defined, for reasons described elsewhere [14]. As of January 1997, about 10,000 industrial facilities in California (of which about 2500 were in Los Angeles County) had notified state agencies of their intent to comply with the General Industrial Permit.

Federal and state storm water permits take a pollution prevention approach. Facility operators are required to develop a site-specific Storm Water Pollution Prevention Plan (SWPPP) with Best Management Practices (BMPs) designed specifically for their facility. This approach contrasts with the discharge standards of the NPDES wastewater discharge permit system, which specify numerical discharge limitations based on available control technologies. A significant limitation of the storm water regulatory structure is the inherent difficulty in evaluating both compliance by the regulated community and progress in reducing pollutants in discharges. The structure of the regulations and reasons for those limitations are described in more detail in a previous publication [15].

A key feature of the regulations is that facilities annually monitor storm water discharges by collecting runoff samples, conducting laboratory analyses to quantify certain constituents in the runoff, and reporting the results to the responsible agency [11]. As a result, a body of data on runoff constituents has accumulated since 1993 in the hands of state agencies. The intent of the monitoring requirements is clearly both to provide information to facility operators so they can detect potential problems and evaluate their own BMPs' effectiveness, and to allow regulators to assess progress both on a facility-specific level and at the level of aggregate pollutant discharges into particular watersheds [16]. If the data were reliable, they might also serve the purpose of characterizing discharges by industry sectors and by industry as a whole in a form that would support regional, state, and local decisions about controlling pollutants to most effectively protect receiving waters.

The data are not ideal for those purposes, for a number of reasons. Data generated under the monitoring requirements are limited to grab samples of runoff collected once or twice per year, and analyzed for concentration of a small number of constituents specified in the regulations or judged by the facility operator as likely to be present. A more thorough understanding of a facility's runoff characteristics would require evaluating pollutant loads generated over an entire wet weather season, or alternatively evaluating long-term average concentrations using data from flow-weighted composite samples collected during representative storms throughout a season. Other reasons are explored in more detail in the Methodology section below.

The existence of the broad and time-specific collection of data accumulated under the General Industrial Permit allows some evaluation of certain major areas of uncertainty such as those described above. Despite the acknowledged limitations, no better data are available at present for such assessments. It is clearly important those assessments be conducted to the extent currently possible to support ongoing efforts to protect specific receiving waters and to evaluate effectiveness of regulations that impact tens of thousands of businesses in California. The overall purpose of this paper was to illuminate key areas of uncertainty regarding runoff constituent characteristics from a given industrial sector in a given geographic area, in the context of assessing progress by facilities in reducing constituents in their runoff under the regulations' pollution prevention approach. The analysis is proposed as a necessary first step in understanding the current and potential impact of regulatory controls. The analysis presented in this paper is intended to derive all conclusions the available data are capable of supporting, although those conclusions ultimately are quite limited. A second important purpose of this paper was to assess the usefulness of the monitoring data being collected. The limited conclusions we have achieved demonstrates the incomplete nature of the data, and suggests potential improvements in the data that would support other conclusions essential to assessing effectiveness of the regulations.

The general objective of this research was to evaluate water quality discharge constituent data for a sample of industrial facilities to assess sector-specific pollutant discharge characteristics, and their changes over the time since the General Industrial Permit has been in effect. There were four specific objectives. First, the research evaluated constituent concentration data for a single industry sector in a single geographical region, comparing results to those of other sector-specific analyses. This is a screening-level evaluation upon which future research can build, preferably with load-based discharge data. Second, the data were analyzed for information that might be immediately useful in regulatory decisions, specifically regarding which constituents should be required for analysis by facilities of the metal finishing sector. Third, the research attempted to identify any impact of pollution prevention efforts implemented under the storm water regulations for the selected industry sector that may be observed from the self-reported monitoring data. The research accomplished this by investigating changes in water quality constituent concentration from a sample of facilities that had recognized their duty to comply. This result also was a screening-level determination, intended to draw conclusions about the ability of the monitoring data to capture any such trends as well as about the trends themselves. Fourth, the research analyzed limitations to this approach, assessed the usefulness of self-reported monitoring data for these purposes, and recommended modifications to regulatory requirements that might generate data better suited to such evaluations.

2. Methodology

The research evaluated self-reported data of chemical constituent concentrations in storm water runoff from industrial facilities of the metal plating industry in the greater Los Angeles, CA, geographic area. Data were reported to the California Regional Water Quality Control Board, Los Angeles (RWQCB/LA), under the General Industrial Permit. Data were analyzed in three ways. First, data from the sample were compared to similar data from US EPA [9] and Line et al. [10] to improve understanding of discharge characteristics from the selected industry sector and to assess the current degree of understanding by testing similarity of different studies' results. Second, data were evaluated for specific results of interest to the regulatory sector. In particular, two factors were of immediate interest: the proportion of facilities identifying presence of certain constituents; and the median concentrations of these constituents in facilities where they were identified compared to their potential effects in the environment. Third, data were evaluated to attempt to detect trends in discharge characteristics within the sample over the 3-year period for which monitoring results are available to date.

A single industrial sector was evaluated to reduce variability in results from the influence of factors such as widely different production technologies and schedules. The metal finishing industry was selected for a number of reasons. It is subject to the General Industrial Permit; it is represented by a large number of facilities filing monitoring reports under the General Industrial Permit; and it is of concern to storm water quality because a typical facility makes use of many toxic substances that may be present in storm water discharges. A single region was used to avoid the influence of potential confounding factors such as difference in regulatory climate, economic strength and environmental awareness. Los Angeles County was chosen because it has the largest number of industrial facilities reporting under the General Industrial Permit of all counties in California [17].

2.1. *Data acquired for Los Angeles metal plating facilities*

The present research acquired data from metal finishing facilities that had filed a Notice of Intent (NOI) to comply with the General Industrial Permit, and had subsequently submitted annual reports containing monitoring data for at least one year of the period 1993 through 1995. That definition does not cover all metal finishing facilities in the Los Angeles region both because of incomplete compliance and because the regulations do not apply to all facilities. The metal finishing industry is part of Sector AA of US EPA's Multi-Sector Permit, defined as fabricated metal products manufacturers. Under the Multi-Sector Permit and the General Industrial Permit, facilities in Sector AA need to comply only if their industrial activities are exposed to storm water.

As of 1995, 180 facilities in Los Angeles County had filed NOIs identifying on-site industrial activities to include operations described by Standard Industrial Classifications (SICs) 3471 through 3479, electroplating and metal finishing. By comparison, the US Bureau of the Census identified 391 facilities in Los Angeles County with SICs 3471 through 3479 for calendar year 1993 [18]. Not all 180 NOI filing facilities submitted monitoring results for all years, and some failed to meet this requirement in any of the three years. Data for one or more years were acquired from a total of 130 facilities.

The 130 facilities tested for a variety of constituents. The 1992 version of the General Industrial Permit specified only four constituents for which all facilities were required to analyze their samples: pH, total suspended solids (TSS), specific conductance, and total organic carbon (TOC). The parameter oil and grease (O & G) was permitted to be substituted for TOC. The General Industrial Permit also specified runoff be tested for other pollutants the facility operator judged likely to be present. For the metal finishing industry, this might reasonably include a number of metals and other substances used in plating chemistries, such as cyanide. More recent regulations, promulgated by US EPA under the Multi-Sector Permit, specify four additional mandatory analytes for Sector AA: total iron; total aluminum; total zinc; and nitrate plus nitrite nitrogen. Those requirements were not in place at the time the data evaluated here were collected. Constituents for which at least one facility in the sample conducted analyses in any of the three target years are listed in Table 1 divided into mandatory constituents, metals, and others.

Data for this research were collected for a total of 13 constituents: three "conventional" pollutants, nine metals including arsenic, and cyanide. These are also identified in Table 1. The number of sample facilities testing for each constituent varied from year to year and among constituents. Aluminum and iron were not selected for this research because few facilities of the sample reported test results for either aluminum or iron. The more recent Multi-Sector Permit requirements specify aluminum and iron for mandatory testing, but few facilities of this sample elected to test for them because they are much less important to a typical metal finishing operation than plating metals (such as chromium and copper), and they are much less likely to be present in plating facilities' runoff than at other facilities of the fabricated metal products industry. Similarly, no nutrients were selected, because fewer than 10 facilities of the sample tested for any nutrients, although three nutrients were included in the US EPA data: phosphorous, total Kjeldahl nitrogen, and nitrate plus nitrite nitrogen. Specific conductance was not selected because it is known to correlate poorly to suspended and dissolved solids and is not a meaningful parameter for other pollutants. Finally, this research did not evaluate pH data. Acidity of facility runoff may be expected not to vary far from neutrality, except in cases of an immediate spill of caustic or acidic substances.

Table 1
Substances in monitoring reports by one or more facilities in the Los Angeles metal platers sample, 1993 to 1995

Mandatory testing	Metals	Other
pH	Aluminum	Cyanide[a]
TSS[a]	Antimony	BOD
Specific conductance	Arsenic[a]	COD
Oil & grease[a]	Barium	TTO
TOC[a]	Beryllium	Benzene
	Cadmium[a]	Toluene
	Chromium[a]	Ethylbenzene
	Cobalt	Total xylenes
	Copper	Acetone
	Iron	Surfactants
	Lead[a]	Hardness
	Mercury[a]	Turbidity
	Molybdenum	BAS
	Nickel[a]	TDS
	Selenium	
	Silver[a]	
	Thallium	
	Vanadium	
	Zinc	

[a] Constituent selected for this research.

Concentration data for each constituent for each facility were conditioned as follows. For facilities where the monitoring plan included sampling at multiple on-site locations, each location was treated separately. Multiple-location sampling was intended by the General Industrial Permit only where facilities are composed of physically and hydraulically separated areas, so concentrations from different sampling points are not expected to be correlated, justifying treatment as independent data points. Data for multiple samples from a given location, on the other hand, were expected to be correlated, especially those representing multiple grab samples from a single storm event. To control for this correlation, we produced a single data point for each location by arithmetically averaging all concentration data reported in a single year for a single location.

Non-detect data were treated in two different ways for different analyses. If a given constituent was detected in only one runoff event of a given year, the concentration value for each non-detect event was assigned to be one-half of the detection limit reported by the facility (varying among facilities). This approach conservatively assumed the constituent was likely to be present in some amount at a given facility during any runoff event of a year in which it was shown to be present at least once.

On the other hand, if all sampling events failed to detect a given constituent in a given year, we replaced the non-detect value with zero. While this approach is not consistent with the more conservative analysis described above, it was adopted to allow comparison with summary statistics published elsewhere [9], one of our goals in this paper. The rationale for this method is to avoid presuming the constituent to be present in any amount at all facilities, on the grounds that facilities where a substance is not in use may actually discharge zero mass of the constituent in runoff. Facilities with at least one event detecting a constituent are less likely to discharge zero mass in the next event.

However, using that method, the computed sample mean and variance for concentration data are strongly affected by non-detect occurrences replaced by zero values. Those statistics are, thus, strongly affected by the selection of facilities in the sample and, in turn, by choices of sample facility operators whether to conduct analyses for certain constituents. That is because data submitted by facilities where constituents were absent strongly affects the computed mean and variance, while facilities where operators chose not to test for the same constituent do not affect mean and variance. We calculate mean concentrations and standard deviation for comparison to US EPA results [9] but because these statistics are affected by sample selection, we suggest they are not meaningful in our further goal of characterizing expected runoff concentration at a facility where the analyte constituent is in use. Instead, analysis in the following section uses the median for a central tendency statistic, and calculates the median using detected values only. We suggest that parameter is more useful to estimate constituent concentrations typical of an industry sector.

The available data are inherently limited by the structure of the regulations, for several reasons. The self-reported chemical constituent data may not be representative of varying concentration in facility runoff with changing industrial activities and changing long-term conditions. Little agency guidance was provided [19], and little enforcement effort was made to verify adequacy.

One reason is spatial variability of industrial activities. The General Industrial Permit specifies samples should be collected from locations "representative" of the facility's runoff pollutants, but regulatory oversight was not adequate to ensure facilities collected runoff from areas including industrial activities.

Another key reason is variation in constituent concentration with time. Within a given storm, constituent concentration during early stages of runoff is likely to be different than after hours of rainfall have washed exposed industrial surfaces. Regulations do not stipulate at what point in a storm runoff should be sampled, so data from multiple facilities were not collected in a consistent manner. Also, sampling requirements were satisfied by grab samples, which are unlikely to capture the average concentration within a given storm event. Few facilities in the sample collected runoff composites, and these were excluded from the analysis because data would not be comparable to the grab samples of the other facilities.

Further, concentration may be expected to vary among different storm events. Facilities were required to collect storm water samples during the wet weather season from only a small number of runoff events—one storm in the 1993 season, and two storms for all seasons thereafter. (The more recent Multi-Sector Permit stipulates a total of two samples, one each during the second and fourth year of the permit, for the four additional constituents added by the new regulations.) It is unlikely that sampling data from one or two storms each year is representative of constituents generated by changing manufacturing activities and other conditions at a typical, operating manufacturing facility.

Finally, some data were missing. Facilities were required to sample storms only if significant runoff commenced during normal operating hours or within the 2 h following scheduled facility operating hours. Some metal platers in the Los Angeles sample claimed not to have experienced two storms sufficient for runoff sampling in a given wet weather season, and therefore failed to submit any analyses for some years—the reason data were available for only 130 facilities of the 180 filing NOIs.

Data were also of questionable consistency among facilities. Each facility was required to develop and implement its own monitoring plan, adapted to measure any pollutants that might originate with the facility's particular industrial activities. Since regulatory agencies did not prescribe or enforce a standard methodology, the sampling and monitoring procedures may vary sharply among facilities. Of greater concern are the potential variability and inadequacy in quality assurance and quality control protocols, which also receive little regulatory oversight. Facility personnel may be expected to vary widely in training, expertise, and diligence in storm water sampling.

Limitations in available data suggest this research ideally should be replicated with well-controlled data collected especially for loads analysis under consistent research methods, for example using flow-weighted composite samples over multiple years. However, collection of data over multiple years from a sufficiently large sample to be statistically meaningful would be prohibitively costly and time consuming. A careful analysis of currently available data is justified before more extensive efforts are conducted.

2.2. Data characterization and comparisons to other published data

Our results compare data acquired for the Los Angeles sample of metal platers to data reported by US EPA for group-applicant facilities of Sector 29, Fabricated Metal Products [9]. Sector 29 is analogous to Sector AA in the Multi-Sector Permit; both are broader sets of related industrial activities that encompass metal finishing activities. It is the most closely related sector for which US EPA data are available. The sample size was roughly comparable, composed of 115 reporting facilities, not all of which tested for every constituent.

The US EPA data were self-reported monitoring results from facilities under the storm water general permit, which therefore suffer the same limitations in representativity and quality control as for the Los Angeles sample, described above. Consistency of sampling design and analytical methods, and quality control for analytical results, may be somewhat better because all data are from group applicants, who may have implemented similar methods and operated under some oversight. On the other hand, the sample of facilities was drawn from a nationwide pool, so facilities were subject to more variability in precipitation and other geographical factors than the Los Angeles sample. US EPA developed statistics for facility runoff concentration data reported prior to 1 January 1992, for a single year's monitoring results; therefore the data cannot be used to assess trends over time.

US EPA reported data for three metals plus eight conventional pollutants. Five of these are the same as constituents evaluated in the present research. US EPA reported mean, median, and upper fifth percentile concentration data assuming normal distribution. We compared these results to the same statistics for data from the Los Angeles sample, computed separately for each monitoring year. The comparison both serves to check validity of the Los Angeles sample results and investigates whether annual fluctuation in the monitoring results is significant in comparison to the magnitude of the measured concentrations.

We also compared our data to results reported by Line and colleagues [10]. Those data were acquired by a single research team, with well-controlled analytical quality and sampling protocols replicated across all facilities. Runoff samples were also controlled for collection time. Each sample was designed to capture the "first flush" of discharge from a given storm event. The researchers employed a rigorous method for selection of representative sampling points on each facility. All facilities were located in North Carolina, subject to relatively uniform climate, rainfall, and hydrogeologic conditions compared to the US EPA nationwide sample. Runoff samples were drawn from a single wet weather season, 1993–1994, and analyzed for concentration of eight metals and presence or absence of 10 organic substances.

The principal limitation to the Line data is the small number of facilities investigated. Data were limited to one field sample each from a total of 20 facilities, only two within the fabricated metal products industry (the same broad classification as the 100-plus facilities of the US EPA sample). It is not likely that data from two facilities are adequate to capture variability in concentration of pollutants generated by industrial activities that can vary widely within an industry sector. It is also not clear whether a single field sample, even when carefully chosen for spatial representativity and consistency of time within a given storm discharge, is representative of pollutants generated by changing conditions at a working industrial facility. However, these are the best-controlled industrial runoff concentration data of which the authors are aware, and are valuable for comparison to the present results.

2.3. Data analysis for regulatory decisions

Despite the limitations of the publicly-reported data, two forms of results describing industry sector characteristics were believed useful to support decisions about regulatory controls to protect the environment from pollutants in runoff from the metal plating sector. The first was the proportion of facilities reporting presence of a given constituent, particularly metals. That figure is some evidence to suggest which metals should be included among the mandatory-testing constituents specified for Sector AA in the Federal Multi-Sector Permit and for similar facilities in the California General Industrial Permit. The second was a parameter describing central tendency of the concentration data. An estimate of the typical concentration that can be expected from a given facility of this industry type can help in assessing relative concern with various constituents. The typical concentration may be compared to concentrations shown by other research to have some impact on human health or on organisms in the environment.

Our statistical analysis was limited by the representativity of the self-reported data, but was attempted to determine whether the method would be useful if the data were reliable. The authors do not suggest developing numerical discharge standards for facilities or for industry sectors based on global estimates of concentrations at which environmental impacts are observed. Such an approach would necessarily assume that concentration of pollutants in facility discharge correlates in some way to concentration experienced by organisms in the environment, an assumption not supported here. Effective policies to control environmental impacts should be based on estimates of total pollutant load from facilities in a specific watershed, and on characteristics of the receiving water. Those data are not available. The recommendation is that facilities' pollution prevention plans and regulators' enforcement activities should emphasize measures to control those constituents found at concentrations relatively high compared to concentrations impacting aquatic life at facilities where the constituents are reasonably likely to be present.

The central tendency parameter evaluated here was the median of each constituent concentration measured at facilities where the constituent was detected, that is, omitting non-detect occurrences from the computation. The median of detected occurrences for facilities in the Los Angeles sample was compared to three standards or objectives from regulatory requirements based on concentrations at which aquatic impacts are observed. The first standard was the Water Quality Objectives promulgated by the California Regional Water Quality Control Board, Los Angeles Region, in its Water Quality Control Plan (or Basin Plan) [20]. These are ambient water quality objectives intended to be protective of aquatic life in inland surface waters. The second was the US EPA's National Primary Drinking Water Standards Maximum Contaminant Limits (MCL) [21]. The third standard was the California Ocean Plan's Estimate of Chronic Toxicity (ECT) [22], ambient concentration water quality objectives for coastal ocean waters.

2.4. Trends in discharge characteristics within the sample

Three analyses were conducted on the monitoring reports' concentration data: proportion of facilities detecting each constituent; median concentration in facilities detecting each constituent; and direction of change in measured concentration at each facility. The three measures together are expected to help assess effectiveness of the regulations in reducing storm water pollutants; or, if such trends are not identifiable, to evaluate effectiveness of the monitoring data.

In assessing pollution prevention, concentration data are not the most effective measure. If BMPs were effective they would reduce the total mass of constituents discharged with storm water in a given year, presumably by reducing the annual total mass of pollutants generated on-site and left exposed to storm water. Concentration alone would poorly measure this in the absence of data on annual total precipitation, because even if long-term concentration values were steady or declined, total loads would vary greatly with total rainfall. Therefore, our trend analysis was conducted for 2 years with similar rainfall. With that restriction, concentration data would be a reasonably powerful indicator if the measured grab-sample runoff concentration reported under regulatory requirements reliably reflected the annual average concentration. The limitations in representativity and quality control described above are the principal limitations to the results, but the large sample of similar industrial facilities in a single geographic region makes this a more powerful analysis than available in any previous research.

About 685 mm (27 inches) of rain were measured at the Los Angeles Civic Center in water year 1993, and about 24 inches in water year 1995 [23]. Both were "wet" years, compared to the 120-year average for rain at the Los Angeles Civic Center of about 350 mm (14 inches). These 2 years are the most meaningful for comparison. (The middle year of the target period, water year 1994, recorded about 200 mm (8 inches) of rain, or about 67% of the long-term average.) As an added advantage, the 2-year interval is more likely to capture any reduction in pollutants from BMP implementation than a 1-year interval.

The first trend data analysis used the percent of monitoring events at a given facility in which each measured constituent was detected. If a substantial number of the sample facilities' pollution prevention efforts succeeded in eliminating use of a given substance for production, or completely avoiding that substance being exposed to storm water, then the proportion of non-detects would be expected to increase over the life of the General Industrial Permit. It is not known whether zero or very low discharge of any of these constituents is achievable by BMPs available to the metal finishing industry, so it is by no means certain the proportion of non-detects will increase even with diligent pollution prevention efforts. This analysis would identify such results if they were achieved.

The second analysis used the median concentration of each constituent for a second purpose. The central tendency of concentration for each constituent aggregated across all facility locations may be expected to decrease in years of similar rainfall if pollution prevention efforts were successful in at least some facility locations. As a potential confounding factor, the median of all detected values might increase if some facility locations reduced their discharges to below the detection limit. Those data points would then be excluded from the sample, leaving in the calculation only facilities with the higher, unchanged concentration values. Although this calculation is not a reliable indicator by itself, it is useful when considered along with the proportion of facilities where the constituent is detected.

The third analysis evaluated the direction of change, if any, in the reported annual concentration of selected constituents for each individual facility location. This analysis may be the most powerful of the three in detecting storm water pollution prevention among

R0025397

facilities of the sample. The relative concentration of measured constituents over time, in years of similar rainfall, may be a valid indicator of changing pollutant generation. Concentration may be expected to decrease at a given facility if its pollution prevention efforts are successful.

3. Results and discussion

Results fall into three categories: characterization of the industry, with comparison to previous research; central tendency data analysis to support potential regulatory discussions; and trends over time in the sample concentration data.

3.1. Comparisons to previously published data

Table 2 presents summary statistics for nine constituents. Of the 13 constituents evaluated, those four detected by fewer than four facilities in any of the 3 years are omitted in Table 2. Table 2 compares the concentration data for the Los Angeles metal plating facilities sample to similar data reported by US EPA [9], Line and colleagues [10], and the NURP studies [6].

Los Angeles metal finishers data included one high outlier each for chromium, copper, and nickel during 1994, and for zinc during 1995. Each of these was reported at an order of magnitude greater than any other data point for those constituents in any year. These were removed, assuming they may have been misreported or spurious results. Data for lead in the 1994 sample included one unusually high reading, about twice the magnitude of concentration reported at any other facility. This was not removed because the same facility reported high concentrations during all 3 years, so the data were assumed to reflect actual conditions at the facility, and therefore necessary to reflect variability of conditions in the sample. Decisions about which data points, if any, to censor are necessarily somewhat subjective, and clearly affect the resulting statistical analysis. This effect is another limiting factor in the use of the self-reported data.

Results of the US EPA analysis reported concentration data for five of the same constituents in its sample of 115 metal fabricating facilities. Reported concentrations were generally comparable to concentrations reported by the Los Angeles metal finishing facilities, considering the substantial variability among the three years of the Los Angeles data. Concentration of copper was somewhat lower in the Los Angeles metal finishers than the US EPA metal fabricators. O & G concentration was similar in the two studies, with the US EPA mean concentration bracketed by a highly variable set of Los Angeles data. (Overall mean concentration of reporting facilities in 1995 was about half the mean in 1993.) TSS mean concentration was somewhat lower in the Los Angeles facilities, ranging from about one-third to about one-half the US EPA facilities' mean. Reported concentration of lead was similar, though somewhat higher in the Los Angeles sample facilities, ranging from 20 to 80% higher than the mean of US EPA facilities. Concentration of zinc was also similar.

Median concentrations for the Los Angeles sample facilities were substantially lower than mean concentrations, most particularly for lead, TSS, and zinc. This is consistent with the occurrence of a few high-magnitude data points, as noted above, and as demonstrated by the high standard deviations for some parameters. This behavior was mirrored even more strongly in the US EPA data, where the standard deviation was not reported, but the median zinc concentration was about one-half the Los Angeles sample median while the mean concentration was nearly twice as high and the 95th percentile was higher by a factor of two to three.

The presence of a few high data points and a large number of non-detects argues that the data may be better fitted by a log-normal distribution, demonstrated to be a an accurate depiction for storm water pollutant data by researchers such as Driscoll et al. [24]. However, since US EPA and NURP data were reported assuming a normal distribution, the same assumption was used to calculate summary statistics of Table 2.

Comparison to data reported by Line et al. [10] for two North Carolina metal fabricating facilities showed the mean and median concentrations for the Los Angeles sample to be substantially higher, by an order of magnitude or more. Line et al. did not detect cadmium at either facility, suggesting that cadmium was not used at either location. Line et al. also did not detect O & G at either facility, to a reported detection limit of 5 μg/l, although that constituent was detected in more than 80% of the Los Angeles sample facilities each year, as noted below. This fact supports the observation that samples at two facilities are unlikely to be statistically representative of the range of characteristics in an industry sector.

Compared to NURP data for mean concentrations, the Los Angeles metal finishers sample mean concentrations were higher by about an order of magnitude for copper and zinc, and about equal for lead. This is not surprising given that NURP data are for urban catchments zoned for industrial land uses, not for specific facilities. Runoff from industries of multiple sectors, from transportation land uses, and from other activities may be expected to be lower in metals than metal fabrication facilities. The relatively high concentration for lead may reflect automotive activities. NURP data were somewhat higher in TSS, also to be expected if the catchment included more open space and more streets than the facility sampling data.

Table 2
Summary statistics for Los Angeles metal platers constituent concentration data (mg/l) compared to other research

Non-detects treated as zero concentration. See Table 3 for number of observations and number of non-detects in each sample.
[a] Sample censored to omit one high outlier point of questionable accuracy.

The usefulness of these data, based on assumed normal distributions and including zeros for non–detect events, is called into question by the substantial differences in central tendency concentration estimates between the US EPA nationwide sample and the Los Angeles sample, coupled with the substantial variation between years in the Los Angeles sample. It is likely that the selection of facilities in the sample has a strong influence on the magnitude of the calculated means. This is perhaps especially so for constituents where smaller proportions of facilities reported no detectable concentrations, and perhaps further exacerbated when comparing years of differing rainfall. Since the US EPA data encompass a much wider variability in rainfall, facility activities, and other factors, the nationwide sample of 115 facilities is suggested to be of marginal usefulness in predicting runoff concentrations for facilities of a particular region, for purposes such as estimating total load of constituents from a given watershed originating with a specific industrial sector.

3.2. Data analysis for regulatory decisions

The first analysis examined the proportion of metal plating facilities where storm water discharges were expected to contain measurable quantities of various constituents. The Los Angeles County self-reported monitoring data were analyzed to count the number of facilities testing for each constituent in which the constituent was detected. Table 3 shows the proportion of locations where each constituent was detected, for each of the 13 test constituents for which at least 10 facilities conducted analyses in any one year.

Of the 13 test constituents, four were identified in detectable concentrations by at least 80% of facilities in all three years, and are labeled "frequently detected" in Table 3. More than 95% of facility locations detected zinc in each of the 3 years, and between 80 and 90% of facilities detected copper. These results are not surprising. Zinc is widely detected in storm water discharges [17]. Copper is particularly widely used in metal plating activities, and O & G is present in detectable quantities in most industrial discharges. Total suspended solids (TSS) were reported at between 91 and 95% of locations, surprising only in that fewer than 100% of facilities identified soil sediments or particulates in detectable amounts. Of the four, only copper is not specified as a mandatory analyte either in the General Industrial Permit or the Multi-Sector Permit.

Five constituents were identified at between 25 and 75% of facilities in all 3 years, and are noted in Table 3 as "commonly detected." These included total organic carbon (TOC) and four metals: nickel, chromium, lead, and cadmium. TOC was present in detectable amounts at about two-thirds of locations in each of the 3 years. A significantly and consistently smaller proportion of facilities reported detecting TOC than reported detecting O & G.

None of the four metals is specified as mandatory-testing for facilities of Sector AA, and presumably for that reason a relatively small number of facility operators chose to test their samples for these substances. No more than 62 facilities, or fewer than one-half of the sample facilities, analyzed for any one of these metals in any year. However, they were widely found when tested for. In 1995 nickel and chromium were present at roughly two-thirds of facilities testing their discharges for these metals, and lead and cadmium were present at approximately one-third of facilities. This result suggests that those four metals may be commonly expected to be present in storm water discharges from metal plating facilities, and therefore that regulations might specify monitoring for the four metals at all metal plating facilities.

Table 3
Metal plating facility locations detecting constituents for each target year

		Number of locations tested			Percent detects		
		1993	1994	1995	1993	1994	1995
Frequently detected	Zinc	56	58	61	98	97	100
	TSS	129	123	137	96	95	91
	Copper	57	57	61	88	84	89
	O&G	109	115	119	82	100	85
Commonly detected	TOC	28	30	34	62	73	66
	Nickel	58	57	61	45	61	69
	Chromium	58	55	59	36	42	59
	Lead	44	58	62	32	47	39
	Cadmium	31	40	48	26	25	29
Seldom Detected	Silver	20	33	42	0	12	17
	Cyanide	13	28	35	8	25	14
	Mercury	18	4	9	11	0	11
	Arsenic	24	15	14	0	7	0

Substances detected at fewer than 25% of the locations include mercury, cyanide, silver and arsenic. These substances are widely recognized in the regulated community as highly toxic, capable of long-term health impacts and environmental damages if released even in small quantities, and subject to hazardous waste and toxic spill reporting regulations. It is not surprising that few facilities release these substances in quantities that would produce measurable amounts in storm water discharges.

The second analysis compared the median concentration of detects to relevant environmental standards. Table 4 shows the median of detected concentrations in each of the three years for the 13 test constituents. Table 4 also shows the Basin Plan objectives, the ECT, and the MCL for those constituents for which they have been promulgated. Table 4 shows the computed ratio of the 1995 median concentration of detects to each of the three standards, as a way to normalize the Los Angeles platers' runoff concentration for potential environmental and human health effects. Four constituents have notably high ratios: silver and copper as a proportion of ECT, which represents effects for aquatic life; and cadmium and lead for MCL, which represents effects of human exposure. Table 2, presented above, shows copper to be present at about 85 to 90% of facility locations at which the analysis was conducted; lead at about 30 to 45% of facilities; and cadmium at about 25 to 35%. This result suggests the three constituents should be strongly considered for mandatory monitoring in regulatory programs designed to protect receiving waters from pollutants in runoff from metal finishing facilities.

3.3. Trends in discharge characteristics within the sample

Data discussed in the previous sections were also used to assess trends in runoff constituents. The median concentrations in Table 4 for the two years of similar rainfall, 1993 and 1995, might be expected to decline if pollution prevention were highly effective at a large proportion of the sample facilities. That trend is mildly visible in TSS, zinc, and (to an even lesser extent) lead. The opposite trend is suggested in other constituents, most strongly in TOC, O & G, nickel, and chromium.

[a] Water quality objective for aquatic life, Los Angeles Region Basin Plan, CRWQCB (1994).
[b] Estimate of chronic toxicity, California Ocean Plan, CSWRCB (1997).
[c] Maximum contaminant limit, national primary drinking water standards, USEPA (1996).
[d] Concentration data not included: substances detected by fewer than four facilities conducting analyses in both 1993 and 1995.
[e] Maximum contaminant limit goal, for substances where MCL has not been promulgated.

The increased median concentrations may signal ineffectiveness of any pollution prevention efforts, or may be caused by confounding factors. For instance, the samples included an increased number of facilities reporting data for metals, including new facilities in the sample each year where facility operators expected those metals to be present. This analysis may be useful over the long term, as pollution prevention becomes widely practiced, but in the early stages of the General Industrial Permit may be insufficiently powerful to detect pollution prevention achievements by individual facilities. Pollutant reductions of a small magnitude may be masked in this aggregate statistic by natural variability in constituent concentration and changing sample composition as compliance improves.

A companion analysis in Table 3 is the proportion of locations where each constituent was detected for the two years of similar rainfall. If the hypothesized improvement in pollution prevention over time were present in these facilities, Table 3 results might show a decreasing proportion of facilities where constituents are detected. Comparing percent detects for 1993 and 1995 in Table 3 shows a small reduction over time for TSS; increases of more than 20% for nickel and chromium; an increase of 7% for lead; and increases of 1 to 4% percent for zinc, copper, O & G, TOC, and cadmium. The substantial increases for nickel, chromium, and lead are probably attributable to increased testing for those metals among facilities where operators judge they are likely to be present—in other words, increased compliance effectiveness—while other facilities elect not to test, also permissible under permit requirements.

This approach, like the other aggregate data analysis method used, may be unable to detect pollution prevention accomplishments given the limitations of the sample and the data. Further, it is not clear that currently available pollution prevention measures are capable of achieving zero or very low discharge concentrations for these constituents. A data assessment of this form, conducted over several years as compliance increases and additional data become available, may be one way of determining whether some facilities can essentially eliminate any of these constituents from their runoff.

Evaluation of data on a facility-specific basis may be more effective at detecting pollution prevention achievements than the two aggregate measurements described above. That is the rationale for our third analysis, using the data to evaluate the change in concentration of measured constituents at the individual sample facilities for the years 1993 to 1995. This result should show a reduction in concentration over time at any facility where storm water pollution prevention efforts were effective over this period.

Table 5 shows the number of facility locations reporting pollutant concentration changes, categorized by direction of change for each of the constituents. Fig. 1 graphs the relative proportion of facilities where concentration increased and those where concentration decreased for eight constituents for which a large number of facilities conducted analyses during both 1993 and 1995. Pairs of data where the constituent was tested for but not detected are included in the "little or no change" category of Table 5. The expected trend was

Table 5
Trends in concentration of measured constituents at Los Angeles sample of metal plating facilities, 1993 to 1995

	Number of facilities			Proportion of facilities		
	Decrease	Increase	Little or no change[a]	Decrease	Increase	Little or no change[a]
Metals						
Arsenic[b]	0	0	11	0.00	0.00	1.00
Cadmium[b]	2	2	9	0.15	0.15	0.69
Chromium	5	10	10	0.20	0.40	0.40
Copper	6	12	5	0.26	0.52	0.22
Lead	2	8	11	0.10	0.38	0.52
Mercury[b]	2	1	4	0.29	0.14	0.57

Silver[b]	0	0	10	0.00	0.00	1.00
Zinc	3	17	6	0.12	0.65	0.23
Other constituents						
Cyanide[b]	1	0	7	0.13	0.00	0.88
O&G	15	35	10	0.25	0.58	0.17
TOC	5	8	0	0.38	0.62	0.00
TSS	21	35	13	0.30	0.51	0.19

Research for each constituent are limited to the number of facilities testing for that constituent during both years of the comparison.

[a] Includes facility locations where constituent was tested for but not detected in both 1993 and 1995, and locations where change was less than 30% of median of detects for 1995.

[b] Small samples: fewer than five detects among facilities reporting analytical results for both years.

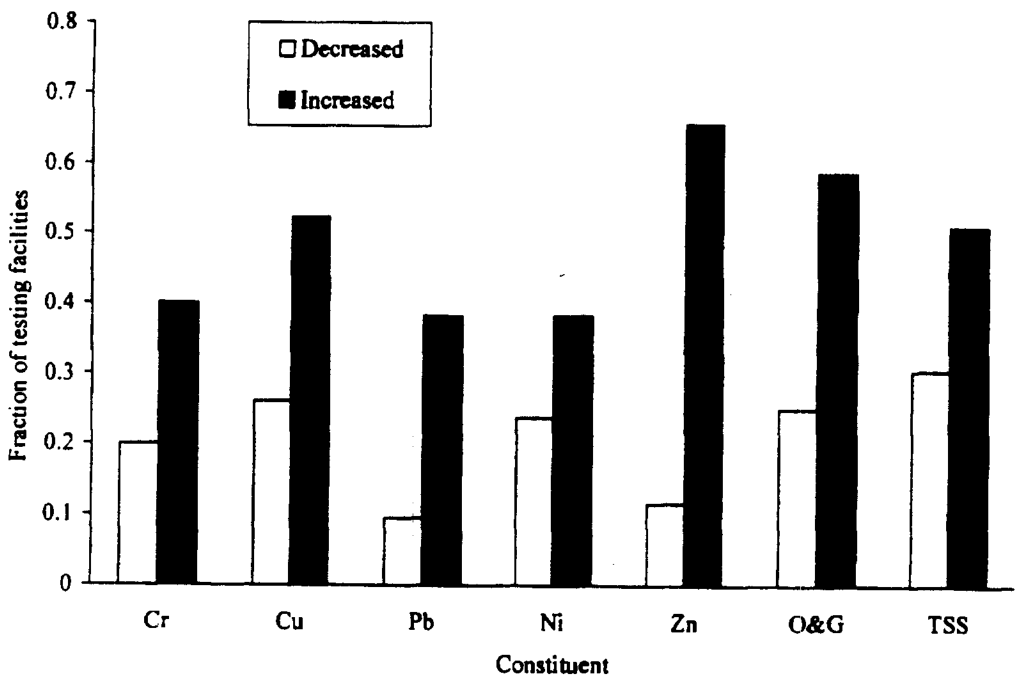

Fig. 1. Proportion of facility locations where constituent concentration decreased versus increased.

not observed. Remarkably, the opposite trend is apparent: measured concentration in runoff increased over the 2-year period for more facilities than those where it decreased, for every one of the eight constituents with at least five data points to compare.

Any of a number of confounding factors may account for this. The self-reported monitoring data may fail to capture full natural variability among storm discharges. Data variability caused by inconsistency and inadequate quality control among multiple regulated facilities may obscure any meaningful trends. Changes in concentration achieved by pollution prevention efforts may be small compared to baseline or background concentrations and to natural variability. Implementation of pollution prevention activities by the metal plating industry sector during the permit's initial 3-year period may be incomplete, or the measures chosen may be ineffective. Changing economic activity may have caused an increase in production over the target period, with a commensurate increase in pollutant-generating industrial activities at the sample facilities. Pre-existing contaminants at a facility may not be adequately removed, contained, or washed through the system. The presence of such a consistent pattern for all constituents strongly suggests the presence of some systematic confounding influence sufficiently powerful to mask any pollution prevention achieved by this sample of facilities during the first two years of BMPs specified under regulatory requirements.

Runoff constituent data reported by facilities under monitoring requirements of the current regulatory structure were found inadequate to support meaningful analyses of facility conditions or progress. Regulations requiring those data to be collected and reported affect a large number of businesses throughout the US, on the order of tens of thousands of facilities in California alone. The data are intended for multiple purposes beyond the assessment of regulatory effectiveness attempted here, such as alerting facility operators to changing conditions they should address with BMPs. However, if US EPA or state agencies intend to monitor progress by industrial sectors as a whole, they should consider more complete and better-controlled studies for more pollutants of concern, perhaps for a smaller number of facilities. More complete evaluations would capture variability at a given facility across entire wet weather seasons; and would correlate results with ancillary factors such as timing of rainfall, type of industrial activities at a facility, facility production rate, and BMPs implemented. Better-controlled studies would ensure consistent sampling techniques and quality control procedures at all facilities, and would limit the facility group to geographic areas of similar environmental and institutional conditions.

4. Conclusions

Storm water runoff quality is known to vary widely among industrial categories, and among facilities of similar types. Runoff chemical composition characteristics are not currently well understood, and improved understanding is critical to ongoing efforts to protect waters of the US from possible impacts by pollutants discharged with storm water associated with industrial activities. This research evaluated water quality data reported by metal finishing facilities in Los Angeles County, CA, as required under regulations pursuant to the US Clean Water Act. Similar data are being acquired and reported nationwide. These results are an initial attempt to systematically evaluate those data, and use the data to evaluate the effectiveness of the regulations and the potential impact of industrial activities on water quality in surface waters of the US. Important limitations to the data limit the conclusions that may be reached. Conclusions fall into three main areas.

First, data on runoff concentration of constituents in a US EPA analysis of metal products fabricating facilities appear roughly comparable to runoff concentration data reported by the sample of metal plating facilities in Los Angeles County that comply with field sampling, analysis, and monitoring reporting requirements of the California General Industrial Permit. The US EPA data have been previously presented as an initial screening estimate of pollutant concentration to be expected in runoff from facilities of particular industrial sectors. The variability of statistical treatments of the runoff constituent concentrations across three years in the Los Angeles sample, coupled with the variability in conditions of the nationwide sample of facilities reporting to US EPA, calls into question the validity of those data for planning purposes in developing control strategies for a given watershed or urban center. It is possible that a better prediction of expected concentration for planning purposes would be obtained using central tendency of detected data points only, in combination with estimated proportion of facilities where a constituent is detected. Alternately, an improved method for handling non-detect data might be considered.

Second, a number of potentially toxic metals widely detected in runoff from the sample facilities are not specified for required testing by state or federal regulations. The proportion of facilities detecting specific pollutants was relatively consistent for each of the three years' monitoring data evaluated, suggesting this statistic is among the more reliable among this paper's analyses. Zinc and copper were identified in 80% or more of the facility locations in the sample. Metals identified by more than 25% of the locations, but fewer than 75%, were nickel, chromium, lead, and cadmium. Fewer than 25% of the locations detected mercury, silver, cyanide, or arsenic, all substances with known highly toxic properties and all controlled under federal, state, and local regulations that reduce the likelihood of discharge to surfaces contacted by storm water. These conclusions should be tested by similar evaluations of the same industry sector in other regions, after accounting for possible regional variation in activities conducted at metal plating facilities.

Third, the self-reported runoff constituent concentration data currently available did not reveal any systematic progress in pollution prevention by the selected industry sector in a given region using any of the three analysis methods attempted here. Indeed, the data collected may not be adequate for such an assessment. That evaluation was one of the stated intentions of the regulatory requirement that facilities collect and report monitoring data. It is suggested that any pollution prevention achieved in the early years of the regulatory controls may be too small to discern against "background" variability using aggregate measures, such as central tendency of concentration and proportion of monitoring facilities detecting the constituents. A facility-specific analysis, intended to overcome these limitations, also failed to detect a trend toward pollution prevention, and in fact suggests the opposite trend, a systematic increase in concentration of constituents in monitored storm water discharges in the two years of similar rainfall. We could not determine whether this effect was due to incomplete or inadequate pollution prevention efforts by the regulated community; masking of long-term pollutant discharge trends by natural variability in the many factors affecting measured runoff constituent concentration; inadequacies in the self-reported monitoring data; or some combination of factors. Future research should apply methods presented here to incorporate additional monitoring data as it becomes available in future years. Detection of such trends may require more carefully designed and controlled monitoring of selected samples of industrial facilities, and may require observation periods substantially longer than the three years available here.

WATERSHED MANAGEMENT

A Framework for Assessing Time-Scale Effects of Wet Weather Discharges

WET WEATHER

PROJECT 92-BAR-1

Water Environment Research Foundation

1998

ABSTRACT

Wet weather discharges are a major cause of impacts on surface waters, and their effective management has become a high priority. Addressing wet weather toxic impacts requires comprehensive and robust assessment of their effects. However, toxicity assessment requirements for wet weather events differ markedly from those for continuous flow discharges. The intermittent nature of wet weather discharges means that time scales of exposure are a key element in selecting test systems. This study provides a framework for assessing wet weather discharge effects, and it recognizes that a time scale of response approach (rather than the traditional organism-based approach) is required for selecting toxicity tests. In this approach, the time-scale characteristics of response, independent of the test organism, are the main criteria for selecting toxicity tests. This approach and associated test system selection procedures formed the basis for developing an impact assessment protocol for wet weather discharges. The protocol starts with a design specification, addressing specific questions related to general program objectives. Primary design elements consider sampling location and sampling frequency. Collected samples are subjected to a time-scale toxicity analysis appropriate to one of three time scales of differing duration (intra-event, event, and long-term) defined in this project. Toxicity testing follows a tiered approach, moving from basic to advanced screening and, if necessary, to confirmatory testing. The protocol is designed to be an integral part of the Water Environment Research Foundation's Framework for a Watershed Management Program.

The lack of appropriate methods to measure intra-event toxicity has led to the modification of existing tests to provide systems that more closely reflect storm event conditions. Information generated in laboratory and field studies conducted at different locations in the United States have been used to facilitate the design of wet weather event assessment programs.

ENVIRONMENTAL STEWARDSHIP THROUGH
INNOVATIVE SCIENCE AND TECHNOLOGY

The Water Environment Research Foundation (WERF) was established to advance science and technology for the benefit of the water quality profession and its customers. Funded through voluntary contributions, WERF manages research under four major Thrust Areas: Collection and Treatment Systems, Human Health and Environmental Effects, Residuals Management, and Watershed Management. WERF seeks cost-effective, publicly acceptable, environmentally sound solutions to water pollution control problems. A 15-member Board of Directors composed of water quality professionals; volunteers from utilities, academia, consulting firms, and industry; a Utility Council and Corporate Council composed of subscribing entities; and a Research Council of knowledgeable leaders in environmental sciences and engineering are actively involved in applied and basic research program management.

While WERF manages the research and coordinates the parties involved, the actual work is carried out by individual organizations, primarily utilities, universities, and industrial and commercial firms. To ensure objectivity, an independent advisory committee of distinguished scientists and engineers helps select researchers, oversees the studies, and provides periodic review and advice. Benefits accrue in the form of services, technological advances, and information for direct application by the profession for its customers.

The Water Environment Research Foundation is successfully building a cooperative research and development program serving the water quality profession. The Foundation's goal is to apply sound and objective scientific information to better serve the public.

This report was prepared by the University of Illinois and the Water Research Center as an account of work sponsored by the Water Environment Research Foundation (WERF). Neither WERF, Subscribers of WERF, the University of Illinois, the Water Research Center, nor any person acting on their behalf: (a) makes any warranty, expressed or implied, with respect to the use of any information, apparatus, method or process disclosed in this report or that such use may not infringe privately owned rights; or (b) assumes any liabilities with respect to the use of, or damages resulting from the use of, any information, apparatus, method, or process disclosed in this report.

The research on which this report is based was funded, in part, by the United States Environmental Protection Agency (EPA) through Cooperative Agreement No. CR 818249 with the Water Environment Research Foundation (WERF). Unless an EPA logo appears on the cover, this report is a publication of WERF, not EPA. Funds awarded under the Cooperative Agreement cited above were not used for editorial services, reproduction, printing or distribution.

This report was reviewed by a panel of independent experts selected by WERF. Panel members are listed elsewhere in the report. Panel members may have included staff of EPA, but this report does not necessarily reflect the views and policies of EPA and no EPA endorsement should be inferred. Mention of trade names or commercial products does not constitute WERF or EPA endorsement or recommendation for use. Similarly, omission of products or trade names indicates nothing concerning WERF's or EPA's positions regarding product effectiveness or applicability.

BENEFITS

- Provides a tiered protocol for assessing the effects of wet weather events on receiving water ecosystems;

- Reviews literature associated with the effects of episodic exposure on receiving system biota and ecosystems and evaluates available tests for wet weather discharge impact assessment;

- Modifies standard test methodologies to produce a battery of complementary tests that are appropriate for wet weather event time-scale toxicity assessment;

- Provides a predictive tool for wet weather impact assessment based upon a simple conceptual model developed from hydrograph characteristics and contaminant concentration data;

- Demonstrates that continuous physicochemical and stage monitoring before, during, and after storm events is a key element of any wet weather discharge monitoring program; and

- Addresses variability of exposure during wet weather events and calculates an event toxicity unit (ETU), which provides an estimate of the toxicity of the event as a whole.

7.0 LABORATORY-BASED STORM EVENT ANALYSIS

7.1 Introduction 7-1

7.2 Where Do I Start? 7-1

7.3 Analysis Design Questions 7-2
- 7.3.1 Where Do I Sample? 7-2
- 7.3.2 What Do I Sample? 7-3
- 7.3.3 When Do I Sample? 7-4

TABLE OF CONTENTS, CONT.

7.3.4 What Constitutes a Reference Sample? 7-4
7.3.5 How Can Toxicity Change Through a Storm Event? 7-5
7.3.6 How Do I Design a Sampling Program to Identify/Separate Water Column/Sediment Effects? 7-7
7.4 Test System Questions 7-8
7.4.1 What Is the Best Test System for Toxicity Analysis? 7-8
7.4.2 What is a Basic Screening Test and When Should I Use One? 7-9
7.4.3 What is an Advanced Screening Test and When Should I Use One? 7-9
7.4.4 What is a Confirmatory Test and When Do I Use One? 7-10
7.4.5 What are the Characteristics of an Optimal Test Battery for Storm Event Analysis? 7-10
7.4.6 What is the Optimum Screening Test Battery for Analyzing Intra-Event Toxicity? 7-10
7.4.7 What is the Optimal Screening Test Battery for Analyzing Event Toxicity 7-11
7.4.8 When Do I Need to Conduct Sediment Toxicity Testing? 7-12
7.5 Sampling Questions 7-12
7.5.1 When and Where Should I Sample to Determine Intra-Event, Event, and/or Long-Term Toxicity in a Watershed? 7-12
7.5.2 How Long Can I Store a Sample? 7-12
7.5.3 How Much Sample Should I Collect? 7-16
7.5.4 What Should I Expect Sampling and Analysis to Cost? 7-16
7.5.5 Where Should I Sample in a Sewer System, in Relation to an Outfall, or in a Drainage Network? 7-17
7.5.6 When and How Should I Collect Composite Samples? 7-17
7.6 Wet Weather Toxicity Questions 7-20
7.6.1 How Do I Characterize Intra-Event, Event, and/or Long-Term Toxicity? (Effect vs. Impact) 7-20
7.6.2 How Many and What Type of Events Should I Sample to Characterize Toxicity? 7-21
7.6.3 What Happens to Toxicity in Closely Spaced Events? 7-22
7.6.4 Are There Some Events that Should Not Be Sampled? 7-22
7.6.5 What is the Toxicity Associated with Rainwater? 7-22
7.7 Water Quality Questions 7-23
7.7.1 Where Do I Sample to Adequately Assess Water Quality? 7-23

EXECUTIVE SUMMARY

Objectives

This report presents a summary of the research record developed for a project sponsored by the Water Environment Research Foundation (WERF) entitled, "Region Specific Time-Scale Toxicity in Aquatic Ecosystems." The project was initiated in September, 1993, with the following research objectives:

- Develop a database for frequency and duration of exposure for contaminants in combined sewer overflow (CSO) and stormwater runoff;
- Review the literature to identify biological test systems appropriate for use in detecting acute and chronic effects of CSO and stormwater discharges;
- Conduct a series of field studies to quantify the relationships between chemical toxicity and the frequency and duration of exposure of aquatic organisms to contaminants during wet weather discharges; and
- Develop an ecosystem-based management context for wet weather discharges that integrates the need for both regulatory criteria and the protection of ecosystem health.

An interim report, *Selecting Biological Test Systems to Assess Time Scale Toxicity,* was published by WERF to disseminate initial project findings (Objectives 1 and 2). Under the umbrella of Objective 3, the project team undertook literature reviews to quantify relationships between chemical toxicity and the frequency and duration of exposure–time-scale toxicity. Objective 4 of the research—to develop an ecological context for wet weather discharge assessment and management—is the subject of this report.

Background

To address time-scale toxicity, it is necessary to implement a comprehensive and robust assessment of the effects of wet weather discharges. To meet this goal, it is necessary to understand how test systems respond to wet weather discharge conditions and how to integrate assessments of direct toxicity with in-stream biosurveys and chemical analysis. Although methods for sampling and impact analysis of continuous flow effluents are well developed, and for the most part standardized, no standard methods exist to determine the effects of storm-related episodic exposure conditions common to wet weather discharge events. Furthermore, the direct toxicity assessment requirements for episodic wet weather events differ markedly from those for continuous flow discharges, such as standard Whole Effluent Toxicity (WET) testing, since the assumptions for the latter are inappropriate for some wet weather event analysis. The intermittent nature of wet weather discharges means that the time scales of exposure are a key element in analyzing the responses of test systems.

Protocol

Establishing a time scale for wet weather discharge assessments requires a careful analysis of program objectives, location, storm characteristics, sampling needs, and receiving system. Program objective issues set a time scale for analysis and are constrained by the time-scale characteristics of the receiving system/discharge combination, which is the subject of the analysis. The time scales identified in this research are: 1) intra-event, which addresses short-term variability in an event and encompasses time scales of seconds to hours, 2) event, which provides an integration of change that occurs during a single event and encompasses time scales of hours to days, depending on the type of storm, 3) long-term, which characterizes event differences and provides an integration of wet weather characteristics and encompasses time scales of days to months. Location issues include position in the watershed and the constraints a specific site places on hydrology, expected water quality, and ecology. Storm issues are seasonality, frequency, return period, and intensity class, all of which alter water quality expectations and affect short- and long-term concentration-duration relationships, defining toxicity and eventual receiving system impact. Sampling issues define the precision required in contaminant identification and the associated identification of concentration variability, characterize the dynamics of contaminants in treatment technologies (and eventually pipes and open channel flow), assist in the determination of contaminant fate, and establish time-scale bounds for biological effect analysis. Receiving system issues are associated with the physical, chemical, and biological/ecological characteristics of the receiving system, which combine to constrain the types of time-scale analysis that are needed, or even possible.

Time-Scale Definition. The intra-event, event and long-term time scales were determined based on analysis of a database of frequency and duration of exposure for water quality changes developed from literature analysis of time-related contaminant change in combined sewer overflow (CSO) and stormwater runoff. This research project characterized water quality change using continuous monitoring and time sequenced sampling for contaminant analysis. Chapter 2.0 and Appendix A summarize regional hydrologic characteristics to provide information on storm event characteristics to assist in defining storm events. This library provides a regional perspective on wet weather related flows, including the mean time between storms, categorization of storm events, and a hydrograph characterization of typical storm events. From this analysis of potential time-related contaminant change, a wet weather toxicity assessment approach was developed.

Time-Scale Toxicity. This approach recognized that current continuous discharge assessment methods were organism-based in that the time scale of exposure is defined by the life history or other characteristics of the test species. The research in this program adopted a time scale of response approach in which the time-scale characteristics of the response, independent of the organism producing that response, are the major criteria for selecting a toxicity testing procedure. Implementation of a time-scale of response approach, and associated test system selection procedures, form the basis of a receiving system impact assessment protocol for wet weather discharges, which is provided in Chapter 3.0 of this report. The protocol presented for the development of a wet weather toxicity assessment program uses information on the expected time-scale changes in concentration/duration exposure to select a test system that will adequately respond to the physical and chemical conditions associated with wet weather discharges both during and after an event.

Protocol Application. The protocol starts with a design specification developed from general program objectives and refined by study plans that address specific questions related to these objectives. Primary design elements consider sampling location and sample-collection frequency, defined by study objectives and location. Samples collected are then subjected to an appropriate time-scale toxicity analysis that follows a tier-testing approach. Tier testing is initiated with basic screening tests that establish the presence or absence of toxicity in wet weather event discharges, and allow a classification by degree and nature of toxicity. Advanced screening tests are then used to identify sources, characterize event toxicity to assist in defining an event toxic unit, and define effect characteristics to guide both short- and long-term assessments of receiving water impact. Based on the results of basic and advanced screening tests, analysis can continue to a confirmatory tier that determines or confirms actual effects in the receiving water ecosystem. Location issues were identified by this research as critical elements of the protocol. When selecting sampling locations for a wet weather discharge assessment, it should be recognized that while the nature of the location may define aspects of sampling frequency and biological or ecological test system validity there might also be feedback from sampling or testing issues used to set sampling locations. Three objective-related sampling location categories, in-pipe, receiving system - single discharge, and receiving system - multiple discharge, were identified and used to define sample frequency and test system application. The protocol for time-scale toxicity assessment is designed to be an integral part of the WERF Framework for a Watershed Management Program.

Selecting Biological Test Systems

Supporting the protocol, Chapter 4.0 presents an objective methodology for selecting biological test systems according to key test-selection criteria that are based on both wet weather event assessment and general test requirements. One criterion, relating to previous application to wet weather event assessment, stands alone but the remainder are grouped into categories of 1) time-scale issues, 2) measurement issues, 3) ecological relevance, and 4) cost. As part of this project, information on test systems was developed and summarized to provide a basis for scoring test systems in relation to criteria, and weightings based on levels of importance related to specific time scales of analysis. Chapter 4.0 provides a summary of applicable test systems and an example of test system selection.

Test System Development and Application

Chapter 5.0 and Appendix B summarize the development and/or application of a range of techniques used for, or in support of, basic and advanced screening methodologies that can be used for toxicity characterization, following the establishment of high or moderate toxicity in screening tests. The advanced screening methods described are 1) a toxicity identification evaluation (TIE) procedure, which allows identification of specific contaminant groups giving rise to toxicity in a sample, 2) a simple model that can be used to predict site-specific, receiving-system toxicity from hydrograph characteristics and expected chemical contaminants with known toxicity, 3) a toxicity prediction modeling approach for heavy metals based on empirical measures of wet weather event toxicity, and 4) a simple storm sewer drainage model that can be used for estimating storm hydrographs to define sampling requirements and assist in identifying sources of contaminants.

Regional Studies

Information on the study sites, and the storm event assessment information developed as a part of this research are provided in Chapter 6.0. Research focused on three field study sites. The main study site was the Copper Slough Watershed near Champaign, IL. Other locations used on the Trinity River Watershed in Ft Worth, Texas, and the Cuyahoga River Watershed at Cleveland, Ohio. In-pipe toxicity was assessed in storm water samples taken from the Kaufman Lake storm sewer on the Copper Slough watershed and three locations on the Trinity River watershed (Cra, Eastern Hills, and Pylon). Receiving waters were assessed in the Copper Slough, the Trinity River (Sycamore Creek), and Mill Creek on the Cuyahoga River. In total, over 50 storm events were assessed in this research.

In the 1994 campaign, fifteen storms were assessed from May through November, concentrating on Copper Slough watershed sites (upstream and downstream from a sewage treatment plant). In the 1995 campaign, two storms were assessed in Fort Worth, Texas, and one in Cleveland, Ohio. In addition, three storms were assessed at the Kaufman Lake Storm Sewer (KLSS) in the upper portion of the Copper Slough. In 1996, seven storms were assessed at the KLSS, including a comprehensive two-week campaign that sampled multiple storms and coordinated laboratory toxicity testing, in situ toxicity assessments, and biosurveys. An additional storm event in Fort Worth and a storm sequence in Cleveland were also assessed in 1996.

Critical Questions and Answers

The information developed from the literature reviews, modeling, field, and laboratory research was used in Chapters 7.0 and 8.0 to define and provide answers to questions, which users should ask when designing wet weather event assessment programs. These chapters also provide relevant information and answers using information generated in the study for the field sites described in Chapter 6.0. Chapter 7.0 covers issues relating to laboratory-based analyses, while Chapter 8.0 deals with field-based analyses. These two chapters are not intended to provide complete, definitive answers to all the questions the designer of a wet weather analysis program might ask, but the responses to common questions represent the range of information developed as a part of this research.

Conclusions

A number of conclusions have been reached as an outcome of this research; several are critically important when addressing wet weather discharge impact assessment.

First, it is essential to have a measure of hydrograph response in parallel with any toxicity assessment of stormwater, and it is essential to apply test systems that are appropriate to the time scale of exposure. This research also found that contaminant concentrations present during wet weather events follow predictable patterns of a first flush high concentration, followed by lower concentrations later in an event due to dilution from rainfall/runoff. Other peaks in contaminant concentration can be related to differential concentration peak times of travel from points in the watershed or are associated with sediment resuspension that occurs later in storm events.

Second, to assess the effects of the episodic contaminant levels associated with wet weather events on organisms or systems, it is necessary to move away from the organism-based approach used for continuous discharges to a time scale of response approach. Unfortunately, no single test system adequately meets all criteria required for wet weather event impact assessment, and standard WET tests, designed for continuous exposure conditions, are inappropriate for assessing some wet weather events. This research found that modifications to standard toxicity testing methodologies can produce new test systems that are more appropriate to wet weather event time-scale toxicity assessment. These account for post-exposure responses of organisms to short-duration exposures to contaminants.

Third, in the over 50 storms studied, discharges from a number of locations consistently showed moderate or high in-pipe toxicity; however, the in-pipe toxicity did not always impact the receiving water as measured by in situ tests or biosurveys. A critical finding was that changes in toxicity during an event can occur rapidly and sampling intervals as short as five minutes or less are needed to accurately measure event toxicity characteristics. Furthermore, at a single location, a sequence of storm events can produce varying levels of toxicity.

Fourth, this research found that regional testing indicated no fundamental differences in the characteristics of the toxic response to wet weather events that could be attributed to specific regional characteristics. The differences in toxicity appeared to be source- and site-specific, and generally tracked a response pattern that identified both first flush and later responses.

Finally, this research reaffirmed that the assessment, monitoring, and management of wet weather events needs must accommodate ecosystem/watershed issues in a time-scale toxicity framework.

Research Needs

What can be summarized from the extensive literature review, laboratory, and field studies conducted as a part of this research is that the special needs of wet weather discharge impact assessment are only now being defined in the context of time-scale toxicity, and research is needed in both fundamental and applied areas of toxicity testing and impact assessment. A number of fundamental and applied research needs have been identified as an outcome of this research, of which four are critically important when addressing wet weather discharge impact assessment.

First, research is needed to address test-system responses to variable exposure concentration and frequency of contaminants, monitoring fundamental organism processes and identifying specific mechanisms of effect. This lack of fundamental understanding of individual organism response translates to an even greater gap in our understanding of community/ecosystem response, where time-scale toxicity issues of wet weather events must be integrated with time scales of response of the communities and ecosystems. These longer time scales must consider both constant and episodic exposure. Second, research is needed on the contribution of storm flows to contaminated sediments, mechanisms of sediment contamination during storm events, and effects of the resuspension of contaminants associated with sediments during storm events. Third, because response to a toxicant is affected by environmental conditions, research is needed on the effects of physical stress on organisms and the impact of unstable habitat conditions on time-scale toxicity. Finally, research is needed to translate advances in the fundamental understanding of the physics, chemistry, or biology/ecology of the environment into useful tools to guide management and regulatory programs. Since there are few standard measures of time-scale toxicity, research is needed to provide the detailed, management practice specific, methods for impact analysis. Once a reasonable basis is provided for impact analysis, research is needed to validate management practice impact and, most importantly, develop predictive tools/models that will assist in the design of better management practices.

CHAPTER 1.0

INTRODUCTION

1.1 Introduction to the Project

This report is the final report for the project "Region Specific Time-Scale Toxicity in Aquatic Ecosystems." The project was initiated in September, 1993, with a review of biological test systems available for the measurement of time-scale toxicity and progressed to field and laboratory studies to assess time-scale toxicity. In both field and laboratory campaigns, the research has been directed toward the collection of data on biological test system responses to stormwater-related changes in water quality and the evaluation of test systems using criteria developed as part of initial project research. Test systems were identified from procedures developed in a test system selection process that has been the subject of constant review and evaluation throughout the project.

The project team identified four overall research objectives:

- **Objective #1**—Develop a database for frequency and duration of exposure for contaminants in combined sewer overflow (CSO) and stormwater runoff;

- **Objective #2**—Conduct a comprehensive review of the literature to identify biological test systems appropriate for use in detecting acute and chronic effects of CSO and stormwater discharges;

- **Objective #3**—Conduct a series of field studies to quantify the relationships between chemical toxicity and the frequency and duration of exposure of aquatic organisms to contaminants during wet weather discharges; and

♦ **Objective #4**—Develop an ecosystem-based management context for wet weather discharges that integrates the need for both regulatory criteria and the protection of ecosystem health.

Research conducted has progressed through several stages. Initially, Objectives #1 and #2 activities were emphasized, resulting in publication of an interim report—*Selecting Biological Test Systems to Assess Time-Scale Toxicity*—and completion of initial literature reviews. These reviews supported initial Objective #3 research to quantify relationships between chemical toxicity and the frequency and duration of exposure–time-scale toxicity.

The 1994 campaign involved sampling at several locations in a watershed receiving stormwater runoff and the use of a range of methods including common biosurveys, in situ use of caged organisms, and time-based storm event sampling. Samples were subjected to both chemical analyses and a toxicity test battery. The results from this initial campaign clarified issues relating to time-scale toxicity, such as sampling location and frequency and test-method selection. The data indicated that biosurveys produced little information on short-term time-scale toxicity. Further, toxicity test battery results suggested the need for specific examination of time-of-exposure issues in the laboratory. Therefore, in 1994, an extensive laboratory-based testing program was initiated to examine time-of-exposure to common whole effluent toxicity (WET) species (*Hyalella azteca* and *Ceriodaphnia dubia*), and the project team began planning to deploy successful test systems in different regions.

The 1995 field and laboratory campaign can be characterized as an effort focused by the results of initial research, which was further sharpened by experiences gained from regional field and laboratory studies. Field studies were conducted in Fort Worth, Texas, as well as Champaign, Illinois, and were supplemented with storm event samples collected as a part of the Mill Creek Watershed Project in Cleveland, Ohio. Laboratory studies were conducted at the University of North Texas (UNT) and the Environmental Research Laboratory, Duluth, Minnesota (ERL-D). The 1995 laboratory studies continued time-of-exposure experiments and expanded the laboratory analysis program to include fathead minnow (*Pimephales promelas)* and to evaluate stock and dilution water effects on results through testing at the UNT and ERL-D. In addition, analysis of further test systems was completed. Additional development work was carried out with the Microtox and *Ceriodaphnia dubia* IQ (enzyme inhibition) tests to increase their utility for monitoring wet weather events. A successful four-month deployment was made of the Mussel Monitor, monitoring multiple storm events from August through November, 1995. This field and laboratory research resulted in the production of an interim document, *Protocol for Wet Weather*

Testing and Assessment. The protocol integrated existing standardized impact assessment and analysis procedures with time-scale-specific analysis to support the assessment of both short-term and long-term changes in receiving system condition or quality.

The 1996 campaign was designed to address specific issues identified in the previous research. Specifically, an intensive sampling program was initiated at a storm sewer (Kaufman Lake Storm Sewer) near Champaign, Illinois, to provide a detailed water quality and toxicity record for a multiple storm sequence, relating storm event toxicity to in-stream impact monitored by sampling benthic macroinvertebrates and both in situ and sediment related toxicity. In addition, laboratory-based studies included toxicity identification evaluation (TIE), and completion of time-scale toxicity research. Other aspects of the research have featured a cooperative study with the Northeast Ohio Regional Sewer District (Mill Creek in Cleveland, OH) assessing storm event toxicity and continuing cooperation with the City of Fort Worth (further studies of the Cra site).

This sequence of laboratory and field- related research reflects the increased understanding of storm event toxicity. Initial studies evaluated a range of test systems and their responses to storm event conditions. The extent of the toxicity of storm water discharges and receiving water impact was found to be site-specific. Field investigations in Fort Worth, Texas, demonstrated the importance of sampling for toxicity screening near sources of stormwater. Consequently, the focus of the research shifted so as to determine the presence and timing of toxicity during storm events, and the decrease in toxicity with distance from the source, using both laboratory and in situ methods. With this progressive understanding of storm events, the interval between sequential stormwater samples taken for laboratory testing was decreased to as little as 150 seconds. This intra-event analysis supported the development of methods to better characterize toxicity during storm events and provided insight into methods of sampling suitable for storm event analysis.

1.2 Analysis of Existing Approaches and Issues

Issues surrounding the effect of wet weather related discharges on the environment have grown in importance as the regulatory focus of the Clean Water Act has shifted from effluents with continuous flow to episodic discharges produced by storm events. This change in focus and the changing regulatory scene necessitated a shift in approach when developing procedures for wet weather discharge impact assessment. The new approach demands careful integration of sampling and analysis procedures, coordinated with what is termed "time-scale" toxicity assessment and receiving system effects assessment.

Toxicity can be defined as the inherent potential or capacity of a test substance to cause adverse effects on living organisms. These effects can be either:

- Sublethal—that is, detrimental to responses such as enzyme function, bioluminescence, growth and reproduction, but not resulting in death within the exposure period; or

- Lethal—that is, causing the death of organisms by direct action. Death is usually defined as the cessation of all visible signs of movement or activity.

Considerable evidence indicates that elevated levels of contaminants in wet weather-related discharges can elicit a response in test systems. However, the measurement of a response to storm water discharges does not in itself constitute toxicity or mean that the discharge will cause an impact on the receiving water biota. A comprehensive and robust assessment of the effects of wet weather discharges can only be achieved by an understanding of the nature of test system responses and the effective use of an integrated assessment approach involving direct toxicity assessment as well as in-stream biosurveys and chemical analysis.

Although methods for sampling and impact analysis of continuous flow effluents are well developed and, for the most part, standardized (US EPA 1993a; 1994), no standard methods exist to determine the effects of storm-related episodic exposure conditions common to wet weather discharge events. Further, the assumptions supporting effect assessment for continuous flow effluents, such as standard WET testing, are inappropriate for some wet weather event analyses. The direct toxicity assessment requirements for episodic wet weather events differ markedly from those for continuous flow discharges since the assumptions for the latter are inappropriate for some wet weather event analysis. The intermittent nature of wet weather discharges means that the time scales of exposure are key in analyzing the responses of test systems, and the relevant time scales of exposure need to be reflected in any toxicity assessment program.

1.3 Report Organization

This report is organized into ten chapters. This introduction constitutes Chapter 1.0, and Chapter 2.0 deals with time-scale issues and develops a time-scale framework to support a comprehensive time-scale toxicity analysis by identifying the conditions that lead to organism exposure to contaminants in receiving systems (Objective #1). Chapter 3.0 provides a protocol for time-scale toxicity assessment, which considers issues of time scale and location in the identification of procedures for time-scale analysis. Chapter 4.0 is a review of biological test systems useful for time-scale toxicity analysis. This chapter builds on the review of the literature completed to meet Objective #2 and published in 1994 as *Selecting Biological Test Systems to Assess Time-Scale Toxicity*. Chapter 5.0 provides a review of methods developed and applied in this research. Chapter 6.0 provides information on the study sites and a summary of storm events monitored. Chapters 7.0 and 8.0 have been prepared to provide access to the extensive research record developed as a part of this project. Questions associated with time-scale toxicity, and laboratory and field assessments have been addressed by relating elements of the research record to support question responses. Chapters 7.0 and 8.0 are provided in a question and answer format and should be considered a supplement to the protocol reviewed in Chapter 3.0 in that these chapters will assist in dealing with specific implementation issues in time-scale toxicity analysis. Chapters 9.0 and 10.0 provide a summary of research findings and identify critical research needs in the further development of time-scale toxicity analysis. Appendices provide detailed information supporting regional storm event characterization, details on method development and application, and an ecosystem-based management paradigm.

CHAPTER 2.0

TIME-SCALE ISSUES

2.1 Introduction

The focus of this research project was time-scale toxicity, that is, toxicity in aquatic systems resulting from wet weather events. Many factors—physical, biological, chemical, and hydrological—influence, or are influenced by the time scales of wet weather events. For example, regional differences in hydrological patterns can influence event characteristics, including toxicity, while natural patterns of variation in biological communities cause their degree of sensitivity to vary. Clearly, understanding these relationships can help target a wet weather event assessment program and aid in the interpretation of the results obtained in order to arrive at appropriate management decisions.

In this chapter are discussed some of the more important relationships and influences on wet weather event toxicity, and the concept of a time-scale framework for wet weather event assessment is introduced. This framework forms the foundation for the wet weather event assessment protocol and the biological test system selection methodology that are developed in Chapters 3.0 and 4.0.

2.2 Time-Scale Issues in the Physical/Chemical Analysis of the Environment

Time scales required for wet weather event assessment can be short or long. For example, to analyze toxicity associated with a transient change in the concentration of a contaminant requires a short time scale, measured in seconds to hours. In contrast, where it is necessary to account for accumulation of sediment or contaminants or to assess habitat alteration in the receiving waters, a long time scale, measured in days to years, is required. Short time-scale analysis can be storm- and location-specific. Long time-scale analysis includes effects of multiple storm events or multiple locations over larger spatial scales.

Time-scale considerations are critical to both the design of an analysis/assessment program and the eventual interpretation of data from that program. Selecting which parameters to measure often depends on storm event characteristics. An intense thunderstorm often deposits a large amount of rain in a short time, while another, longer storm can consist of gentle rain falling for hours or days. To ensure precision and accuracy of contaminant concentration or flow variability measurements, the time scale must match the wet weather event. High frequency sampling might be required for short events, while long events might require careful collection of composite samples from the entire storm.

In addition, other factors can determine time scales. Since a detention basin is designed to hold a given volume of water, which then drains slowly to the receiving waters, the detention time becomes relevant when natural flows are modified. Because treatment technologies are designed to meet specific needs, the time scale for a performance analysis might be treatment-technology-specific, as well as site-specific.

The time scale appropriate to receiving system impact assessment will be site-specific, as well as specific to the indigenous aquatic life. For example, a headwaters stream will have a short hydraulic concentration time for any rainfall event so that it is important to sample headwaters with a short interval between samples. Other factors determine the time scale of assessment at specific sites. An area of sediment deposition in a stream requires a time scale of assessment that spans the period of deposition, which might be further modified by decomposition rates. When aquatic life is considered, a major time consideration is life span. Organisms might be short or long-lived, each species requiring a different time scale for testing or analysis. Finally, time must be considered in terms of the duration of exposure, which, along with the concentrations of contaminants, determines toxicity.

Establishing a time scale for wet weather discharge assessments requires a careful analysis of location, storm characteristics, sampling needs, and receiving system and program objectives.

- **Location issues** include position in the watershed, as well as the constraints a specific site places on hydrology, expected water quality, and ecology;

- **Storm issues** include seasonality, frequency, return period, and intensity class—all factors that alter water quality expectations and affect short and long-term concentration-duration relationships, which define toxicity and eventual receiving system impact;

- **Sampling issues** define the precision required in contaminant identification and the associated identification of concentration variability, characterize the dynamics of contaminants in treatment technologies (and eventually pipes and open channel flow), assist in the determination of contaminant fate, and establish time-scale bounds for biological effect analysis;

- **Receiving system issues** are associated with the physical, chemical, and biological/ecological characteristics of the receiving system, which combine to constrain the types of time-scale analysis that are needed, or even possible; and

- **Objective issues** set a time scale for analysis and are constrained by the time-scale characteristics of the receiving system/discharge combination, which is the subject of the analysis.

Spatial and temporal scales must be considered when analyzing wet weather-related water quality issues in watersheds. With large spatial and temporal scales, the emphasis is on source development and contaminant loading. With smaller spatial scales, the emphasis is on concentration and duration of exposure. Further, spatial and temporal scales are important factors that define cause and effect. As scales of analysis are reduced, a better definition of cause and effect is possible.

2.3 A Time-Scale Framework for Wet Weather Event Assessment—Hydrology

2.3.1 Introduction

Objective #1 of the research project supports a comprehensive time-scale toxicity analysis by identifying the conditions that lead to organism exposure to contaminants in receiving systems. The objective was to develop a database for frequency and duration of exposure for contaminants in combined sewer overflow and stormwater run-off, and this was approached in several ways. One approach investigated regional hydrologic characteristics that would help define storm events, and a library was assembled that provides information on storm event characteristics (Appendix A). This library provides a regional perspective on storm event characteristics and supports analysis of specific studies conducted in various regions. Analyses have been performed on the Kaskaskia River near Champaign, IL; Johnson Creek in the Willamette River Basin at Sycamore, Oregon, The Cuyahoga River at Independence, Ohio (representative of Cleveland, Ohio), Ware Creek near Toano, Virginia (representative of Virginia coastal areas), the Trinity River in Fort Worth, Texas, and the Salt River in Phoenix, Arizona. At each site, hydrologic data were used to characterize hydrographs of typical storm events (Appendix A) and to develop summaries of percent of total storms in small, medium, and large categories, and the mean time between storms (Table 2-1).

Table 2-1. Summary of Watershed Analysis

Watershed	Data Collection Period	Storm Events (% by Category)			Mean Time between Storm Events (Days)			
		Small	Medium	Large	Spring	Summer	Fall	Winter
Kaskaskia River, IL	1986-89	59.3	31.6	9.1	6.06	6.66	9.47	7.24
Johnson Creek, OR	1989-93	64	22.4	13.6	4.36	6.45	4.36	4.45
Cuyahoga River, OH	1989-93	72.2	18.2	9.6	4.21	4.46	4.37	4.62
Ware Creek, VA	1989-93	67.3	24.0	8.7	4.28	4.44	4.70	4.57
Trinity River, TX	1989-93	80.4	9.6	10.0	5.07	6.88	7.56	6.08
Salt River, AZ	1983-91	67.3	24.0	8.7	5.8	N/A	6.4	2.8

2.3.2 Summary

The hydrologic analyses performed as a part of this study yielded a library of information that serves as a regional foundation for the prediction of frequency and duration of exposure for contaminants in CSO discharges and stormwater run-off. The analysis identified regional differences in the times of storms, the time between storm events, storm size, and hydrograph characteristics for storm events. These factors all affect the contaminant exposure profile, and, therefore, the toxicity of an individual storm event. Discussion of the requirements for toxicity assessment of storm events can be found in Chapter 7.0. Hydrologic analysis also provided detailed information for local field sites (such as the Copper Slough, Mill Creek in Cleveland, and Fort Worth study sites near the Trinity River), where expected storm and flow conditions assisted in the design of sampling programs.

2.4 A Time-Scale Framework for Wet Weather Event Assessment—Toxicity/Biology/Ecology

A number of time-scale issues affect the potential impact of wet weather events in receiving systems and on how toxicity tests can reflect wet weather event time scales. Of these issues, the most important is how long the organisms are explosed to a contaminant. This, together with the exposure concentration, defines the contaminant "dose." The concentration/duration of exposure relationship is the foundation for procedures for any toxicity analysis, and is particularly important when considering receiving system impact assessment procedures for wet weather event application.

A test system is defined as a measurement or analysis unit that integrates a complex response and is used to examine or assess the effect of toxicants (Herricks, Milne, and Johnson, 1994). Test systems can range from simple biochemical assays to experimental manipulation of ecological systems. In standard test methods, such as WET testing procedures, the time scale established in the procedure is based on the time required to produce a specific response (e.g., LC_{50} or EC_{50}) in the species selected for testing. This is an "organism-based" approach, which has supported the development of methods to measure acute or chronic toxicity, which in turn have been, and continue to be, widely used in toxicity testing and assessment programs (e.g., WET testing). The organism-based approach differs from a "time scale of response" approach, in which the time-scale characteristics of the response, independent of the organism producing that response, is the major criterion for selecting a toxicity testing procedure. The "time scale of response" approach is emphasized in wet weather analyses and associated test system selection procedures. Therefore, in a wet weather toxicity assessment program, an expected concentration/duration condition is used to select a test system that will adequately respond to exposure conditions, specifically the time scale of the exposure.

Although wet weather event time scales vary widely at the same location, as well as regionally, the project team identified three time scales for a starting point for a time-scale toxicity determination in wet weather assessments. If a measure is intended to assess an intra-event effect, the analyses must accommodate rapidly changing conditions. In the **intra-event time scale**, concentrations might vary by several orders of magnitude, and exposure times might be as short as seconds, certainly minutes and possibly a few hours. In practical terms, intra-event time intervals are measured in minutes for short duration events and hours for longer events.

[illegible]
assess the toxicity variation within a single storm event
characterize the range of toxic conditions in an effluent with changing flow
characterize the range of conditions occurring at a site during a storm event
identify toxic contaminants and their dynamics
identify concentration vs loading effects
identify sources of contamination and location
identify likely mechanisms of toxicity
predict receiving system effects based on site-specific toxicity

The second time scale is event, when measures of concentration variability are reduced by sampling approach (e.g., composite sampling) and the duration of exposure can be hours to days. The actual determination of an event time scale is both storm- and site- specific. In general, an event time scale spans the time from the initiation of runoff to the termination of the receding limb (Bras, 1990). This time span can be determined both hydrologically (Linsley, Kohler, and Paulus, 1975) and by observation of water quality changes (e.g., return to pre-storm specific conductance values). In the Copper Slough watershed at downstream locations, the average event duration determined hydro logically was 1.36 days with a standard deviation of 1.5 days (a maximum of 8.88 and a minimum of 0.29) and from 1.5 to 4 days based on water quality change. The event time scale is also modified by treatment technologies, particularly detention facilities. When stormwater is detained and released slowly after rainfall has ceased, the actual event duration can be extended well beyond normal storm hydrograph expectations. An event time-scale analysis finds application when within-event change is "averaged" using composite samples, or storm-related change is modified by detention and mixing management practices.

For convenience, event time scales fall into two categories: Category #1 would be appropriate for short-duration, convective storms in which event duration is measured in hours, and Category #2 where event duration requires multiple composite samples, or best management practices (BMPs) extend a storm's influence so that an event duration is measured in days (24-hour increments).

[illegible]
analyze whole storm effects
measure the effects of event mean concentrations of contaminants
assess the effects of total contaminant loading during a storm
analyze event-related toxicity as modified by management practices (e.g. detention)
assess BMP performance against water quality criteria
identify sources of contamination and location
relate intra-event or short duration storm events results to common WET testing that uses fixed exposure times of 48 to 96 hours
assess short-term response of specific receiving system components to a whole storm; confirm receiving system effects predicted from other testing

Finally, a **long-term** time scale is typical of multiple storm events or storm-related residuals that produce a chronic exposure condition. The long-term time scale is particularly applicable when separating wet weather events from other watershed influences.

[illegible]
assess the effects of multiple storm events
assess the chronic effect of single or multiple storms
compare seasonal change in storm event effect
compare effect among multiple sites
assess community or ecosystem effects of storm water discharge(s)
determine receiving system state and condition with the intention of monitoring confirmed wet weather event effects

An indicator for a long-term time scale must meet different criteria from those appropriate to shorter time-scale indicators. Further, it should be recognized that longer time scales introduce greater complexity in the determination of cause and effect, requiring either a greater number of indicators for confirmation of effect or indicators that require a longer time span for completion of analysis where multiple events and other interacting factors affect results. Wet weather toxicity testing and assessment must reflect the varying, extended residence time in the receiving system for both non-conservative and conservative contaminants in wet weather discharges. Finally, a wet weather toxicity testing and assessment program also includes a receiving system "residuals" component that considers the extended duration of potential exposure associated with accumulated contaminants directly attributed to wet weather discharges.

These three time-scale divisions recognize that effect identification, test system selection, actual measurement of an effect (physical, chemical, biological/ecological, etc.), and analysis and interpretation of consequence must all meet criteria that are specific to an identified time scale.

Table 2-2 is a summary of the types of measurements appropriate to different time scales. For a wet weather-based test system selection, if toxicity is the indicator, then in short-term exposures (intra-event time scale) where concentration transients might be very large (e.g., orders of magnitude), rapid responses will be the best indicators. When analyzing whole events, for example as modified by BMPs, the time-scale analysis selected (event time scale) should reflect the fact that BMP effluents will have some characteristics of the storm event (e.g., episodic nature with variable volume and concentrations associated with the effluent), but BMP effluents will typically be less variable with longer, but not constant, effluent flow times. Finally, toxicity analysis related to extended contaminant residence or accumulation of contaminants will require tests appropriate for a long-term time scale, where exposure durations are very long.

2.5 A Time-Scale Framework for Wet Weather Event Assessment—Ecology

2.5.1 Seasonal Effects

The impact of wet weather events potentially reveals seasonal changes due to the biological variability of the system. Many aquatic species show seasonal patterns in presence or abundance. In particular, many insect species have aquatic larval stages but terrestrial adult stages. Some of these insects represent particularly pollution-sensitive groups, for example stoneflies and mayflies, so the impact of a wet weather event on the aquatic community might be more severe during the season when these aquatic forms are present.

Table 2-2. Example Measurements Used to Apply the Time-Scale Concept

MEASUREMENT CHARACTERISTICS	TIME SCALE		
	INTRA-EVENT	EVENT	LONG-TERM
PHYSICAL	Discharge vs. time	BMP modified discharge	Discharge/channel morphology characteristics
CHEMICAL	Hydrograph sequenced contaminant concentration	Flow-weighted average or composite sample concentration	Sediment accumulation
BIOLOGICAL/ ECOLOGICAL	Physiological and/or behavioral response, modified whole effluent analysis procedures, time-scale toxicity measures	Effect testing using whole effluent approaches ; may include acute or sub-chronic testing	Sediment toxicity and/or field bioassessments
INTEGRATIVE	Simulation/modeling, bacteria and toxicity assessment	Standard exceedance frequency, habitat	Watershed comparisons
AESTHETIC	Debris sampling/ quantification	Public attitude surveys	Public involvement groups

Intimately related to seasonal variability is the effect of organism life history. Most, if not all, organisms show varying degrees of sensitivity to contaminants at different stages of their life cycles. Usually, the

R0025445

young and developing stages are most sensitive. Consequently, the greatest impacts of wet weather events on community structure and long-term population viability occur when the most sensitive life stages are present.

2.5.2 Habitat

Habitat changes are associated with wet weather events at different time scales, from short-term sediment deposition and local scouring to major channel shifts. Sediments associated with wet weather events sometimes contain contaminants that have direct toxic effects on sediment biota either through immediate toxic action or through bioaccumulation. The hydraulic characteristics of storm events can also resuspend sediments, potentially exposing water-column biota to contaminants.

In addition to toxic effects, heavy sediment deposition alters the physical habitat, thereby affecting the receiving system ecology. Sediment removal and scouring from the hydraulic influence of wet weather events are other mechanisms of physical habitat alteration.

2.6 A Time-Scale Framework for Wet Weather Event Assessment—Watershed and Drainage System Location

The location issues important in establishing a time scale for wet weather discharge assessments consider the fundamental physical, chemical, and biological/ecological processes that operate in the watershed. These processes operate over different spatial and temporal scales and can be specific to a location in the watershed. For example, in a low-order stream reach, the changes in physical and chemical conditions produced by a wet weather event, as measured from baseline/baseflow conditions, will be of short duration. Although event duration is short, the magnitude of change is often great. Further, one can expect limited residual effects in a low-order stream because of high transport rates out of the system. To analyze or interpret wet weather event effects in a low-order stream, the focus is on contaminant concentration, rather than loading, while interpretation is simplified because the limited watershed area restricts possible sources. Furthermore, the potential for contamination is usually limited by the small watershed area associated with these small streams. In contrast, the changes in physical and chemical conditions produced by a wet weather event in high-order streams have longer durations. Although the change in physical and chemical conditions might still be rapid, the magnitude of this change is moderated by the increased baseflow and dilution capacity of these larger streams. In high-order streams, event duration is often long, reflecting the extended concentration time for flows from tributaries. In addition, the effect of contaminants can be extended, because residuals are stored or only slowly transported within these larger rivers. To analyze or interpret wet weather event effects in these larger rivers that have larger watersheds, the focus typically shifts to contaminant loading, and interpretation is complicated by the potential effects of multiple sources. Furthermore, larger watershed areas also introduce the complications produced by a more diverse land use that can be expected to alter both baseline/baseflow conditions and wet weather conditions.

It is possible to extend this analysis of location to considerations of toxic potential. The disturbance of any watershed, natural or anthropogenic, is expected to alter run-off volume and chemical characteristics of the run-off (Borman et al., 1968; Vitousek et al., 1979; Webster and Patten, 1979; McDowell and Likens, 1988; Close and Davies-Colley, 1990; Edwards and Helvey, 1991). The result is that water quality alterations are magnified by the combined effects of disturbance and the concentration of contaminants. The effects on receiving system aquatic life are short-term if the natural assimilative capacity of the stream/watershed system is not exceeded and long-term if deposited contaminants lead to residual effects. As noted above, watershed location (stream order) is critical in determining the relative importance of concentration or loading. When low-order streams are compared with high-order streams, the effects of changes in run-off volume and contaminant concentration are less likely to be moderated by ambient flows and lead to acute toxicity and profound, short-term change in receiving system biota. In high-order streams, contaminant concentrations might not be acutely toxic, but the residual effects produced by deposition, storage, or slow transport lead to chronic toxicity and the effects on receiving system biota are subtle. As the ratio of disturbed to undisturbed land increases, the risk of severe impact also increases. Recent analyses indicate that any increase in impervious area above 15% to 20% will severely limit ecological integrity (Shaver et al., 1995).

This complex set of relationships among spatial scale, duration of effect, location, and risk of impairment requires that wet weather discharge assessments use techniques appropriate to both time scale and watershed location. It is possible to use watershed location, and location-specific time scale and exposure characteristics as the starting point for selection of assessment procedures.

CHAPTER 3.0

PROTOCOL FOR TIME-SCALE TOXICITY ASSESSMENT

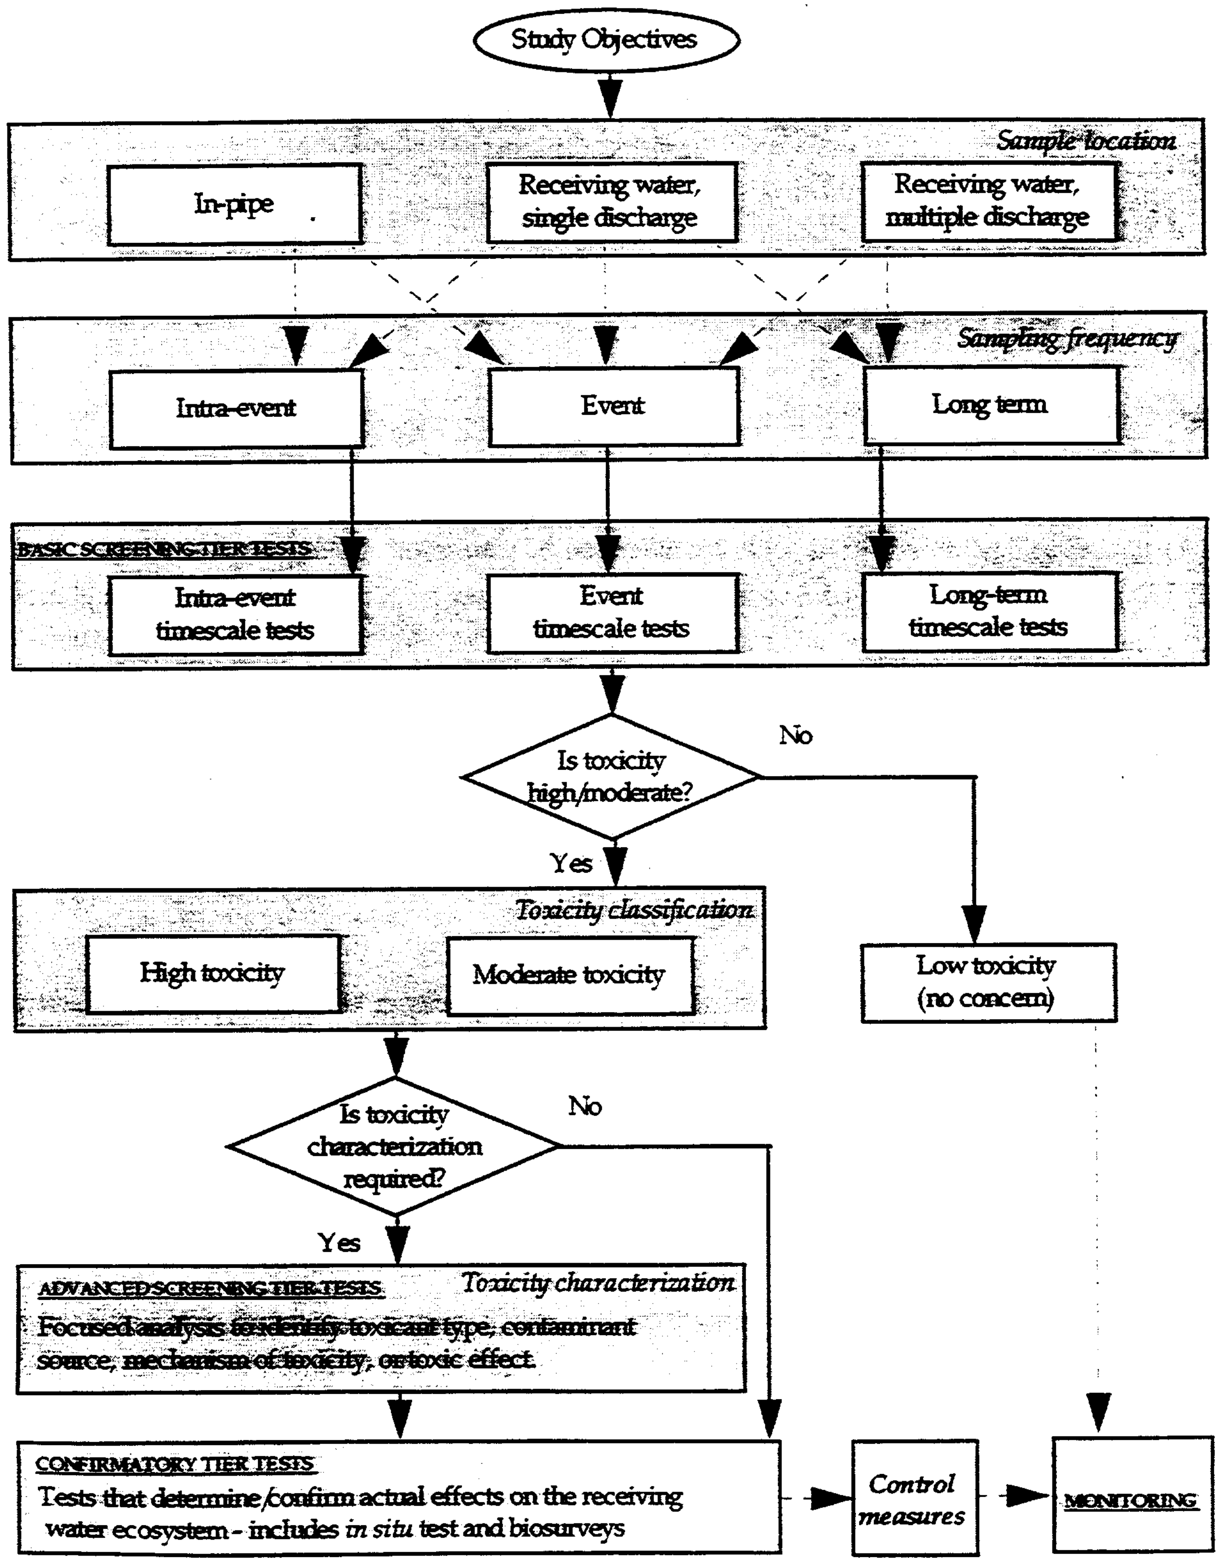
3.1 Introduction

The protocol for the assessment of wet weather discharge effects on receiving systems starts with a design specification and ends with consideration of watershed issues, which are important in defining sampling location and frequency. The development of this design specification is based on general program objectives and refined by study plans that address specific questions related to the objectives. Primary design elements take into account sampling location and sample-collection frequency. Samples collected are then be subjected to an appropriate time-scale toxicity analysis that follows a tier testing approach. Tier testing is initiated with a comprehensive set of screening procedures that may involve both basic and advanced screening tests. A schematic illustration of the protocol is given in Figure 3-1, and Chapters 7.0 and 8.0 of this report provide more detailed information about applying the protocol.

Basic screening tests establish the presence or absence of toxicity in wet weather event discharges and allow a classification by degree of toxicity. Advanced screening tests can then be used to identify sources, characterize event toxicity to assist in defining what we will term an event toxic unit, and define effect characteristics to guide both short- and long-term assessments of receiving water impact. Based on the results of basic and advanced screening tests, analysis might continue to a confirmatory tier that determines or confirms actual effects in the receiving water ecosystems.

Further analysis might focus on a long-term monitoring program to detect any low-level or cumulative effects on the receiving water ecosystem. Monitoring can confirm that there are no such effects after an initial identification of low stormwater toxicity or after implementing control measures to reduce stormwater toxicity, such as a detention facility. Time-scale toxicity testing can be combined with chemical analyses, habitat analysis, and other assessment program elements, and the results used in an integrated assessment that will meet a range of study objectives.

Figure 3-1. Schematic Overview of Time-Scale Toxicity Test Application Protocol



3.2 Sampling Location

The first stage of assessing wet weather discharge effects is the selection of sampling location(s). Applying a time-scale context when locating sampling sites recognizes that different locations might be subject to both different concentration profiles in a storm event and different event durations. The differences in location also reflect the influence of hydrologic change on channels and stability and the level of chemical complexity that occurs in samples. Samples from sewer networks might contain run-off from one or a few significant sources. Samples from receiving systems might reflect a few sources in headwaters locations or multiple significant sources in downstream locations. Furthermore, the sampling location within a watershed helps determine which biological or ecological tests are needed to address differences in flora and fauna along ecosystem gradients.

When selecting sampling locations for a wet weather discharge assessment, it should be recognized that while location might dictate aspects of sampling frequency and biological or ecological test system validity, sampling and testing results determine sampling locations. The appropriate sampling location depends on the objective of the study and wet weather event characteristics. Three objective-related sampling location categories are proposed: (1) in-pipe; (2) receiving system-single discharge; (3) receiving system- multiple discharges and outlined in Table 3-1.

Although the time-scale approach defines the general location of sites, other aspects need to be considered. These include safety of access and, where in situ tests are used, selection of sites with similar depth, flow, and substratum characteristics.

For receiving system sampling, an appropriate reference site must be selected. Depending on the system and the study objectives, this may be either an upstream, non-impacted site or a site on another, non-impacted watercourse.

3.3 Sampling Frequency

The second stage of time-scale analysis is the selection of sampling frequency. Applying a time-scale context in a wet weather discharge assessment program requires that sampling frequency be set to meet multiple requirements. These requirements could include: identification of the effect on receiving systems from wet weather events; providing support for test system selection; allowance for the actual measurement of event effect; and support for the analysis and interpretation of event consequence.

Table 3-1. Defining Sampling Location	
In-Pipe	If the objective of a stormwater study is analysis of a defined drainage area or assessment of performance of control facilities, an in-pipe sampling location may be specified to enable toxicity testing of stormwater at the point of discharge. Where it is not possible to sample in-pipe, a near-discharge location will ensure minimum mixing with receiving waters. The dilution and dispersion available in the receiving water for toxic in-pipe samples must be considered before any conclusions can be drawn on the potential environmental impact. In-pipe sampling at points in a sewer system is particularly valuable in source identification.
Receiving System - Single Discharge	If the objective of a study is the assessment of a single discharge, sites can be selected to provide a reference sample and a well-mixed discharge/receiving system sample that identifies the effect of the discharge as modified by receiving waters (particularly applicable when in situ biological testing is used). In single discharge location selection, sampling location is based on both discharge and receiving water characteristics at the discharge site. Single discharge locations are useful in initial source identification, in defining event-related discharge variability with receiving water variability, and as an initial stage of receiving water impact assessment.
Receiving System - Multiple Discharges	If the objective of a study is: 1) establishing reference conditions for a location in a watershed; 2) the assessment of multiple, or diffuse-source discharge effects at a site or sites; or 3) long-term surveillance of dynamic (wet weather)/static (baseflow) receiving system condition, then location of sampling points will be based on both discharge locations and receiving water characteristics. Multiple discharge sampling locations requires a commitment not only to large spatial scales, but also to extended temporal scales, including multiple year studies.

The appropriate sampling frequency depends on the objective of the study and wet weather event characteristics. In general, with more frequent sample collection it is possible to improve understanding of parameter variability and assist in ascertaining concentration/duration values for contaminants to support development of exposure bounds for biological test system selection and use.

Three sampling-frequency categories are proposed for the initial development and implementation of a wet weather discharge assessment program: (1) intra-event; (2) event; and (3) long-term. Each category provides information appropriate to the types of objectives addressed by the relevant time scale. Details of these are found in the Table 3-2.

Table 3-2. Defining Sampling Frequency	
Intra-event	Time-based or flow-based sampling to characterize variability within a single storm event. Multiple, discrete samples are collected to track toxicity through the event's duration. *Sample collection procedures include collection of multiple samples during the event using either fixed time interval sampling or flow proportional sampling. Primary dependence is on discrete, grab samples, but event length can dictate that consecutive time-specified composite samples be collected during an event. Continuous logging of water quality change facilitates identification of intra-event variability and supports time or water quality change-based sample intervals.*
Event	Event sampling is designed to characterize average conditions or average change produced by an event. Samples will be time-based or flow-based composites, giving an integrative sample representing the whole event. *Sample collection procedures include single or multiple composite samples collected to represent average conditions over a given time period, typically approximating storm duration. For short duration, Category #1, events, typical of convective storms, a single composite may be used. For longer duration, Category #2 events, multiple composite samples may be collected over several days. Event sampling for a BMP may also use single or multiple composite samples collected over a time appropriate to the design "fill/drain" cycle produced by a single event. Continuous monitoring of water quality change provides a basis for actual identification of event duration and time or water quality change-based sampling for accurate event composite samples.*
Multiple-Event	Long-term sampling requires consideration of multiple events. Sample collection procedures should provide sufficient information to address natural system variability, identify single event effects with certainty, and support separation of event effects from other influences on receiving system quality. *Sample collection procedures depend on study objectives and system complexity. Discrete sampling may be used but dependence is primarily on periodic composite sampling and the use of in situ monitoring techniques (which do not require sample collection). Continuous monitoring of water quality change provides a basis for development of comparisons between storm events and providing a long-term record for evaluating intra-event, and event sampling efforts.*

3.4 Biological Tier Testing

3.4.1 Test Tiers

Biological/ecological testing operates at different tiers of complexity ranging from simple screening tests to more complex definitive and confirmatory procedures. Biological testing involves both laboratory toxicity analysis and field-based organism, population, and/or community/ecosystem analyses. The project team proposed a two-tiered assessment strategy for wet weather event discharges (Table 3-3).

Table 3-3. Defining Biological Testing Tiers

Screening	Using simple, cost-effective tests to make preliminary decisions about hazard or risk	
	Basic:	Initial tests or analyses intended to illuminate the problem and supply sufficient data to identify toxicity and classify samples to be of no, moderate, or high toxicity.
	Advanced:	Advanced screening tests lead to a more focused analysis and might be selected to identify sources of contamination, better characterize individual storm events for later comparison or classification, or identify toxic effect that can be used to direct confirmatory testing toward appropriate targets.
Confirmatory	Analysis based on long-term testing procedures that involve field-based environmental/ecological analyses (such as in situ tests and biosurveys) to confirm effects predicted by earlier test tiers. Confirmatory testing integrates with monitoring efforts that are designed to identify unanticipated long-term or low-level effects.	

In this tier testing scheme, the basic screening tier uses accepted screening or range-finding procedures, modified to provide a measure of undiluted sample effects and to consider time scale of exposure issues. The advanced tier screening tests and initial confirmatory analyses take the place of the predictive tier commonly used in hazard evaluation schemes. Therefore, screening tests might be followed by confirmatory tier analyses based on study objectives or lead directly to establishing long-term monitoring programs.

R0025453

3.4.2 Test Time Scales

In the time-scale approach to wet weather event assessment, the time of exposure for the selected test system is based upon study objectives and site-specific characteristics. For each testing tier, tests must meet multiple criteria, including the appropriate time-scale requirements (Table 3-4); the appropriate exposure duration (time scale) is defined by the interval between discrete samples or the characteristics of the composite samples.

Once the appropriate biological testing tier(s) and testing time scale(s) have been identified, the most appropriate test systems must be selected. As the range of possible test systems increases, the task of selecting the most appropriate test for a given purpose becomes more difficult. Moreover, it is unlikely that a single test will fully meet all the criteria required for a particular tier application. Chapter 4.0 presents a simple and objective methodology for test selection that builds on an earlier project report (Herricks, Milne, and Johnson, 1994). Test selection is based on how test systems meet the required time-scale criteria. In all cases, a battery of tests (that is, two or more) should be used for basic and advanced screening for the different time scales.

3.4.3 Classification of Toxicity

The classification of time-scale toxicity is developed for intra-event and event time scales using basic screening test data; both sample specific toxic response and the number of samples exhibiting toxic response during an storm event/sample collection campaign must be considered. For either discrete or composite samples that are collected during a storm, the concentrations of pollutants present varyies through the hydrograph, possibly by several orders of magnitude. The highest concentrations of most pollutants are associated with the first flush. As rainfall continues, the concentrations of toxicants decline with dilution, although actual concentrations depend on source location, loading, and concentration time (time of travel). If concentrations of toxicants are sufficient to elicit a response in test systems, it can be used to classify the toxicity of an event. Basic screening test systems with pre-storm samples and samples from reference sites have shown that a variable, but low, level of toxic response (less than 20% effect) is common for the test systems used. Based on the expected "background" effect, a toxicity classification has been developed:

- **No toxicity**: Responses measured in undiluted samples do not exceed 20%
- **Moderate toxicity**: Responses measured in undiluted samples are between 20 and 70%
- **High toxicity**: Responses measured in undiluted samples are greater than 70%.

Table 3-4. Defining Biological Testing Time Scale

Time scale	Biological testing tier		
	Basic	Advanced	Confirmatory
Intra-event	Laboratory tests with exposure durations of minutes to a few hours measuring responses in undiluted samples.	Laboratory tests with exposure durations of minutes to a few hours measuring responses in a concentration series to derive $EC(LC)_{50}$ value, which may simply establish toxicity or be used to identify causes or sources of toxicity.	Laboratory tests with exposure durations of minutes to a few hours measuring responses in undiluted samples or concentration series. Tests may simply establish toxicity or used to confirm the causes or sources of toxicity.
Event	Laboratory tests with exposure duration appropriate to the event timescale are used. Test durations of 24 h or less are appropriate for Category #1 events. Because test durations of greater than 24 hours are appropriate for Category #2 it is often convenient to develop exposure regimes in increments of 24 h. Response is measured in undiluted samples.	Laboratory tests with exposure duration appropriate to the event timescale are used. Test duration of of 24 h or less are appropriate for Category #1 events. Because test durations of greater than 24 hours are appropriate for Category #2, it is often convenient to develop exposure regimes in increments of 24 h. Response is measured in a concentration series to derive $EC(LC)_{50}$ value. Tests may simply establish toxicity or be used to identify causes or sources of toxicity.	Laboratory tests with exposure duration appropriate to the event timescale are used. Confirmatory testing often employs exposures of 24-96 h to provide correlative measures to common WET protocols, particularly when testing is used to establish toxicity or to confirm the causes or sources of toxicity. Chronic laboratory tests to investigate the impact of loading on toxicity or in situ deployments to verify impact in the receiving water may also be used.
Long-Term	Laboratory tests used in intra-event or event analysis of undiluted samples. Single events are integrated to provide a picture of multiple event toxicity.	In situ deployments to verify impact in the receiving water.	Biosurveys

For samples taken in receiving systems or end-of-pipe locations where pipe flows might be diluted by the receiving system, sample toxicity is determined by comparing responses for the storm event samples with those measured during pre-storm conditions. A minimum of two pre-storm samples should be collected, although the number of pre-storm samples collected should reflect the variability in receiving system quality. The classification of the toxicity of an event reflects the subtraction of pre-storm values from the maximum toxic response observed during the storm where multiple samples are tested or the response of the composite where a single sample is tested. For in-pipe analysis where no dilution with receiving waters occurs, and a low or absent dry weather flow precludes pre-storm sampling, toxic response is used directly in the classification scheme.

The classification of toxicity is also based on the consistency in toxic response observed in different test systems exposed to the same sample. Different test systems are expected to show different sensitivities to pollutants and, given the complex nature of wet weather discharges, it is not surprising that different test systems exhibit different toxic responses. Therefore, toxic response can be further classified based on the number of test systems showing a toxic response. If only one test system responds above a no toxicity threshold, the toxicity is considered specific. The toxic response can be considered moderate or high (according to the level of response), giving rise to a specific/ moderate or specific/high classification. If two or more test systems show a toxic response, the toxicity is considered general. A moderate general toxicity occurs when there is a consistent indication of moderate toxicity in samples, particularly if there is a high degree of variability in the percent effect among test systems. A high general toxicity occurs in samples when multiple test systems have high toxicity.

Further classifications of samples taken during storm events (intra-event) are based on the frequency and position of toxic response observed during a storm event. If toxic response is observed in few samples (< 20%), with no pattern, the toxicity is considered infrequent. If toxicity is observed in 20% to 50% of samples, the toxicity is considered intermediate frequency. If toxicity is observed in the majority of samples (>50 %), the toxicity is considered consistent. Sample toxicity can be grouped, and response groups might be related to position in the hydrograph (e.g., first flush or hydrograph peak).

On this basis, a sample would be characterized as having no toxicity if a < 20 % response is indicated by all test systems in the battery of tests selected for analysis. A sample would be classified as specific moderate toxicity if a 20% to 70% response was measured for only one test system and a general moderate toxicity if a 20% to 70% response was observed for two or more test systems. A sample would be classified with either specific or general high toxicity dependent on the number of test systems with a response of greater than 70%. Sample toxic response would be used to characterize storm event toxicity, so that the observation of toxic response in only one or two samples at a wide interval would result in a storm event being classified as infrequent and specific/general, and moderate/high toxicity depending on the nature of the responses in the test systems. This system also allows classification of toxicity based on time of occurrence during the hydrograph, such as moderate, first flush. Table 3-5 summarizes the scheme proposed for classifying wet weather event toxicity. The nature of the classification depends on the sampling frequency adopted, and for event toxicity where a single composite sample is tested, the issues of number of samples showing toxicity and their position in the hydrograph are irrelevant.

For each location, there is usually a series of classifications that are event-specific. Since the concern is with the toxic potential of the discharge, the actual classification (and the need for further action, such as toxicity characterization) should be based on the worst case situation rather than an average of the series of values.

It is important to recognize that for in-pipe analysis, the available dilution and dispersion in the receiving water must be considered before any conclusions are reached on the potential environmental impact of storm events.

3.5 Protocol Integration in Watershed Analysis

3.5.1 Introduction

Application of the time-scale toxicity assessment protocol is governed by the physical, chemical, and biological processes in the watershed. These processes operate over different spatial and temporal scales and might be specific to a location in the watershed (Section 2.6). Watershed-focused management is needed to meet ecosystem integrity goals. With this recognition, the U. S. Environmental Protection Agency (US EPA) has developed a Watershed Protection Approach (WPA). The WPA helps to create water quality programs that:

- Feature watersheds or basins as the basic management units;
- Target priority watersheds for management action;
- Address all significant point and nonpoint sources; and
- Address all significant pollutants or stressors.

Table 3-5. Scheme Proposed for Classifying Wet Weather Event Toxicity

Toxicity Classification	Response in Tests (%)	Test Systems Responding	% of Samples Showing Toxicity and Position
Intra-Event			
No toxicity	<20	2 or more	-
Moderate/specific/infrequent/first flush	20 - 70	1	<20, first flush

Event			
No toxicity	<20	2 or more	-
Moderate/specific	20- 70	1	-
Moderate/general	"	2 or more	-
High/specific	> 70	1	-
High/general	"	2 or more	-

- Set clear and achievable goals;
- Involve stakeholders during all stages of the program;
- Use the resources and expertise of multiple agencies;
- Are not limited by any single agency's responsibilities;
- Consider public health issues; and
- Consider all aspects of ecosystem health including habitat.

WPA projects also feature a strong monitoring and evaluation component, which is intended to provide data necessary for management decision making.

The Protocol for Time-Scale Toxicity Assessment should be considered an essential element of the strong monitoring and evaluation component of US EPA's WPA. A starting point for the incorporation of time-scale issues in watershed management is the Protocol's recognition of the importance of watershed location on sampling frequency and influence of land use related contaminants sources on the selection of tests in a test battery. The Protocol guides selection of sampling techniques and test systems that consider relationships among spatial scale, duration of effect, location, and sources of contaminants. The Protocol recognizes that measuring the effect/impact of wet weather discharges/flows on receiving system biota and associated measures of ecological integrity begins with an understanding of both contaminant concentration and duration of exposure.

3.5.2 Connecting to the WERF Watershed Management Strategy

The Water Environment Research Foundation (WERF) has recognized the importance of a watershed management framework as part of the search to identify alternative ways to use existing management and technical abilities to solve environmental problems. This watershed management framework provides a structure within which the time-scale toxicity test application protocol and wet weather flow/discharge management strategies can operate.

The WERF watershed management strategy is similar to the WPA. For example, Clements et al., 1996, identify nine elements for a watershed management framework: (1) geographic management units; (2) stakeholder involvement; (3) a basin management cycle; (4) strategic monitoring; (5) basin assessment; (6) a priority ranking and resource targeting system; (7) capability for developing management strategies; (8) management plan documentation; and (9) implementation. A critical element of this framework is identification and coordination of stakeholder roles in six core activities: strategic monitoring, basin assessment, assigning priorities and targeting, developing management strategies, management plan documentation, and implementation. The Protocol for Time-Scale Toxicity Assessment is designed to be an integral part of the WERF watershed management strategy. The Protocol assists in developing an accurate, high quality assessment of wet weather flow/discharge effects on receiving systems. Because time-scale effects differ from the effects of continuous flow, the time-scale toxicity test application protocol is a critical element of strategic monitoring and basin monitoring. Furthermore, time-scale toxicity analysis supports ranking, targeting, developing, and implementing management strategies. Therefore, the issues raised in Section 5.4.1 should be considered in the WERF watershed framework dealing with wet weather flows.

CHAPTER 4.0

BIOLOGICAL TEST SYSTEMS FOR TIME-SCALE TOXICITY ANALYSIS

4.1 Introduction

Reviewing available biological test systems and assessing their suitability for the assessment of wet weather event impacts was one of the early project activities. A detailed review was published in an interim report, *Selecting Biological Test Systems to Assess Time-Scale Toxicity* (Herricks, Milne, and Johnson, 1994). This chapter summarizes the findings on test system availability and suitability for wet weather event assessment and provides updated information on tests that have recently become available. It then presents a methodology for objectively selecting test systems for a particular application. Finally, an example is given for applying this system in the selection of a test battery.

4.2 Biological Test Systems with Potential for Wet Weather Event Assessment

Virtually any living system can be used in a bioassay (Schaeffer and Herricks, 1993). Unfortunately, not all living systems respond in the same manner to the same contaminant, nor can the response from a single organism necessarily be extrapolated to other members of the same species, other communities of organisms, or to the ecosystem (Herricks, 1993). For this reason, a major requirement for test system selection is the identification of the system or systems that both respond to a contaminant of interest and provide a basis for extrapolating effects to determine the risk of environmental damage.

The test systems available include any biochemical, physiological, or behavioral response that can be measured experimentally, or a range of structural and functional population, community, or ecosystem parameters that can be monitored for change. Test systems, as well as monitoring or assessment procedures, can operate at any level of the biological/ecological hierarchy and can be applied either simultaneously or sequentially in test batteries. To identify an appropriate test system, it is necessary to select procedures that measure a response that can be related to a contaminant or environmental condition of interest.

Test systems can be categorized according to the level of the biological/ecological hierarchy associated with the analysis or according to specific physical or chemical conditions of the receiving system. The biological/ecological hierarchy runs from the sub-cellular, enzyme level to the entire ecosystem (Figure 4-1). Test systems are available across most of the spectrum, from assays of biochemical function through assessments of whole communities. In practice, test systems generally stop short of the ecosystem level for practical reasons.

Figure 4-1. Biological and Ecological Organization Hierarchies

BIOLOGICAL HIERARCHY

Enzyme → Cell → Organ → Organ-System → Organism

ECOLOGICAL HIERARCHY

Organism → Species/Population → Community → Ecosystem

As a general rule, tests at the lower end of the biological/ecological hierarchy are more easily implemented under controlled conditions, but interpretation, in terms of an ecological context, is challenging. In contrast, tests at the top end of the hierarchy are more difficult to apply in a controlled manner, but the ecological relevance of the test endpoint is generally much clearer.

Table 4-1 lists the range of available test systems identified as potentially applicable for wet weather event assessment, categorized according to the biological/ecological hierarchy.

Table 4-1. Test Systems for Wet Weather Event Assessment

Biochemical Responses
- *Enzyme activity*
  - General metabolic enzyme activity
  - Mixed Function Oxidase (MFO)
  - Cholinesterase activity
- *Stress Proteins*
  - Heat shock proteins (HSP)
  - Specific stress proteins

Whole Organism Bioassays
- Lethality
- Bioaccumulation

Behaviorally-Based Sublethal Tests
- Preference avoidance
- Shell-valve closure in bivalves
- Locomotion in invertebrates

Physiologically Based Sublethal Tests
- *Basic physiological functions*
  - Heart rate
  - Respiration and ventilation rate
  - Muscular movement
  - Bioluminescence
- *Systems Integrating Physiological Function*
  - Feeding rate
  - Scope for growth
  - Growth
  - Whole body condition indices
  - Reproduction

Population and Community Responses
- Colonization
- Artificial streams
- Enclosures
- Biosurveys

4.3 Test Selection Criteria

To be deemed suitable for application in any context, biological tests must meet a number of different criteria, relating, for example, to response range, precision, cost, and ecological relevance. For application in the context of wet weather event assessment, additional criteria relating to time scales become important. The time-scale analysis concept, introduced in Chapter 2.0, is based upon the fact that wet weather event impacts have different time scales of effect and origin. This leads to the recognition of the three time scales (intra-event, event, and long-term) used as a starting point for applying wet weather assessment protocols.

Several key test-selection criteria, based on both wet weather event assessment and general test requirements, were developed and evolved over the course of the project. These categories indicate the broad issues that need to be considered when selecting tests for wet weather event assessment. Within each category, the individual criteria indicate the specific test requirements that must be considered. The test selection criteria are:

- *Previous application to wet weather events*

  This criterion relates to the number of studies in which the test has been successfully used for assessing wet weather events. Previous successful application will always be an important first consideration, not only because it indicates that the procedure is appropriate, but because it provides valuable information on test application methodologies specific to wet weather assessment requirements;

- *Time-scale issues*

  <u>Response induction time</u>—The response induction time relates to the period of exposure required for an effect to be observed. The rainfall periods driving storm events are frequently of less than 4 hours' duration, producing transient changes in contaminant concentrations in receiving waters that might occur over periods of minutes, with some water quality changes lasting for a day or more. Therefore, intra-event tests need to have exposure regimes that reflect the expected changes in receiving waters. Tests assessing event and long-term time scales will require increasing exposure periods to induce effects.

  <u>Endpoint measurement time</u>—This criterion relates to the time between the event and the test results and is a composite of response induction time and response measurement time.

Tracking capability—Tracking capability relates to the ability of the test system to track an effect through the storm hydrograph. Since wet weather events produce a complex set of exposure concentration, duration, and frequency conditions, an ideal test system for wet weather event assessment must have both rapid response characteristics and some level of independence from exposure history to provide an accurate measure of constantly changing conditions.

- *Measurement issues*

Precision - replicability—Test method replicability is the extent of variability between replicates within the test or replicate determinations on a sample.

Precision - repeatability—Test method repeatability refers to test variability within a laboratory when a series of samples are analyzed by the same operator with the same equipment.

Precision - reproducibility—Test method reproducibility is the extent of the variability in the test between laboratories when the same samples are analyzed.

Sensitivity—The threshold level of response (high sensitivity/low threshold of response; low sensitivity/high threshold of response). Sensitivity has been judged by assessing the minimum concentration of a particular contaminant that will elicit a standardized response (for example EC_{50}/LC_{50}) against a maximum concentration of that contaminant reported in wet weather events (Horner et al., 1994). Increasing sensitivity is shown as the sensitivity index decreases.

Contaminant specificity—The capacity of a measure to respond to specific contaminants typically associated with wet weather events. A method is considered to respond to a particular contaminant if the sensitivity index is less than 1.

Availability of standard method—This criterion relates to the existence of standard methods, standard operating procedures, test guidelines, or published methodologies that, at a minimum, have been subjected to peer review.

Response certainty—Response certainty is related to tracking capability but addresses the degree of certainty that a test response is measured. For example, with an irreversible endpoint, such as death, it is certain that if a response occurs, it will be measured. In contrast, growth could be inhibited by a wet weather event, but the response could be masked if the endpoint is measured some time after the event and the organisms can compensate.

♦ *Ecological relevance*

Ecological relevance of endpoint—This criterion relates to whether the endpoint response measured by the test system can be related to likely effects on populations and communities through direct (or indirect) effects on the growth, reproduction, and survival of individuals.

Ecological relevance: in-stream impact—This criterion assesses whether a relationship can be demonstrated between test system response and measured in-stream impacts.

♦ *Cost*

Cost of implementing the test—Implementation costs cover all the material and time costs associated with equipping and training for test application.

Unit cost of conducting test—The unit cost of a test covers the cost of consumables and the time required for conducting the test.

4.4 Evaluation of Test System Suitability for Wet Weather Event Assessment

The relative importance of each of test selection criteria categories varies according to the time scale within which the test is to be applied. For example, where the time scale of interest is intra-event, analysis of effect over very short time scales is required, and time-scale selection criteria are of prime importance, whereas ecological relevance is less important. In contrast, for long-term, time-scale application, ecological relevance is very important, while the significance of time-scale issues diminishes. Table 4-2 indicates the level of importance of the selection criteria categories for each of the three time scales identified as forming the basis of wet weather event assessments.

Table 4-2. Level of Importance of Test Selection Criteria for Different Time Scales

Selection criteria category	Time Scale		
	Intra-event	Event	Long-term
Time scale	High	Medium	Low
Measurement	Medium	High	High
Ecological relevance	Low	Low	High
Cost	High	Medium	Medium

Consideration of test systems in relation to the importance of selection criteria categories identified in Table 4-2 allows an initial evaluation of the suitability of different test systems to application under the three different time scales. Note that this is intended to be a framework to provide a focus for the assessment of test system suitability. Knowledge of how the test systems operate and are applied are also clearly important considerations. Additionally, overriding considerations, for example cost, might be major forces driving test selection.

Table 4-2 has been used to make a preliminary assessment of the test systems identified earlier as likely to be suitable for wet weather event assessment over different time scales. For example, the evaluation of bacterial bioluminescence (e.g., the Microtox test) against the selection criteria categories for intra-event time-scale assessment is shown in Table 4-3.

Table 4-3. Evaluation of Bacterial Bioluminescence According to Selection Criteria

time scale:	good match	(very low response induction, observation and measurement times, high tracking capability etc.)
measurement:	good match	(high precision and sensitivity)
ecological relevance:	good match	(ecological relevance low but importance of this category is low)
cost:	medium match	(unit cost low but implementation cost high)

Therefore, bacterial bioluminescence appears to be a good candidate for intra-event time-scale application. In contrast, traditional lethality tests used in whole effluent testing, with an induction time of 24 to 48 hours, are inappropriate for this time scale, but could be appropriate for an event time-scale application depending on site specific event time scales. Table 4-4 shows the outcome of an assessment with this approach of the suitability of the range of test systems identified earlier for application under each of the time scales.

The measurement of behavioral responses offers considerable potential for assessing the impact of wet weather events. Techniques that could be applied include those measuring preference-avoidance reactions, abnormal locomotor and reproductive behavior, and altered predator-prey interactions (measured both directly by observation and indirectly through population analysis). However, only automated systems are applicable, since it is not feasible to use systems relying on direct observation because of the unpredictable nature of the onset of wet weather events.

Table 4-4. Preliminary Assessment of Test Suitability for Time-Scale Application

Time Scale	Suitable Test Systems	Unsuitable Test Systems
<u>Intra-event</u> (minutes to hours)	general metabolic enzymes cholinesterase preference/avoidance shell valve closure locomotion in invertebrates heart rate respiration/ventilation rate muscular movement bacterial bioluminescence (acute)	mixed function oxidase cholinesterase heat shock proteins specific stress proteins lethality (lab/field) bioaccumulation feeding rate scope for growth whole body condition index colonization artificial streams enclosures biosurveys
<u>Event</u> (hours to days)	heat shock proteins specific stress proteins lethality (lab/field) preference/avoidance shell valve closure locomotion in invertebrates heart rate respiration/ventilation rate feeding rate scope for growth whole body condition index bacterial bioluminescence (chronic)	general metabolic enzymes cholinesterase activity bioaccumulation muscular movement colonization artificial streams enclosures biosurveys
<u>Long-term</u> (weeks to months)	heat shock proteins lethality (field) bioaccumulation shell valve closure feeding rate scope for growth whole body condition index colonization artificial streams enclosures biosurveys	general metabolic enzymes mixed function oxidase cholinesterase activity specific stress proteins preference/avoidance locomotion in invertebrates heart rate respiration/ventilation rate muscular movement bioluminescence

In the assessment of wet weather events, avoidance responses would seem to offer the greatest potential as test systems. These responses might represent the ultimate early-warning systems of pollutant impact as a result of the action of the substance on the organism's sensory systems. Consequently marked responses might be observed before toxicant uptake and accumulation can result in biochemical and/or physiological effects. However, these systems require a considerable body of background data from which subtle behavioral changes can be discerned.

Preference-avoidance responses of invertebrates and fish species to aquatic pollutants, whether present in the water column or the sediments, have been extensively studied (for reviews, see Heath, 1987). This research has also resulted in the development of a number of automated biomonitoring systems using avoidance responses of aquatic organisms to pollutants.

Positive rheotaxis, whereby fish swim against a current, has been used in a number of automated continuous biomonitors (Baldwin, 1990). Toxicant exposure can lead to a loss of positive rheotaxis and the effects are detected by changes in the position of fish relative to light beams across the test chamber or by the fish touching a grid at the rear of the chamber (for review see Heath, 1987, Baldwin, 1990). For invertebrates, such as *Daphnia*, the effects on phototaxis is used as the response in the system (Knie, 1982; Hendriks and Stouten, 1993). Toxicant-induced effects can result in impaired mobility and an inability to respond to changing physical conditions produced by flow changes.

An avoidance behavior response based on shell-valve activity of freshwater and marine mussels has been developed by Delta Consults in the Netherlands (Kramer, Jenner, and Dezwart., 1989). In the test system, toxicant-induced effects on the valve opening/closing pattern are electronically measured and analyzed.

Automated continuous monitors based on physiological parameters, such as heart rate in invertebrates (Morgan et al., 1987), fish ventilation rate (Baldwin, 1990), and muscular movement (Morgan et al., 1987) have been developed.

4.5 Detailed Test System Selection Methodology

4.5.1 Introduction

The approach developed in Section 4.4 provides a general framework for assessing the suitability of a given test to application within each of the three wet weather assessment time scales. In some cases, it is desirable to undertake a more detailed and objective test selection process to choose the most appropriate of those tests identified as suitable for a given time-scale application. To this end, a detailed, objective test selection methodology has been developed, based on qualitative and semi-quantitative assessments of test performance against the individual test selection criteria.

In outline, the test selection procedure involves assessing tests against the criteria identified in Section 4.3, then assigning scores for each criterion and summing the scores to obtain a total score for each test. Since the procedure has guidelines for assigning scores, the tests can be compared in an objective manner to identify those most suited to the required role. Weighting factors have also been developed to reflect (a) the perceived importance of each criterion for assessing wet weather events and (b) the requirements of each of the two tiers of testing.

4.5.2 Score Bandings for Test Selection Criteria

For each of the test selection criteria, five qualitative or semi-quantitative score bands were developed, reflecting progressively better performance of the actual test characteristic against the optimum for the criterion. The bands were allocated scores from zero (worst) to four (best).

Optimum test characteristics vary slightly, depending on the time scale that is of interest. Consequently, the score bandings differ for some of the selection criteria for the different test application time scales (intra-event, event, long-term). In a few cases, criteria are not relevant or not applicable to one or more time scales; in others, different values in the score bandings reflect the differing requirements. The score bandings for each time scale are presented in Tables 4-5 to 4-7.

4.5.3 Weightings

The final component of the test system selection methodology is different sets of weightings for the screening or confirmatory tiers. The weightings follow the rationale developed in Section 4.4 and illustrated in Table 4-2 that for a given time scale, different categories of test selection criteria have different levels of importance. Here, this theme has been developed further to produce individual weightings for each of the test selection criteria. Separate sets of weightings were developed for different testing tiers, to reflect the differing test requirements. For example, ecological relevance is more important for a confirmatory test than it is for a screening test.

Table 4-5. Score Bandings for Intra-Event Time-Scale Test Selection Criteria

Criterion	Score					Notes
	0	1	2	3	4	
Previous application to wet weather events	none	1 study	>1 study	10 studies	25 studies	
Response induction time	>4 hours	≤4 hours	≤1 hour	≤15 min	≤5 min	
Endpoint measurement time	>10 days	≤10 days	≤5 days	≤2 days	≤1 day	working days
Tracking capability	irreversible response	non real time on/off	non real- time tracking	real-time on/off	real time tracking	
Ecological relevance of endpoint	relevance unknown	response correlated with individual response	individual response, relevance unknown	individual response related to population/ community fitness	population/ community response	Individual response relates to growth, reproduction and lethal effects in test species
Ecological relevance - in-stream impact	no relationship	-	-relationship established		direct measure of instream impact	
Precision - replicability	>40%	≤40%	≤30%	≤20%	≤10%	coefficient of variation
Precision - repeatability	>100%	≤100%	≤60%	≤30%	≤10%	coefficient of variation
Precision - reproducibility	>100%	≤100%	≤60%	≤30%	≤10%	coefficient of variation
Sensitivity	>1.0	≤1.0	≤0.5	≤0.1	≤0.01	Standardized test response, max. ww event concentration.
Contaminant specificity	0	1	2-4	5-7	8-9	number of contaminant types test responds to at defined sensitivity
Standard method available	none	no SOP but documented method	no SOP but preferred method	SOP, non-ring tested	Ring-tested SOP available	
Response certainty	completely and rapidly reversible, no record	reversal of response rapid in relation to test duration, no record	reversal of response slow in relation to test duration, no record	irreversible response, no record	real time or pseudo-real time record	'record' refers to capture of data during a storm. Laboratory test on water samples collected through a storm would score 4.
Cost of implementing test	>$20000	≤$20000	≤$10000	≤$5000	≤$2000	
Unit cost of conducting test	>$1000	≤$1000	≤$500	≤$250	≤$100	

Table 4-6. Score Bandings for Event Time-Scale Test Selection Criteria

Criterion	Score					Notes

R0025473

Weightings have been developed for intra-event time-scale tests only, and these are shown in Table 4-8. This time scale of assessment is where time scale of test response is most critical and where test requirements are consistent and independent of study objectives and site-specific factors. For event and long-term time scales of assessment, study objectives, site, and watershed-specific factors become more important in determining the relative importance of test selection criteria. For example, site-specific factors that include best management practice (BMP) presence, issues of concentration time, or hydrograph characteristics determine which time span is appropriate for event analysis. Watershed-specific factors require consideration of both spatial and temporal scale issues, often requiring multiple locations and multiple or sequenced sampling to provide useful long-term assessment results. The weightings are applied by multiplying a test's score for each of the criteria by the weighting factors appropriate for the tier of interest to give a weighted score. The weighted scores are then summed to give a total score that can be compared with that for other tests.

Table 4-8. Weighting Factors for Intra-Event Test Selection Criteria

Criterion	Weighting factor		
	Basic screening tests	Advanced screening tests	Confirmatory tests
Previous application to wet weather events	3	3	3
Response induction time	5	5	5
Endpoint measurement time	4	3	1
Tracking capability	5	3	3
Ecological relevance of endpoint	1	3	5
Ecological relevance - in-stream impact	1	3	5
Precision-replicability	3	5	5
Precision – repeatability	3	4	5
Precision – reproducibility	3	3	4
Sensitivity	4	5	5
Contaminant specificity	4	4	4
Standard method available	2	4	4
Response certainty	2	4	5
Cost of implementing test	5	3	3
Unit cost of conducting test	5	3	3

4.6 Example Application of Test System Selection Methodology

The test system methodology was applied to a range of tests from the candidate tests listed in Section 4.2 for the intra-event time scale to ascertain which tests were most likely to be suitable for deployment in a test battery. Table 4-9 shows the weighted scores for potential intra-event time-scale basic screening tests.

The assessment of methods which can be applied to a wide range of species has focused on standard WET testing species, such as *Ceriodaphnia dubia*, *Hyalella azteca*, and *Pimephales promelas*, since these species are widely available, and the same screening methods should be applicable across regions. From the data, it was evident that only a limited number of cost-effective techniques had response induction and measurement times matching the time scales of exposure required for intra-event analysis, combined with a high tracking capability. Only general metabolic enzymes (such as the inhibition of β-galactosidase activity used in the inhibitory quotient test) and bacterial bioluminescence met these criteria with both tests having scores of 58% and higher.

The behavioral assays (such as preference/avoidance, shell valve closure, and locomotion in invertebrates) and physiological responses (such as heart and respiration/ventilation rates and muscular movement) can provide rapid responses, but the systems cab be affected by physico-chemical changes associated with wet weather events (such as changes in temperature, conductivity or suspended solids) rather than toxicity. Changes in dissolved oxygen, which might be of significance in terms of receiving system impact, can also elicit responses in these tests.

Behaviorally-based automatic monitoring systems, such as those using locomotion in daphnids (Knie, 1982) and fish (Baldwin, 1990) and shell-valve closure in mussels can provide continuous data in real or pseudo real time. The methodology involved in the automated monitors is sometimes complex, and the capital investment required to purchase these monitors is generally high. Furthermore, the relationships between the test endpoint and ecologically relevant parameters is usually uncertain.

The use of clams or mussels is possible with commercially available products (e.g., Mussel Monitor), and these systems have proven reliable and robust. Fish monitors require considerable time for operation, covering fish husbandry, calibration, and maintenance. Nonetheless, the need for continuous monitoring at certain locations might justify the high cost.

Table 4-9. Weighted Scores for Candidate Basic Screening Test Systems for Intra-Event Time-Scale Assessment

Criterion	Microtox	*C. dubia* IQ	Locomotion in invertebrates	Valve position in clams or mussels	Ventilation frequency in fish
Previous application to wet w. events	6	0	0	3	3
Response induction time	20	10	20	20	20
Endpoint measurement time	16	16	16	16	16
Tracking capability	10	10	20	20	20
Ecological relevance of test endpoint	1	1	0	0	0
Ecological relevance - instream impact	0	0	0	0	0
Precision-replicability	12	12	N/A	N/A	N/A
Precision – repeatability	9	9	ID	ID	ID
Precision – reproducibility	9	ID	ID	ID	ID
Sensitivity	16	8	ID	16	ID
Contaminant specificity	8	4	ID	8	ID
Standard method available	6	6	4	4	4
Response certainty	8	4	8	8	8
Cost of implementing test	5	15	0	0	0
Unit cost of conducting test	20	20	10	10	5
TOTAL SCORE	146	115	78	105	76
(% of maximum score)	(73%)	(58%)	(39%)	(58%)	(38%)

ID - insufficient data, N/A - not applicable

Although traditional lethality tests of 24 to 48-hour duration are inappropriate for intra-event testing, previous studies (Abel, 1980a, b; Abel, and Gardner 1986; Jarvinen, Tanner, and Kline, 1988) have shown that episodic exposure (that is short-term contaminant exposure (<4 h) followed by exposure to non-contaminated conditions) can cause significant lethality. Therefore, research has been carried out to assess the usefulness of modified lethality-based tests with standard WET test organisms that are appropriate to the intra-event time scale (see Chapter 5.0).

CHAPTER 5.0

SUMMARY INFORMATION ON METHOD DEVELOPMENT AND APPLICATION

5.1 Introduction

In the previous chapter, a series of key test selection criteria, based on both wet-weather event assessment and general testing requirements, was developed. Two of the key criteria were: (1) previous application to wet weather events; and (2) time scale of response criteria. Unfortunately, these criteria were seldom met, particularly for test application at the intra-event . This indicated a need for development of methods for time-scale based approaches to toxicity assessment.

The shortfall in existing test systems reflects the fact that they were largely developed for assessment of continuous exposure to contaminants, through an organism-based approach. As identified earlier, the requirements for assessment of episodic exposure to contaminants, as in wet-weather events, demand a time scale of response approach. Table 5-1 summarizes the key differences between the two approaches required for assessing continuous and episodic events.

As part of this project, research was initiated to develop or modify testing, analysis, and interpretation methods to support time-scale analysis and to fill the shortfall in existing testing or analysis systems. Methods developed are outlined in this chapter and described in detail in Appendix B. This research also involved an extensive field program that incorporated assessments ranging from analysis of samples from storm events to in situ exposure of organisms and watershed focused bioassessments.

Table 5-1. Differences Between Continuous and Episodic Event Assessment Approaches

Characterization	Continuous exposure	Episodic exposure
Exposure regime	• continuous exposure to contaminants (concentration might fluctuate)	• intermittent exposure to contaminants, with fluctuating concentrations during exposure (BMP may even out fluctuation)
Test regime	• organism-based approach • standard tests (WET)	• "time scale of response" approach • modified tests (time scale to match exposure time)
Sampling regime	• site specific • can target toxicity variability • long-term composite samples appropriate	• storm driven • focus on concentration or toxicity peaks • intra-event analysis requires time-sequenced or flow-weighted grab samples (composites for longer events) • event sampling requires time- or flow-weighted composites

5.2 Time-Scale Toxicity

5.2.1 Introduction

As discussed in Chapter 2.0, existing standard methodologies for toxicity testing generally rely on test systems that operate on time scales that are not appropriate for the full range of time scales required for wet-weather event analyses. A major thrust of this project was to evaluate new methods and adapt existing standard methods to the shorter time-scales of relevance to wet-weather intra-event assessment.

Laboratory experiments were conducted to investigate the effect of short (or pulse) exposures to a range of contaminant concentrations. These concentrations provided a wide range of exposures, including some concentrations that are higher than might be expected in wet-weather discharges. These toxicity experiments were not intended to represent the full complexity of wet weather discharges, rather they were designed to assess short exposure effects using contaminants known to occur in stormwater runoff. The exposure method placed test organisms in a test solution for different time periods (up to 240 minutes) and then removed the organisms to clean water for post-exposure observation. These experiments focused on lethal effects but also included sublethal effects, such as reproduction, enzyme inhibition, and growth. Table 5-2 shows a summary of the range of experiments performed. Contaminant concentrations used were multiples of experimentally-developed 24-hour LC_{50} concentrations. Organism responses were compared between species, between contaminants, and between differing stock cultures and laboratory facilities. The research then attempted to connect the results to actual episodic pollution events, through the sampling and analysis of urban stormwater runoff events.

5.2.2 PE-LET_{50}

5.2.2.1 Determination

A new test and metric for the analysis of time-scale toxicity was developed and applied. The proposed Post-Exposure Lethal Exposure Time for 50% of the population (PE-LET_{50}) adapts the LT_{50} (or time to death) test methodology specifically to the analysis of episodic pollution events. The PE-LET_{50} test, like the LT_{50} test, uses the exposure duration as the test variable; however, the PE-LET_{50} test used for stormwater analysis attempts to adjust test exposure duration to more closely match those of the event. Since episodic pollution events are typically brief (on the order of hours to days), and the duration of pollutant transients during the event are much shorter (minutes to hours), the PE-LET_{50} test procedure uses short exposure durations. When short-exposure durations are used, it is also necessary to incorporate post-exposure observation, for it has been found that short exposures to toxicants can delay effects or allow organism recovery (Abel, 1980a, b; Abel and Gardner, 1986; Jarvinen, Tanner, and Kline, 1988).

The proposed PE-LET_{50} test exposes test organisms to a sample of stormwater, similar to the effluent sample used in a whole effluent test. Typically, several grab samples are collected during an event and exposure times in the test adjusted to sample/event characteristics to provide short exposures (on the order of minutes to hours). After the allotted exposure duration, test organisms are removed and placed in clean water and observed during a post-exposure period. The post-exposure period is long enough to observe the ultimate effect of all samples. Data are then analyzed to obtain the exposure duration that produces the median lethal response in the post-exposure period, the PE-LET_{50}. The PE-LET_{50} is the exposure time necessary to produce 50% lethality of the test population at the end of the post-exposure observation period. The PE-LET_{50} is similar to the LT_{50} metric, yet the exposure durations are discrete, short, and response measured at the end of a post-exposure period. The PE-LET_{50} is compared to other common metrics in Table 5-3.

Table 5-2. Summary of Supplemental Time-Scale Toxicity Experiments Performed

Species	Location	Substance	Concentrations (mg/L)	Exposure Durations (min)	Endpoints Measured
H. azteca	UIUC	Cd	0.06, 0.19, 0.4, 0.6, 1.0, 1.9	15, 30, 60, 120, 180, 240	lethality
		Zn	2.0, 6.4, 13.34, 20, 33.3, 64	15, 30, 60, 120, 240	lethality
	UNT	Cd	0.06, 0.19, 0.4, 0.6, 1.9	15, 60, 240	lethality
C. dubia	UIUC	Cd	0.37, 1.18, 2.5, 3.7, 6.0, 11.84	15, 30, 60, 120, 240	lethality, reproduction, enzyme inhibition
		Zn	0.15, 0.4, 1.0, 1.5, 2.5, 4.8	15, 30, 60, 120, 240	lethality
		Phenol	10, 32, 66.7, 100, 167, 320, 500	15, 30, 60, 120, 240	lethality
	UNT	Cd	0.37, 1.18, 2.5, 3.7, 6.0, 11.84	15, 30, 60, 120, 240	lethality
P. promelas	UIUC	Cd	0.4, 1.28, 2.67, 4.0, 6.67, 12.8	15, 30, 60, 120, 240	lethality, growth

UIUC = University of Illinois, Urbana-Champaign, UNT = University of North Texas.

5.2.2.2 Application

A series of experiments was performed with cadmium and zinc to develop the PE-LET_{50}.testing and ansylsis procedures. These tests revealed that following short Cd and Zn exposure, effects increased during the post-exposure period as evidenced by PE-LET_{50} values that decreased asymptotically with increasing post-exposure measurement time. The asymptotic value approached by the PE-LET_{50} is termed the ultimate PE-LET_{50}, or the exposure duration that ultimately produces a 50% lethal effect. As the post-exposure measurement time increased, the measured PE-LET_{50} value more closely approximated to the ultimate value. PE-LET_{50} values stabilized at 24 to 96 h post-exposure. In general, the 48-h PE-LET_{50} closely approximated the ultimate PE-LET_{50} value.

Table 5-3. Comparison of PE-LET_{50} Metric to Other Metrics in Use or Proposed for Use

Metric	Test conditions	Test characteristic measured	Information provided
LC_{50}	Continuous exposure to range of concentrations	Lethality at end of set duration exposure	The concentration necessary to produce a lethal response within a set duration
LT_{50}	Continuous exposure to single concentration	Lethality at set times during exposure	The speed of a toxic response
pe-LT_{50}	Single concentration exposure, with subsequent post-exposure observation	Lethality at set times during post-exposure observation	The post-exposure time necessary to observe lethality
20-day LT_{50}	Single concentration exposure for a range of exposure durations, with subsequent post-exposure observation	Lethality at 20 days post-exposure	The exposure time required to produce lethality within 20 days
PE-LET_{50}	Single concentration exposure for a range of exposure durations, with subsequent post-exposure observation	Lethality at set times during post-exposure observation	The exposure time necessary to ultimately produce lethality

Figure 5-1 shows an example plot of PE-LET_{50} values for *H. azteca* exposed to cadmium. Further detail on the application of the method can be found in Appendix B.

5.2.3 Event Toxicity Unit

5.2.3.1 Determination

The PE-LET_{50} toxicity test assesses the toxicity of an individual sample collected during an episodic pollution event in units of time (the time of exposure to the sample necessary to produce a 50% effect during a set post-exposure period). If the level of toxicity (and therefore the PE-LET_{50} value) during the event was constant, then the toxicity of the entire event could be quantified as a ratio of the event duration to the PE-LET_{50} value of a sample from the event. This ratio would be a dimensionless parameter that relates the duration of the event to the exposure duration necessary to produce a 50% lethal effect, the PE-LET_{50}. A ratio of exactly one would indicate that the duration of the event was equal to the duration of exposure necessary to produce a 50% effect. A ratio greater than one indicates that the event would be expected to produce >50% effect in the test population. A ratio less than one indicates that the event did not produce exposure conditions (toxicity, duration, or combination of both) necessary to produce a 50% effect. This parameter would increase with increasing event duration and with increasing magnitude of event toxicity (measured by the PE-LET_{50}).

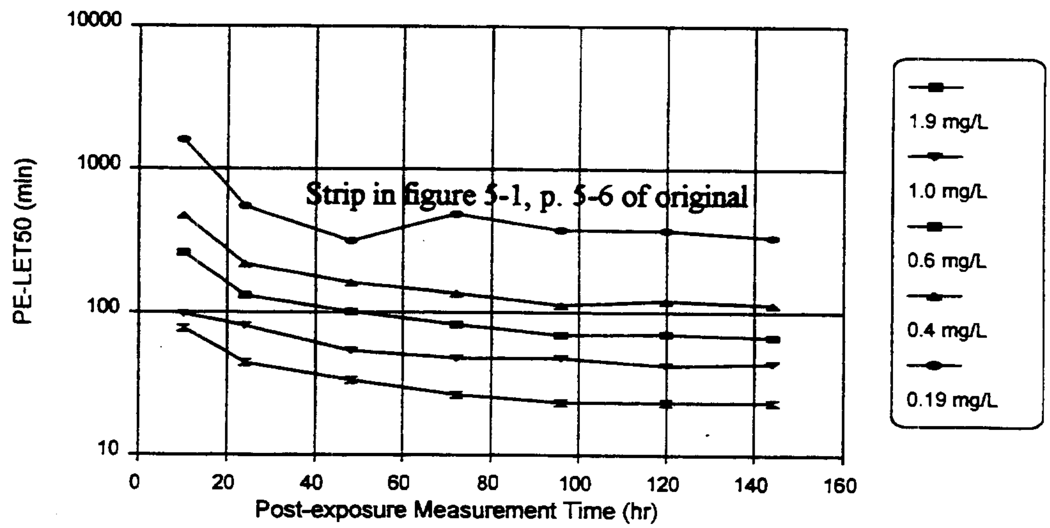

Figure 5-1. Change in PE-LET_{50} over Time for *H. azteca* Cd Exposure

The level of toxicity during episodic events, however, is not constant, and the PE-LET_{50},therefore,varies with time throughout the event. To obtain the same useful time/PE-LET_{50} ratio in this case, the PE-LET_{50} must be defined as a function of time. This is done by performing PE-LET_{50} testing on samples collected sequentially throughout the event. The time/PE-LET_{50} ratio is then derived in this case by integrating the function 1/PE-LET_{50} over time. This ratio has been termed the event toxicity unit (ETU). Figure 5-2 shows an example ETU calculation.

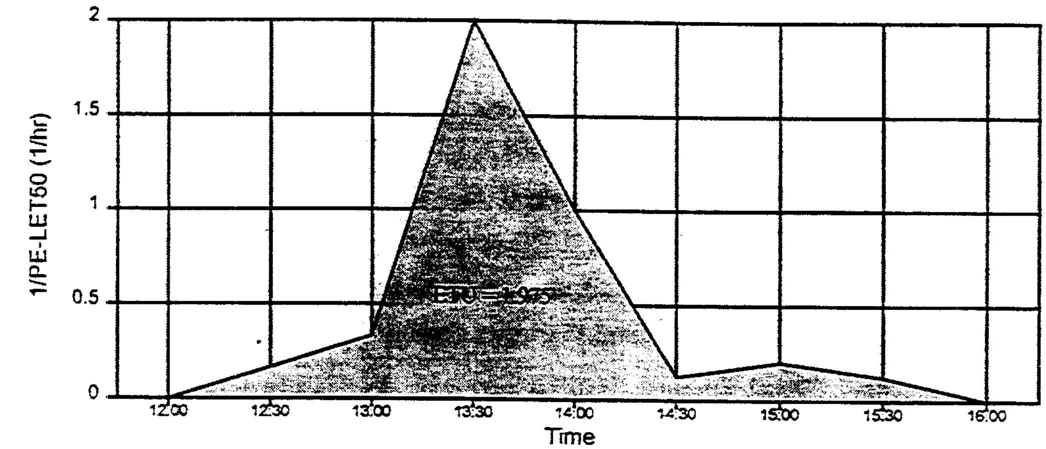

Figure 5-2. Example Calculation of an Event Toxicity Unit (ETU)

The benefit of the ETU is that it is a quantitative measure of total event toxicity. It incorporates both the duration and magnitude of event toxicity. It allows comparison of events that differ in duration, intensity, and sequence of toxic conditions. The ETU analysis does not require a detailed knowledge of contaminant concentrations throughout the event. Furthermore, ETU can also compare actual event conditions with reference exposure situations of known toxicity.

5.2.3.2 Application

ETU analysis was applied to a series of time-varying concentrations of Cd and Zn. Sixteen exposure regimes, including Cd and Zn exposures that varied in concentration and duration, were tested. All exposures consisted of three sequential exposures to varying concentrations of Cd and/or Zn for varying durations. Of the sixteen exposure scenarios, ETU values ranged from 0.42 to 1.81.

ETU analysis was also performed on samples collected from urban stormwater discharge events in Texas and Ohio. Samples were collected from a storm sewer that drains a 48-acre urban/industrial area of Fort Worth, Texas, that is a tributary of the Trinity River. Samples from this site were collected at 30-minute intervals during a four-hour storm event. Samples were also collected from a stream in Ohio that drains a highly devleoped, although predominantly suburban, watershed of approximately 11,600 acres. At this site, time-composited samples were collected during an extended storm event. Sub-samples were collected every 15 minutes for six hours, comprising a single composite. Four composite samples were available for each 24-hour period.

For the Texas site, the PE-LET_{50} values were calculated for six samples that showed significant toxicity in screening tests. Other samples during the event that showed little or no toxicity in 48-h screening tests were assumed to have very high PE-LET_{50} values and, therefore, the 1/PE-LET_{50} value approached zero. The ETU for this storm was 0.98, indicating that the toxicity was at a level expected to cause 50% lethal effect to *C. dubia*. The toxicity results for the Ohio site produced an ETU of 3.28. This event surpassed the magnitude and duration necessary for 50% lethal effect by more than a factor of three. It should be noted that even though the degree of toxicity in the Texas samples was greater than that in samples from the Ohio site (based on 1/PE-LET_{50} values), the severity of the Ohio event was much greater due to the longer duration of the event.

5.3 Basic Screening Test Evaluation

5.3.1 Introduction

A major criterion for time-scale toxicity analysis is the response time of the test system, in particular the need for a test to respond to the short time scales of exposure in stormwater discharges. Two test systems were evaluated as additional basic screening tools in time-scale toxicity analysis, the "IQ" test using *Ceriodaphnia dubia* and the Microtox assay.

5.3.2 *Ceriodaphnia dubia* IQ Test

The "IQ" assay is an inhibition quotient assessment, which measures activity of the enzyme β-galactosidase. Test organisms are fed an enzyme substrate, which is cleaved by the enzyme, producing a fluorescent product. The degree of fluorescence, therefore, is a measure of enzyme activity. The time required for response induction is approximately 15 minutes. Testing conducted with *Ceriodaphnia dubia* showed activity was generally inhibited directly following the exposure period, yet enzyme activity was restored during the following 48 hours. The maximum percent effect generally increased with increasing exposure times and with increasing Cd concentrations. The mean time of maximum enzyme inhibition was 3.30 hours (with a 95% confidence interval of 2.65 to 3.96) after the onset of exposure. Since several of the exposure times were less than 3 hours, often the maximum percent effect was not reached until after the exposure period had ended. For these very short exposure periods, the enzyme inhibition was actually lower directly after the exposure period, reached a maximum approximately 2 to 4 hours later, and then again decreased as the organisms recovered. This time gives some indication of the total time for the transfer of toxicants to the site of action and response manifestation—an important benefit of the IQ assay in time-scale toxicity.

5.3.3 Microtox Assay

A common finding of Microtox assays of stormwater samples was the occurrence of stimulation rather than the expected inhibition of bioluminscence, and this issue was investigated to determine the possible cause. These investigations indicated that the stimulation observed could be due to hormesis—a stimulation occurring as a result of exposure to mild toxicity. Hormesis has been documented repeatedly (Stebbing, 1982), although it is not fully understood.

Analysis of stormwater samples in this study produced a reasonably consistent stimulation in the Microtox assay. The consistency of response suggested a more detailed examination of low concentration response with the Microtox assay would provide sufficient information to identify an increased sensitivity of response not previously reported. A series of studies was initiated to evaluate stimulation/hormesis in the Microtox assay. Six metal contaminants (Cd, Cr, Cu, Pb, Ni, and Zn) along with phenol and sodium lauryl sulfate were tested using procedures consistent with screening level testing used in this project.

The experiments supported the conclusion that it is possible to quantify stimulation at low exposure levels, and, for several contaminants, a concentration-response relationship could be identified for the range of exposure concentrations. It was also apparent from this research that the frequency and magnitude of induced stimulation was affected by several factors. Some contaminants produced more stimulation than others, particularly Cr and the organic compounds, phenol and sodium lauryl sulfate. When the stimulation levels observed in these experiments were compared with stimulation levels observed in stormwater sampling, no single contaminant produced maximum stimulation levels observed in stormwater (up to 60%). Further testing with binary mixtures and simulated stormwater confirmed the utility of using the stimulation response in the Microtox assay as a basic screening response in time-scale toxicity analysis.

5.4 Advanced Screening Tools

5.4.1 Introduction

The time-scale toxicity testing protocol adopted in this research initially calls for basic screening tests, then application of advanced tier testing to confirm toxicity and address issues of impact, source identification, and management options. In this research, advanced tier testing uses advanced screening tools to complement basic screening tools. However, the advanced tools do not necessarily address all concerns that would be addressed by advanced tier testing in a typical hazard evaluation. The following discussions review a number of advanced screening tools evaluated as a part of this research. These tools range from advanced toxicity screening tools, such as toxicity identification evaluation (TIE), to the application of sewer models to assist in both identifying sources of contaminants and defining approaches to sampling sewers based on source location and flow concentration time. A number of advanced screening tools, including toxicity testing and analysis schemes and other methodologies, have been developed or evaluated in this research to identify sources and causes of toxicity (Figure 5-3).

5.4.2 Watershed Modeling—Storm Sewer Model

A watershed focus in time-scale toxicity testing incorporates the sense of land use and location in application of the time-scale toxicity assessment protocol. In urban watersheds, one of the factors that can alter fundamental watershed characteristics is the presence of storm sewers. Storm sewers, by design, collect runoff from areas where land use and other activities might influence its quality and deliver it to a single location. Fortunately, sewers have been the focus of modeling efforts around the world so it is possible to predict the dynamics of sewer flow in a way that assists in time-scale toxicity assessments. For example, the sewer model can accurately predict concentration times for flows from different areas of the watershed. Using this information, it is possible to connect a sewer model with time-sequenced sampling at the discharge to identify possible sources of toxicity/contamination.

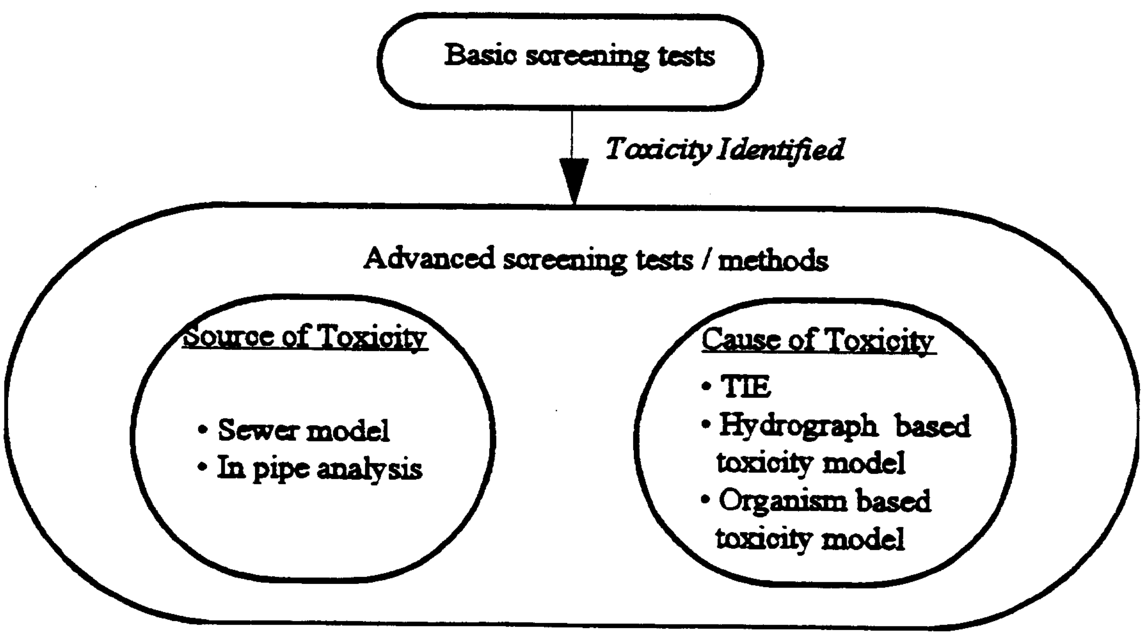

Figure 5-3. Advanced Screening Tools

Application of an available model is often a compromise between detail and availability of model input and the expected use of model output. As this project evolved from a focus on in-stream analysis of time-scale toxicity to include in-pipe and near-outfall assessment, a need developed to model outfall hydrology to assist in both interpretation of toxicity during storm events, and prediction of toxicity as affected by storm sewer system characteristics. The focus on the Kaufman Lake Storm Sewer (KLSS) required an analysis of the sewer "tributary" system to identify possible sources of contaminants. Furthermore, modeling suggested itself as a means to supplement toxicity testing with information on sewer dynamics that would assist in developing contaminant source and frequency and duration of exposure information.

The most widely used model for this type of analysis is the Stormwater Management Model (SWMM). Unfortunately, SWMM is a complex model that requires input data detail that was not readily available for this project. A second model, the Illinois Urban Drainage Area Simulator (ILLUDAS) was developed locally, had minimal input data requirements, and was supported locally. ILLUDRAIN (Ver 2.10) was applied to the KLSS system. Model sensitivity was tested for different antecedent moisture condition (AMC) for several storms. The effect of rainfall amount was investigated using three storms, the one-year, two-hour rainfall, a moderate storm event, and a storm of low intensity. The application of ILLUDRAIN found that the model is sensitive to the percent grassed area in a watershed. Further, the model provides an option for identifying local surface hydrographs. The local hydrograph was found to be useful in identifying potential sources of contaminants by relating contaminant concentrations observed to the concentration time associated with watershed locations.

5.4.3 Toxicity Modeling

5.4.3.1 Introduction

Literature reports and observations made during field testing on this project and a general analysis of contaminant/hydrograph relationships identified through the literature review suggest that toxicity during a storm-related hydrograph should be predictable. To this end, a simple predictive model of site-specific receiving system toxicity associated with storm events was developed. The model was used to assess the expected toxicity of heavy metals in receiving systems. This simplified model did not predict metal speciation or the presence of biologically available metal concentrations. The model simply related expected change in concentration to toxic potential based on published criteria.

5.4.3.2 Hydrograph-Based Toxicity Model

The underlying concept for the development of this model was that it was possible to use regional hydrologic information to describe hydrograph characteristics. Further, it was possible to translate expected contaminant concentration into a toxicity unit (TU) and provide an additive estimate of event toxicity. The model completes an estimation of a hydrograph from a partial specification of hydrograph characteristics. On the basis of this projection and estimates of contaminant input, the model then estimates the expected stream toxicity during runoff events. The hydrograph is a function of the total available overland flow supply, subsurface flow, groundwater flow, slope of the overland and stream segments, and geometry of channels, which can be separated into two elements, a rising limb and a recession limb. To convert predicted or actual contaminant concentrations to effect estimates the toxic unit (TU) defined by the US EPA (1991) was used. A TU is "a measure of toxicity in an effluent as determined by the acute toxicity units or chronic toxicity units measured" and is simply a reciprocal of the LC_{50} or the no observable effect concentration (NOEC). In this model, the acute toxicity unit based on published criteria was used.

An initial model predicted TU values for only one contaminant where TU values were required as model input. The model was modified to allow prediction for five contaminants typical of stormwater discharges (Pb, Cr, Cd, Zn, and Cu), which used the concentration of a contaminant as an input value, not a specified TU. The model did not account for physical or chemical factors that affect biological availability of metals; it simply predicted the toxicity of metals based upon concentrations reported in the literature as being toxic. The revised model calculates a cumulative toxicity using a simple additive assumption and added the ability to model storm events that produce multiple peaks.

The model was used as a tool to assist in developing a conceptual base for time-scale toxicity analysis. For example, a first flush might be expected to produce an initial peak in toxicity followed by a rapid decrease and low levels of toxicity in the remainder of the storm event. Another possible time-scale toxicity scenario finds a second peak of toxicity in a storm event when previously deposited contaminants are resuspended in the water column. When evaluated against storm event monitoring data, the presence of a first-flush-related toxicity was confirmed. Monitoring also confirmed toxicity later in the hydrograph. The model continues to be useful in providing a "what if" analytical tool to determine what changes are needed in initial assumptions to assist in interpreting possible causes of an observed time-scale toxicity result for a storm event.

5.4.3.3 Organism-Based Toxicity Model

Many toxicity models appearing in the literature are based on first-order kinetics of toxic uptake and depuration. These models commonly represent the organism as a single compartment that can ingest, store, and excrete a toxicant. According to this type of model, a toxic endpoint, such as mortality, occurs when the tissue concentration reaches a critical concentration. LC_{50} predictions are based on uptake and depuration rates obtained from the literature or experimental data.

The model developed as a part of this research was used to predict toxic effects resulting from time-variant Zn concentrations. To test this application, the model was applied to data obtained from the Fort Worth field campaign in May, 1995. The model predicted significant Zn toxicity at the industrial site based on predicted total Zn accumulation. These results are also consistent with the ETU value of 1.05, which would indicate a highly toxic event.

CHAPTER 6.0

STUDY SITE SUMMARY INFORMATION

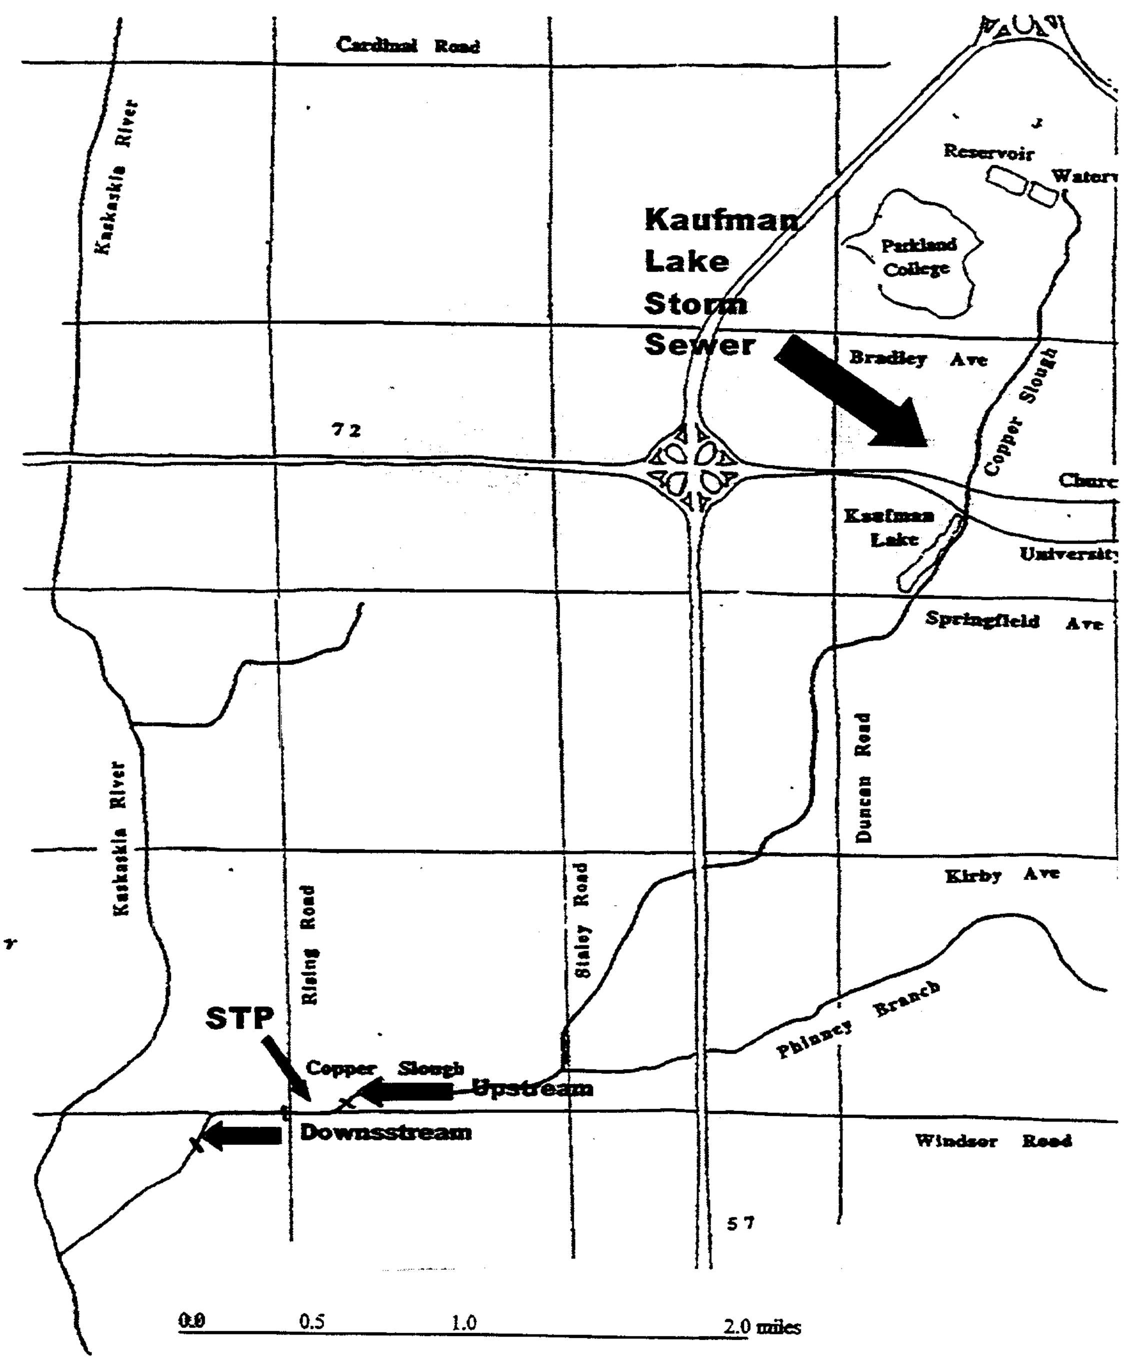
6.1 Introduction

This chapter provides information on the project study sites. The main site was the Copper Slough Watershed near Champaign, Illinois. Regional study sites were the Trinity River Watershed in Fort Worth, Texas, and the Cuyahoga River Watershed near Cleveland, Ohio. In-pipe samples were obtained from the Kaufman Lake Storm Sewer (KLSS) in the Copper Slough watershed and at three locations on the Trinity River watershed (Cra, Eastern Hills, and Pylon). Receiving water samples were taken from the Copper Slough, Sycamore Creek (a tributary to the Trinity River in Fort Worth, Texas), and Mill Creek (a tributary to the Cuyahoga River in Cleveland, Ohio).

6.2 Copper Slough Watershed

The Copper Slough is a tributary of the Kaskaskia River near Champaign, Illinois. The Copper Slough watershed has been the subject of detailed hydrologic, geomorphic, and fisheries analyses for several years and was a National Urban Runoff Program (NURP) study site. The Copper Slough drainage area is approximately 41 km^2. Land use in the watershed is about 40% urban and 60% agricultural. The stream originates in the northwest corner of the City of Champaign, flows through a predominantly urban area for approximately 2 km, and then flows through agricultural and suburban areas to its confluence with the Kaskaskia River. A number of storm sewer outfalls enter the Copper Slough in the upstream, urbanized area. Downstream, the Copper Slough is influenced by a sewage treatment plant (STP) outfall and urban and agricultural runoff. Two main study sites were located in the Copper Slough watershed (Figure 6-1). The first study site was associated with the Urbana-Champaign Sanitary District Southwest Sewage Treatment Plant in the lower Copper Slough watershed, approximately 1 km upstream from the Copper Slough, Kaskaskia River confluence. The second study site was the KLSS System, located in an upstream area of the Copper Slough watershed, approximately 4 km upstream from the STP site.

Figure 6-1. Copper Slough Watershed



6.2.1 STP Study Locations

Field studies were initiated in the Copper Slough Watershed in 1994 focusing on downstream (STP) study locations. Two stations were chosen that represented receiving system, multiple discharge conditions. One was located 100 m below the STP, called "downstream (DS)" herein. The DS location was selected as a maximum impact station, subject to normal stormwater flows and combined sewer overflows (the chlorinated, primary treatment effluent occurring during major storm events). A second station approximately 100 m upstream from the STP outfall, called "upstream (US)" herein, was selected to provide an indication of urban and agricultural stormwater effects in the absence of STP discharges. Summaries of storm events assessed at these stations are provided in Tables 6-1 and 6-2.

Sampling at the downstream locations included time sequenced water sampling, artificial substrate sampling for macroinvertebrates, in situ deployments of invertebrates and fish, and real-time monitoring using the Asiatic clam, *Corbicula*. A continuous record of level, temperature, dissolved oxygen (DO), pH, and conductivity was kept from May, 1994, to November, 1995, with the exception of winter months when ice prevented probe deployment and maintenance.

6.2.2 The Kaufman Lake Storm Sewer System

The KLSS system included a storm sewer that discharged into a short channel, which then drained into the main channel of the Copper Slough (Figure 6-2). The storm sewer outlet had a diameter of approximately 1.25 m with continuous flow during dry weather. Although dry weather flow may be due to ground water infiltration, there is also the possibility of flow maintenance by discharge from local industry. Immediately downstream from the sewer outlet, the channel was wide with a well-established pool with a maximum low-flow depth of approximately 1 m. The site is unusual, because the sewer discharge is to a short tributary to the Copper Slough that parallels the reference stream for approximately 50 m. Thus, it was possible to have reference and experimental sites side-by side, facilitating both laboratory testing of collected water samples (see Section 7.3.5) and in situ studies using both WET species (*Ceriodaphnia dubia*, *Hyalella azteca*, and the fathead minnow) and local species (see Section 8.4.1). Further, the storm sewer discharges into the pool produced conditions where sediment accumulates allowing location of in situ sediment toxicity assays (see Section 8.5.1).

At the KLSS, a number of locations were used to monitor receiving water toxicity:

- A reference site on the Copper Slough (CS REF) approximately 50 m above the confluence with the KLSS tributary outlet;

- A second reference site used for one biosurvey;

- A site just downstream (CONFLUENCE) of the point where the discharge channel joins the Copper Slough;

- A main downstream site (DS MID) about 100 m downstream of the confluence with the KLSS basin outlet; and

- Another site further downstream (DS BRIDGE).

Table 6-3 summarizes the toxicity test data and hydrograph information for storm events at the KLSS in 1995 and 1996. In the study, ten storm events were sampled during the period 7/4/95 to 7/21/96 to provide information on seasonal effects on in-pipe toxicity. Table 6-4 summarizes the toxicity data (Microtox, *C. dubia* IQ and lethality tests) obtained for the receiving water samples taken at the KLSS system during an intensive two-week sampling program between 5/20/96 and 6/1/96.

6.3 Trinity River (Fort Worth) Watershed

Four locations were monitored in the Trinity River watershed during a two-week field campaign in May 1995: Sycamore Creek, Cra, Pylon, and Eastern Hills. A field trailer provided by Fort Worth Department of Environmental Management (FWDEM) was located at the Sycamore Creek site and served as a base of operations. The Sycamore Creek site was monitored continuously during the field campaign using both a Datasonde multiprobe and the Mussel Monitor. Two sites (Cra and Pylon) were also continuously monitored with a Datasonde multiprobe. At Eastern Hills, stage height was continuously monitored. Two storm events on 5/2/96 and 5/27/96 were sampled at all sites and tested for toxicity using the Microtox, *C. dubia* IQ and lethality tests. Subsequent events on 7/9/96 and 8/9/96 were sampled by FWDEM at the Cra site and analyzed. Table 6-5 provides a summary of storm events monitored in the Trinity River (Fort Worth) studies.

6.3.1 Cra

The Cra watershed is approximately 47 acres dominated by industrial land use. Runoff through this watershed begins as sheet flow through an open, first-order channel, picking up runoff from bar ditches along a railroad and drainage from a vacant lot composed of industrial landfill. Before reaching the sampling site, the flow picks up drainage from 33rd Street. Industries located within this watershed include Goodyear, Valley Solvents and Chemicals, and several steel foundries and distribution centers. Previous studies have indicated contamination from heavy metals and organics at this location. The sampling site at Cra was located at the mouth of a storm sewer near American Manufacturing, Inc. just south of 33rd Street. The channel downstream from the sampling location was dominated by emergent vegetation (cattail). The channel substrate was sand to fine silt. Depth at the sewer outfall was 12 to 18 in. The Datasonde probe and hose intakes for the Sigma sampler were attached to the bottom of the storm sewer pipe several feet upstream of its opening into the main channel. The Sigma Sampler was positioned on the left overbank of the main channel in a sampling cabinet installed by FWDEM for previous studies. Water quality measurements were made at 15-min intervals, and 500-mL water samples were pumped every 30 min during a storm event.

6.3.2 Eastern Hills

The Eastern Hills watershed is approximately 154 acres and consists primarily of residential areas. Approximately 85% of the watershed is single family residences, while the remaining 15% is multi-family residences. The major sources of possible contamination are residential sewage from overflowing manholes, miscellaneous materials present in streets, and pesticides and herbicides used for lawn maintenance. The sampling site at Eastern Hills was a large storm sewer pipe located near Weiler Boulevard. The Sigma Sampler was secured on top of a drop box inlet with the hose intake positioned just upstream of the inlet. Since a Datasonde probe was not installed at this site, stage readings were recorded by the Sigma sampler instead. A Druck pressure-sensitive probe was connected to the sampler and submerged next to the hose intake to provide stage readings. The stage was recorded every five minutes, and the stage readings were downloaded to a laptop computer at regular intervals throughout the field observation period.

6.3.3 Pylon

The Pylon watershed is approximately 28 acres and encompasses industrial, as well as agricultural, land uses. Various industries, including Graphic Arts, Ravon Industries, and Pepsi Cola Bottling, are located within the watershed. Pollutants carried by runoff include pesticides, heavy metals, and debris from parking lots. The Pylon sampling site was located near the corner of Meacham Boulevard and Pylon Street along a straight channel reach of an unnamed, first-order stream. A Sigma Sampler was installed on the right overbank of the stream. The Datasonde and the Sigma Sampler hose intake were positioned in the middle of the stream about 10 feet upstream of a triangular weir. The stream channel was approximately 15 ft wide with a trapezoidal channel consisting of concrete. Depth at the instrument location was approximately 1 ft. The presence of the weir had resulted in sediment accumulation upstream from the weir. Sediment from this area had been recently removed as a part of regular maintenance activities of FWDEM. Datasonde measurements were recorded every 15 minutes, and 500-mL water samples were collected every 30 minutes during a storm event.

6.3.4 Sycamore Creek

Sycamore Creek receives runoff from a 30,000-acre watershed with mixed land use dominated by commercial and residential areas. The sampling location was approximately 2,500 ft upstream from the confluence with the Trinity River in a fourth- or fifth-order stream channel. The substrate materials varied from sand to large cobble with concrete debris present. The stream channel was approximately 60 ft wide with steep banks of 20 ft. The reach sampled transitioned from a pool through a riffle/run area around a shallow bend. Samples were near the left bank (looking upstream) in a main channel flow. Debris had accumulated in the riparian vegetation indication previous stream depths of 10 to 15 ft. The depth at the sampling location was approximately 2 ft.

6.4 Cuyahoga River (Cleveland) Watershed

Mill Creek is a tributary of the Cuyahoga River (at River Mile 11.3), flowing east and then south approximately 14.5 km through a completely urbanized watershed including all or part of the following communities: Beachwood, Bedford Heights, Cleveland, Garfield Heights, Highlands Hills, Maple Heights, North Randall, Orange, Shaker Heights, Solon, and Warrensville Heights. The drainage area is approximately 11,600 acres with unmodified channel conditions for most of its length. In general, sampling stations extended from an upstream area affected mainly by residential discharges through midstream stations subject to industrial and CSO influence to a downstream station near the Cuyahoga River.

Sampling in Mill Creek was conducted by the Northeast Ohio Regional Sewer District, and samples were sent to the University of Illinois for laboratory analysis. Stormwater samples were collected from four sites on Mill Creek during the 7/15/95 storm event. These samples were tested for toxicity using Microtox, *C. dubia* IQ and lethality tests. These analyses were part of a larger study assessing the impact of storm discharges at 11 sites in the Mill Creek watershed. As part of the larger studies, chemical analyses, toxicological testing, and benthic surveys were completed in 1995. Reporting on the Mill Creek Watershed Project is available from the Northeast Ohio Regional Sewer District in a report published in August, 1996.

CHAPTER 7.0

LABORATORY-BASED STORM EVENT ANALYSIS

7.1 Introduction

This chapter, and Chapter 8.0, raise questions that users should ask when designing their wet weather event assessment programs and provide relevant information and answers using information generated in this research. This chapter covers issues relating to laboratory-based analyses, while Chapter 8.0 deals with field-based analyses.

These two chapters are not intended to provide exhaustive answers to all the questions the designer of a wet weather analysis program might ask. That would be impossible due to the site-specific and objective-specific nature of any program. What is intended is that these questions will prompt users to ask the right kinds of questions that will lead them to an appropriate design, and the answers will provide guidance on the issues to address.

7.2 Where Do I Start?

Since it can be difficult and expensive to obtain conclusive data on the effects of wet weather events, it is vital that assessment programs are carefully designed to meet specified objectives and also to be cost effective. Two types of objectives must be defined at the outset of the program:

- **General** objectives describing program goals; and
- **Specific** objectives relating directly to the measurements necessary to meet general program objectives.

Assessment programs frequently fail to meet defined objectives even when carried out as specified, because the sample size is insufficient to confirm or reject study hypotheses in a statistically acceptable manner. This problem stems mainly from the high variability in runoff and natural aquatic systems. Sources of variability include spatial differences in parameters in a waterbody, differences in parameters at a location over time (temporal variability), and errors in the measurements of parameters. All these potential problems can be addressed by ensuring at the beginning of the study that the number of samples (location, time, and replicates) taken are sufficient to meet study objectives considering variability and cost constraints. Chapter 3.0 covers elements of wet weather assessment program design, and further detailed information on monitoring program design can be obtained from Mar et al. (1986); Reinelt, Horner, and Mar (1988); Reinelt, Horner, and Castensson (1992); and Horner et al. (1994). See also Sections 7.5.1 and 7.5.4.

Horner et al. (1994) described a procedure for estimating the cost of programs using the formula:

$$TC = C_o + (T \times C_T) + (S \times T \times C_s) + C_r\ (R \times S \times T) \tag{7.2-1}$$

where: TC = Total cost;

- C_o = Fixed overhead cost;
- C_T = Fixed cost for each sampling occasion;
- C_s = Cost associated with visiting each sampling station;
- C_r = Cost to collect and analyze each sample;
- T = Number of sampling occasions;
- S = Number of sampling stations;
- R = Number of replicates on each occasion at each station.

The function R x S x T = the total number of samples, and, for a given budget, the three quantities can be varied so long as the total remains the same. For example, if measurement error is larger than natural variation, then adding replicates would reduce uncertainty more than adding stations or occasions. However, if spatial or temporal variation are most important, adding stations or occasions respectively would be a better strategy.

7.3 Analysis Design Questions

7.3.1 Where Do I Sample?

The locations sampled within a watershed depend on the objectives of the assessment program and wet weather event characteristics. The protocol (see Chapter 3.0) defines three objective-related sampling locations:

- **In-pipe**, where the objective of the study is analysis of a defined drainage area or assessment of the performance of control facilities or assessment of a specific source. Samples should be taken either in the pipe during the discharge or, if this is not possible, at a near-discharge location that provides minimum mixing with the receiving water. The dilution and dispersion available in the receiving water needs to be considered before any conclusions can be drawn on the potential environmental impact.

- **Receiving waters (single discharge)**, where the objective of the study is the assessment of the impact of a single discharge. The locations selected should provide a reference (see Section 7.3.4) sample and a well-mixed discharge/receiving water sample that identifies the effect of the discharge as modified by the receiving water.

- **Receiving waters (multiple discharges)**, where the objective of the study is:
  a) establishing reference conditions for a location in a watershed;
  b) assessing the effects of multiple, or diffuse source, discharge effects at a site or sites;
  c) long-term surveillance of dynamic (wet weather)/static (baseline) receiving water condition

The locations selected should be based on discharge locations and receiving water characteristics and may require consideration of temporal (seasonal, see Section 7.3.3), as well as spatial effects. See also Section 7.5.1.

7.3.2 What Do I Sample?

The sampling program adopted again depends on the objective of the study and includes assessment of both water column and sediment toxicity. In the first instance, a series of water samples should normally be taken from appropriate locations and tested using basic screening tests (see Section 7.4.2) to assess the level of toxicity (toxicity classification, see Section 3.4.3). The frequency of sampling required and the nature of the samples taken (grab or composite) depends on the characteristics of the system under study and the precision called for by the study objectives.

However, over time, runoff pollutants, such as metals, accumulate in the sediment rather than the water column. Therefore, assessing cumulative effects of watershed runoff and nonpoint sources on aquatic systems should include evaluation of sediments and the toxicity to indigenous organisms. Alternative assessment methods are needed to determine the actual environmental effects of runoff.

7.3.3 When Do I Sample?

Since wet weather events do not occur at evenly spaced intervals, it is not appropriate to adopt set monitoring intervals (such as weekly or monthly) but to target sampling to site-specific characteristics in terms of the input and the receiving water characteristics. The results of hydrologic analyses at a site should be used to support sampling programs. For example, information on seasonal occurrence of storms, typical magnitude, duration, and inter-storm periods can all be useful in targeting sampling to maximize the chances of capturing storm event data at minimal cost (see Section 2.3). Information was used in this way to target the sampling program undertaken in this project at Fort Worth. Seasonal storm frequency information was used to select the sampling period at the Fort Worth sites which would have the highest probability of providing storm events (see Section 6.3). Further information on typical intervals between storms was used to predict the number of storms which might be expected within a sampling program of a given duration (for example, see Table 2-1).

In addition to targeting the general sampling period to maximize capture of useful data, one must consider when to sample in relation to organism exposure to contaminants. The protocol (Chapter 3.0) defines three sampling frequencies that are designed to meet specific objectives:

- Intra-event;
- Event; and
- Multiple event.

7.3.4 What Constitutes a Reference Sample?

A reference sample is one that is used to compare with those taken during a storm event. When monitoring in-pipe toxicity, a reference sample can be:

- One or more samples taken before the storm event (that is under dry weather flow); or
- A laboratory control, if there is no dry weather flow.

When monitoring the impact of single or multiple discharges to receiving water, two different types of reference sample can be identified, serving different purposes:

A **local or upstream reference sample** is one that is used for direct comparison with an impacted site to infer the effect of a single discharge, multiple discharges, or runoff zone. Typically, these samples are taken at a site upstream of the impacting discharge or impacted area. The results from samples taken at this site are compared with results from the downstream, impacted site. For example, at the KLSS system, an upstream reference was located about 50 m upstream of the confluence with the KLSS basin (see Section 6.2).

Although an upstream reference site allows the identification of the impact of a particular input, it does not allow an identification of the impact of other input sources or a general degradation in water quality. Collecting a sample from general or background reference sites might aid is making such a distinction.

A **general or background reference** sample is taken from a site that is free of (major) anthropogenic influence and provides a measure of natural background conditions. By comparing the results of tests on samples taken from a general reference site, an upstream reference site and an impacted site, it might be possible to infer the relative importance of the impact of the input under study in relation to that caused by other inputs. A reference site can be situated in the upper reaches of the watershed, above known inputs, or on a different, unimpacted stream. If samples are taken from different systems, then it is vital to ensure that results of toxicity tests are not influenced by differences in physicochemical factors, such as water hardness and pH. See Section 7.5.1 for more detail on this issue.

7.3.5 How Can Toxicity Change Through a Storm Event?

Within an event, the toxicity measured at different times depends on the concentration of substances present in the runoff and their bioavailability to test organisms. The concentrations of substances present, and, hence, the resulting toxicity, are almost infinitely variable depending on rainfall intensity, the length of the antecedent dry period, deposition on urban surfaces or application of chemicals (such as pesticides and herbicides) on farm or residential land during the antecedent period and surface characteristics.

In a storm event, the first flush of runoff typically contains relatively high concentrations of contaminants which may then fall markedly and fluctuate at lower levels for the remainder of the wet weather event. As a result of this contaminant concentration pattern through an event, the highest levels of toxicity would be expected to generally be associated with this first flush. However, the first flush sometimes is not apparent, or is less pronounced, when rainfall is not intense or follows soon after an earlier storm that has removed the majority of the available contaminants. A secondary peak in contaminant concentrations (and toxicity) can appear if a sudden burst of intense rain during the event drives material off surfaces not completely cleaned by the initial runoff (Horner et al., 1994).

Figure 7-1 shows when peak toxicity values in the Microtox, *C. dubia* IQ and lethality tests were measured after the start of storms at the KLSS. Peak toxicity was usually observed with both the Microtox and *C. dubia* IQ tests between 5 and 60 min after the start of storm water runoff at the sewer.

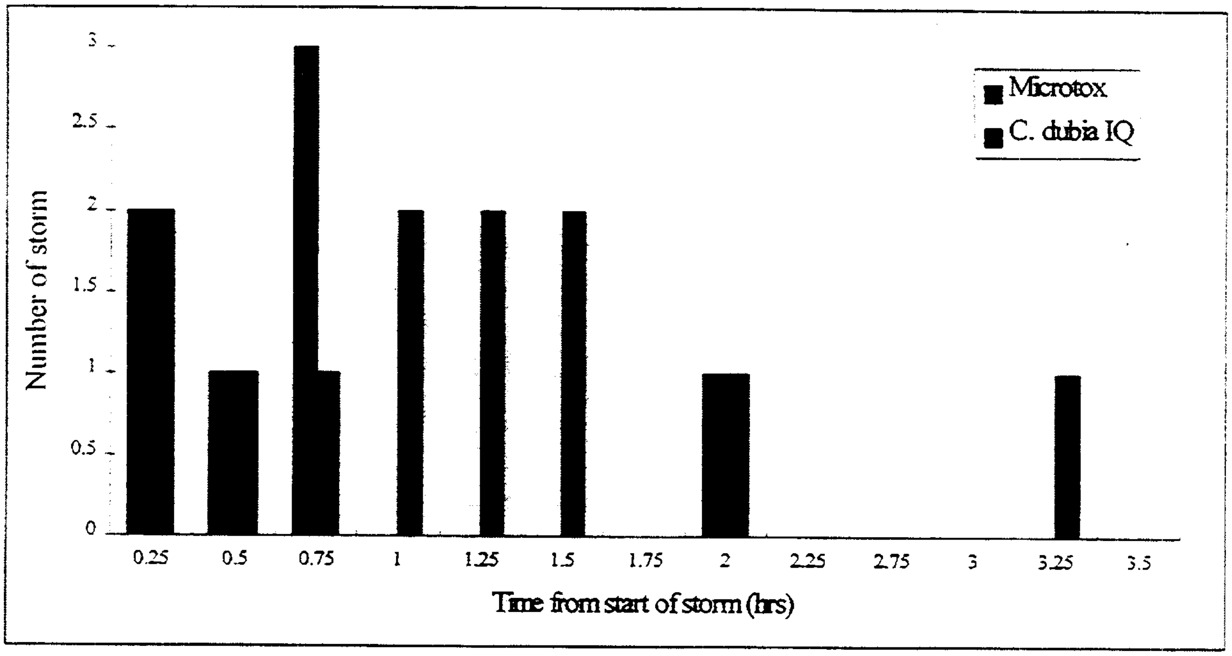

Figure 7-1. Times from Start of Storms to Observation of Peak Toxicity as Measured by the Microtox and *C. dubia* IQ Tests

An example of the pattern of toxicity measured at the Kaufman Lake storm sewer during an event is shown in Figure 7-2. The 7/14/95 storm event started at 12:40 and the highest toxicity values in basic screening tests (Microtox and *C. dubia* IQ) were measured at 12:45. After 30 minutes, responses in both tests had fallen to pre-storm values. These data are consistent with studies carried out with stormwater samples from various Los Angeles River locations with the Microtox test (Raco, 1988). See also Section 7.4.6.

To identify toxicity related to a first-flush effect or toxicity related to another specific period of an event, sufficient sampling will give an adequate profile of effects through the event. This will inevitably require event-triggered sampling with an auto-sampler. The sampling frequency sampling depends on the characteristics of the system and the precision called for by study objectives.

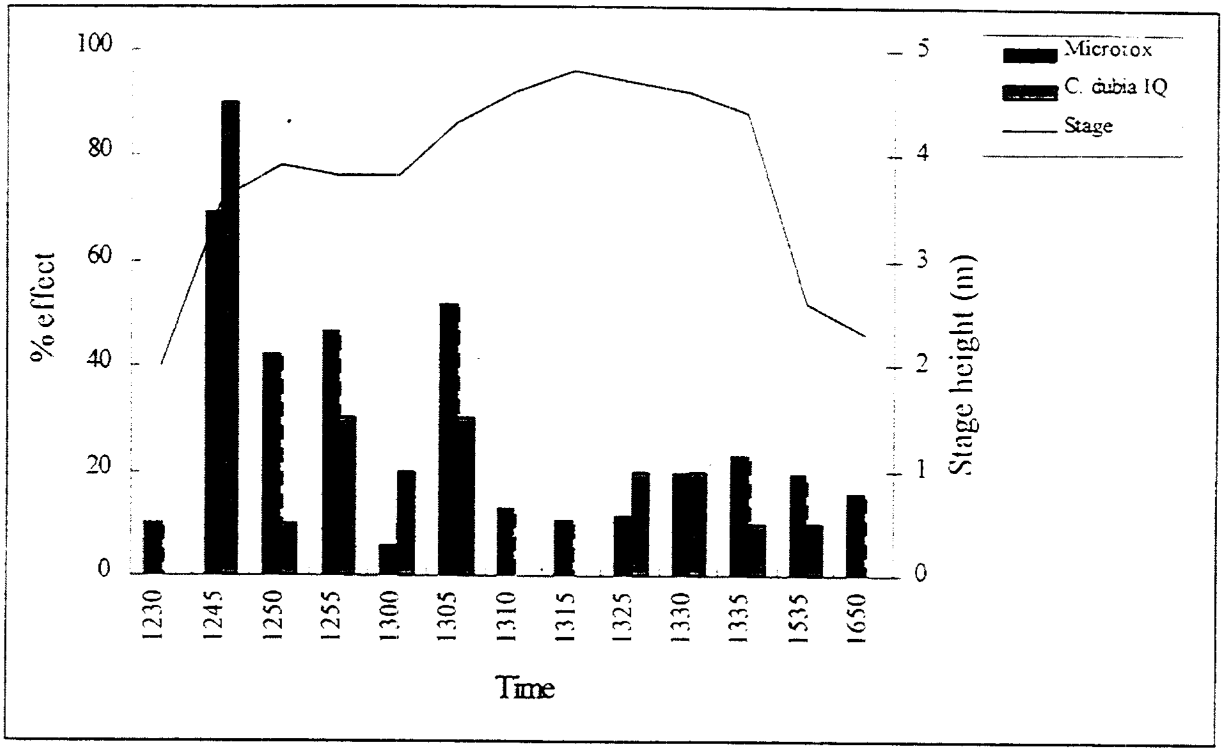

Figure 7-2. Toxicity Data for the 7/14/95 Storm at KLSS

7.3.6 How Do I Design a Sampling Program to Identify/Separate Water Column/Sediment Effects?

The sampling program to identify/separate water column/sediment effects must reflect the time scale of exposure of receiving water organisms.

Acute toxic responses of receiving water column biota to wet weather events are associated with a transient change in the concentration contaminants that can last for only a short time, although post-exposure effects may occur. The extent of these toxic responses in the receiving water depends on the magnitude of stormwater runoff relative to receiving water volume and the extent of dilution. Where dilution is high, contaminant concentrations in the receiving water might not be high enough to directly or rapidly affect aquatic organisms. However, continued runoff with relatively low contaminant levels can eventually cause toxic responses in two ways:

- Cumulative water column stress resulting in chronic effects; or
- Pollutant accumulation in aquatic sediments resulting in effects on epibenthic and benthic organisms.

The sampling program must accommodate the need for separate sampling and testing of water and sediments, as well as combined use of in situ tests and bioassessment programs. The event toxicity unit (ETU) metric developed as an indicator of time-scale toxicity can be used to identify water column effects (see Section 5.2.3). Although identified as an area for further research, this project has developed evidence that suspended solids, possibly resuspended sediment, can contribute to toxicity during a storm event. For this reason, a complete definition of water column toxicity might require separate testing for soluble and solids components of storm samples. In addition, full site toxicity characterization may require sediment toxicity testing, either laboratory- or field-based.

7.4 Test System Questions

7.4.1 What is the Best Test System for Toxicity Analysis?

In assessing the impact of wet weather events, time-scale considerations are the basis for the selection of appropriate toxicity assessment procedures. In the protocol described in Chapter 3.0 to support the assessment of both short-term and long-term changes in receiving water condition or quality, three time-scale divisions (intra-event, event, and long-term) are identified. These divisions recognize that effect identification, test system selection, and actual measurement of effect, analysis and interpretation of consequence must all meet criteria that are specific to an identified time scale. If toxicity is the indicator, then in short-term exposures (intra-event time scale) where concentration transients are very large (orders of magnitude), responses need to match the time scales of exposure found during the storm. When analyzing whole events, particularly as modified by BMP operation, the time-scale analysis selected (event time scale) should reflect the fact that BMP effluents have some characteristics of the storm event (for example episodic nature with variable volume and concentrations associated with the effluent). However, BMP effluents typically vary less with longer, but constant effluent flow times.

As a matter of convenience, event time scales are measured in two categories; Category #1 would be appropriate for short duration convective storms for which event duration is measured in hours, and Category #2 where event duration requires multiple composite samples or BMP presence extends a storm's influence so that an event duration is measured in days. Finally, toxicity analysis related to extended contaminant residence or accumulation of contaminants requires tests appropriate for a long-term time scale, where exposure durations are very long (days to months).

The protocol also recognizes that a tier testing approach is essential to a logical and cost-effective analysis of wet weather discharges that are highly variable. Following an extensive evaluation of test systems, assays, and sampling approaches, the tier testing scheme proposed for wet weather discharge analysis emphasizes basic and advanced testing in a screening tier followed by confirmatory testing, which verifies the predictions of the screening tier where required. The use of a structured tier testing approach allows the required level of information needed to be obtained in a cost-effective manner (see Section 3.4).

Since different test systems are based upon different responses to toxicants, one test cannot be relied upon to respond to all wet weather events. Consequently, an optimized test battery is needed to minimize incidences of false negatives in detecting the toxicity associated with events of different duration. The need for a test battery for each time-scale division is consistent with the consensus view of regulators involved in controlling point source discharges (US EPA, 1991; Environment Agency, 1996).

7.4.2 What is a Basic Screening Test and When Should I Use One?

A basic screening test is a simple, easy-to-use, cost-effective test that measures effects observed in an undiluted sample over a period typical of the storm event(s). Basic screening tests are intended to *illuminate* the problem and supply sufficient information to identify toxicity and classify toxicity as nonexistent, moderate, or high. See Section 3.4 for more information on basic screening tests and their application. An example of test system identification for basic screening tests is provided in Section 4.6.

7.4.3 What is an Advanced Screening Test and When Should I Use One?

An advanced screening test provides a measure of effects observed in a series of a sample dilutions over a period typical of the storm event(s). Advanced screening tests are intended to lead to more focused analysis to identify toxicant type, contaminant source, mechanisms of toxicity, or toxic effect (see Section 3.4). These tests are selected to identify sources of contamination, better characterize individual storm events for later comparison or classification, or identify toxic effects that can be used to direct confirmatory testing to appropriate targets.

7.4.4 What is a Confirmatory Test and When Do I Use One?

A confirmatory test is a laboratory- or field-based procedure to verify effects predicted from earlier basic and advanced screening tiers (see Section 3.4). If high or moderate toxicity is revealed by screening tests, confirmatory tier tests may be used to confirm that there is an impact on the receiving water ecosystem (see Appendix C). Confirmatory testing can be integrated with monitoring efforts that are designed to identify unanticipated long-term or low-level effects.

7.4.5 What are the Characteristics of an Optimal Test Battery for Storm Event Analysis?

The optimum test battery for assessing intra-event, event, or long-term toxicity must be cost-effective, minimize false negatives and false positives, but should not incorporate unnecessary redundancy (that is, tests showing similar responses). Careful consideration of the test battery is required to achieve this balance. Too few tests increases the risk of false negatives (i.e., test not responsive to a particular contaminant), as well as that of false positives (i.e., rogue results from a single test). Results must be interpreted with care (Section 7.9.4). Identifying appropriate test batteries for each time-scale division has been a key element of the project, and the selection procedure used is described in Chapter 4.0.

7.4.6 What is the Optimum Screening Test Battery for Analyzing Intra-Event Toxicity?

For intra-event analysis, toxicity tests performed with grab samples must involve exposure durations that range from minutes to a few hours. A possible test battery, used in this project, includes the acute Microtox procedure, the *C. dubia* and *H. azteca* IQ test, and modified time-scale-specific versions of WET tests using *C. dubia* and *H. azteca*. (see Chapter 5.0 for details of the development and application of these procedures).

Table 7-1 summarizes the results of toxicity tests with the Microtox and *C. dubia* IQ tests on intra-event samples from a series of storms at the Kaufman Lake and Cra (Fort Worth) storm sewers. The data have been analyzed for correlations between the two tests and to ascertain whether each test indicates toxicity during a particular storm event.

The data in Table 7-1 indicate that the Microtox and *C. dubia* IQ tests showed toxicity in the same storm event, but the responses for all samples taken during the event do not correlate closely; the two tests indicate peak toxicity at different times of the storm hydrograph. On this basis, the two tests represent a useful screening battery since both would confirm whether or not there is toxicity in a storm event, but the two tests provide complementary information in terms of when peak toxicity occurred during an event.

Time-scale lethality tests using *C. dubia* and *H. azteca* (in which organisms are exposed to storm water samples for periods of 15 to 240 minutes followed by up to 6 days in clean water) are also considered a component of the basic screening test battery for intra-event analysis. The *C. dubia* time-scale test was used to test samples from the 5/24/95 storm at the Cra storm sewer taken at 6:30 p.m., 7:30, and 9:00. These samples had previously shown a range of responses to the Microtox (47%, 32%, and 3.4% light inhibition respectively) and the *C. dubia* IQ test (90%, 80%, and 80% inhibition of fluorescence). The PE-LET_{50} values of 64.3, 130, and 1,188 min for the 6:30 p.m., 7:30, and 9:00 samples were consistent with the patterns of response for both the Microtox and, to a lesser extent, the *C. dubia* IQ test. Overall, the storm event showed an ETU of 1.05 indicating that this event would cause approximately 50% lethality to *C. dubia* (see Section 5.2.2).

The Microtox test system has been used previously by Raco (1988) to measure responses in storm water runoff samples collected from storm channels at three locations on the Los Angeles River, the San Gabriel River, and Ballona Creek in Los Angeles County. The maximum levels of response measured (as % light inhibition) in storm sewers within Los Angeles County were 16% to 67% (see Table 7-2).

The Microtox test has also been used extensively in a screening role in projects carried out under the US EPA Storm and Combined Sewer Program (for example see Pitt et al., 1990).

7.4.7 What is the Optimal Screening Test Battery for Analyzing Event Toxicity?

For event analysis, the tests used need to have exposure durations consistent with typical site-specific event duration. Depending on event duration, test systems selected for the test battery can be divided into two categories: 1) response induction, observation, and measurement time < 24 hours, or 2) response induction, observation, and measurement time of 24 hours or greater. Category #1 would be appropriate for short-duration convective storms and would include test systems that are also appropriate for intra-event analysis. Category #2 would be appropriate for event composite samples, BMP assessments, particularly when detention facilities are in use. An optimal test battery for Category #2 include comprise standard WET procedures using *C. dubia* and *H. azteca*.

7.4.8 When Do I Need to Conduct Sediment Toxicity Testing?

Sediment toxicity testing might be needed for stormwater discharges that are releasing large amounts of suspended material to receiving water environments. In these discharges, many toxicants might bind to the particulate matter, and any resultant in-stream impacts might not be evident in the water column but rather in the sediment when this material is deposited. These tests can also be used in studies where the objective is to determine whether receiving water impacts are due solely or in part to the resuspension of material during a storm event.

7.5 **Sampling Questions**

7.5.1 When and Where Should I Sample to Determine Intra-Event, Event, and/or Long-Term Toxicity in a Watershed?

The frequency of sampling and the location of sampling stations for intra-event, event, and/or long-term toxicity testing in a watershed must be carefully defined to ensure that study objectives are met while considering variability and cost constraints. Information on when to sample intra-event, event, and long-term toxicity is summarized in Table 7-3. In the cases described in the table, except for intra-event programs targeted solely at in-pipe sampling, sampling should be conducted at locations upstream and downstream of the input. Downstream sites need to take account of the physical mixing zones of inputs. A site within the immediate mixing zone might be required to examine maximum impact, but for the assessment of the wider downstream impact, sites should be outside the immediate mixing zone. Selecting a reference location can be problematic in many studies, because entire watersheds may be highly modified by urbanization or other changes from natural land uses. Readers are referred to US EPA discussions on reference areas (US EPA, 1996) and the discussions in Section 2.6.

7.5.2 How Long Can I Store a Sample?

Any toxicity analysis of water samples should be carried out as soon as possible. General guidelines state that the maximum storage time should not exceed 24 hours. However, it should be noted that sample toxicity can decrease markedly in less time, highlighting the need to test as soon as possible. Stored samples should be refrigerated.

Table 7-1. Comparative Data for the Microtox and *C. dubia* IQ Tests for Stormwater Samples

Location	Date of storm	Microtox data			*C. dubia* IQ data			Correlation between Microtox and *C. dubia* IQ (r)
		Toxicity measured?	Maximum response (%)	Time from start of storm (h)	Toxicity measured?	Maximum response (%)	Time from start of storm (h)	
Kaufman Lake	6/1/96	No	13.8	3.17	No	10	0.17	0.15
	7/14/96	Yes	59.4	0.08	Yes	90	0.08	0.67
Cra	7/9/96	Yes	76.4	0.1	No	22	0.18/0.85	0.33
	8/9/96	Yes	81.3	-	Yes	100	-	0.33

Table 7-2. Microtox Responses Measured in Undiluted Stormwater Samples Taken at Various Los Angeles River Locations (after Raco, 1988)

Location	Date of storm	Range of Microtox responses (% light inhibition) during storm	Maximum Microtox response (% light inhibition) during storm
Los Angeles River	1/4/87	13-36	36
	3/21/87	33-67	67*
	10/22/87	6-13	13*
	12/4/87	10-16	16
San Gabriel River	1/4/87	15-22	22
Ballona Creek	1/4/87	29-40	40*

* Might be an underestimate of potential response as samples were not taken during the first peak of flow

R0025518

Table 7-3. Factors for Determining Time Scale of Toxicity Testing

Intra-event	Event-triggered samples are required, taking discrete samples through a storm event. Precise timing and sample frequency depend on the resolution required by the program objective.
Event	Flow proportional composite samples are taken by automatic samplers at each location. Sampling should encompass pre-storm conditions and the entire storm (as defined by hydrologic or water quality analysis), which might require collection over 24 hours or longer. The duration of the sampling is determined by the hydrograph in the receiving system.
Long-term	For the analysis of long-term toxicity, the sampling program depends on the study objectives and complexity of the system under consideration. Discrete sampling can be used, but periodic composite sampling is the mainstay of long-term toxicity monitoring. In situ and biosurvey monitoring techniques should also be used (see Chapter 8.0). Where events are widely spaced in time, each storm is treated as a single entity and a picture of multiple event toxicity is built up from single events. If multiple event toxicity is being determined, it might be necessary to sample receiving water between storms to build up a profile of changes in dry weather flow toxicity. Sample collection procedures should adequately address natural variability, identify single event effects with certainty, and support separation of event effects from other influences on receiving water quality. If events follow each other more closely, then the sampling regime can be extended to encompass all the events. Discrete sampling can be used, but periodic composite samples should be relied upon mainly. Sediment and water column toxicity should measured during the program. In situ monitoring techniques should also be used (see Chapter 8.0). The frequency with which storm events are sampled over time should reflect the pattern of events at a particular location (see Section 2.3).

In the course of the testing program, a series of storm water samples were tested after varying periods from the time of collection. Only stormwater samples showing toxicity in the original tests were selected for re-testing. Table 7-4 summarizes which samples were re-tested using the *Ceriodaphnia* IQ and lethality tests and the length of time between re-testing.

Table 7-4. Summary of the Repeat Tests on Stormwater Samples Using Basic Screening Tests

Location	Date of storm	Tests carried out	Time between tests (days)
Cra (Ft Worth)	5/24/95	*C. dubia* IQ and lethality tests	29
Cleveland	6/17/95	"	14
Kaufman Lake (Champaign)	7/4/95	"	7

Statistical analysis of the original and repeated tests assessed whether the differences in responses on the two occasions were significantly different from zero (paired t-tests). Table 7-5 shows the results of these analyses and indicates that for *C. dubia* IQ tests changes in toxicity were not related to the original level of toxicity or the time between tests. For the *C. dubia* lethality tests, changes in toxicity appeared to be related to the initial level of toxicity. However, overall the data indicate that it is difficult to predict what effect the storage of samples will have on their toxicity. Changes in toxicity are likely to be dependent on the types of contaminant present, and whether these are conservative or non-conservative.

Table 7-5. Summary of Statistical Analyses of Repeated Tests on Stormwater Samples

Location	Time between tests (days)	Significance of comparisons of tests	
		C. dubia IQ	*C. dubia* immobilization
Cra (Ft Worth)	29	NS	P<0.05
Cleveland	14	P<0.05	NS
Kaufman Lake (Champaign)	7	P<0.05	P<0.05

For the chemical analysis of samples, maximum acceptable storage times vary for different determinands, depending on their stability or how effectively they can be preserved. Guidelines for the storage of samples for chemical analysis should be consulted.

Sediments should ideally be tested as soon as possible after collection but can be stored refrigerated for up to 14 days before testing (ASTM, 1996).

7.5.3 How Much Sample Should I Collect?

The amount of sample required will depend on the analyses (toxicity testing and chemical analyses) to be performed on it. In determining the volume of sample needed it is important to allow some contingency and when using automatic samplers to remember that the capacity of the machine will limit the maximum volume of any one sample. Table 7-6 shows the amount of sample required for different types of toxicity and chemical analyses.

Table 7-6. Volume of Sample Required for Different Types of Toxicity and Chemical Analysis

Type of analysis	Volume of sample required (ml)	
Toxicity tests	Screening	EC_{50}
Microtox	4	5
C. dubia IQ	80	155
C. dubia lethality	80	155
C. dubia time scale	100	194
H. azteca lethality	200	388
H. azteca time scale	1,000	1,940
Chemical analysis		
Ammonia	100	
Metals (Total)	100	
Metals (Dissolved)	100	
Pesticides	2000–4000	
PAHs	2000–4000	
TSS	250	

7.5.4 What Should I Expect Sampling and Analysis to Cost?

Analytical costs vary according to the type of test and the number of samples that can be processed at one time. Typical analysis costs for metals range from approximately $10 to $20 per metal per sample. A simple pesticide scan can range from $250 to $400 for organochlorine, and organophosphate, pesticides, and chlorinated herbicides. Many laboratories have custom analysis sets for pesticides commonly used in the area, and analytical costs can be reduced by selection of specific pesticides or pesticide groups. Typical polycyclic aromatic hydrocarbon (PAH) analysis varies from $250 to $350 per sample. Total organic carbon (TOC) costs range from $40 to $60 per sample; chemical oxygen demand (COD) is approximately $20 to $30 per sample; ammonia nitrogen $15 to $25 per sample and pH, total suspended solids (TSS), conductivity, hardness, etc. typically costs from $5 to $25 per analyte per sample.

7.5.5 Where Should I Sample in a Sewer System, in Relation to an Outfall, or in a Drainage Network?

The selection of sampling locations in a sewer system is based on the objectives of the study. A common objective is to determine the source of identified toxicity, but that objective should recognize that toxicity might originate from a range of sources in a sewer system, even rainwater (see Section 7.6.5). A first level analysis identifies "watersheds" in a sewer network and sample at nodes in that network. For example, a typical sewer system has smaller diameter pipes as primary collectors, then progressively larger pipes to carry greater expected volumes. Sampling locations to define watershed input can be easily identified by pipe diameter changes in a network. If the objective is source identification, then sampling points should be selected upstream and downstream from a suspected source. To address the rainfall "background" toxicity, parallel testing of rainwater might be required.

There are numerous "special" sampling issues that should be considered in sewer system sampling. For example, if an outfall is to a receiving system that has different water surface elevations (e.g., a tidal system, or a detention facility that might surcharge), then sampling in the pipe should be at a location where backwater effects are not observed.

7.5.6 When and How Should I Collect Composite Samples?

Composite samples should be used if the focus of the analysis is on the event time scale, particularly if the study involves a detention facility, which tends to average the quality of a discharge over time. In intra-event analysis, the event duration, particularly single storms that last several days, can dictate that consecutive time-sequenced composite samples be collected. Compositing is intended to provide a sample representative of average toxicity over a given time. The most reliable compositing method is a flow-weighted composite, where samples are triggered based on flow volume passing a sampling point. If the flow conditions are expected to be constant, a time-weighted composite can be collected.

The compositing interval must be selected with care so that is consistent with the event being evaluated and so that recommended sample holding/storage times are not exceeded. For example, a long duration storm, which produces a multiple day hydrograph, requires interval composite sampling where more than one flow-weighted composite sample is required, usually defined based on a fixed time interval associated with analysis criteria. Some events, particularly in the Pacific Northwest can be of low intensity and long duration. Again, special compositing techniques can be required that incoťporate either flow-weighted or time-sequenced sampling to produce an accurate storm composite.

As part of time-sequenced storm event sampling, various post-sampling composites were made to assess the effects of compositing samples on toxic response in *C. dubia* (assessing both toxicity and IQ enzyme response) and Microtox. Sampling of the storm event began at 19:10 on February 26, 1996, and was initially set for 30-min intervals. With the onset of the storm, the sampling interval was approximately 2.5 minutes. A second event was sampled from 20:40 at five-min intervals. Composites were made of the entire sampling sequence, compositing equal volumes from samples collected at 30-min intervals. A second composite was made of the early storm event with equal volumes composited from samples collected at 2.5-min intervals. A third composite was made of the late storm event with equal volumes composited from samples collected at 5-min intervals. The results of toxicity testing on the discrete samples are shown in Table 7-7, together with the build-up of the composite samples.

Table 7-8 shows the results of toxicity analyses of the composite samples. In the total event composite (#1), individual samples ranged from 0% to 100% toxicity to *C. dubia* while the composite produced 40% toxicity. *C. dubia* IQ results ranged from 0% to 100% effect, with all samples after 19:44 producing 100% effect. The composite sample also produced 100%. Microtox results were variable, with initial samples in the sample sequence, along with samples collected after 21:05, inhibiting light output. The composite sample produced no response in the Microtox assay. For other composites, when *C. dubia* toxicity (as inhibition of IQ response or lethality) was observed in individual samples, the composites produced no toxicity (<20% effect criterion). The results for the Microtox assay indicated toxicity in composite #2 where only stimulation was observed in individual samples. This result appears to be anomalous. The Microtox result for composite #3 was considered nontoxic (<20% effect), while four of the individual samples had a toxic response of 20% or greater.

Table 7-7. Toxicity Analyses of Discrete Samples and Build-Up of Composite Samples

Sample time	Build-up of composites		*C. dubia* lethality (% effect)	*C. dubia* IQ (% effect)	Microtox (% effect)
19:10	1		10	0	24.64
19:40	1		100	20	17.51
19:44		2	0	80	-45.29
19:47.5		2	0	100	-23.71
19:50		2	0	100	-15.75
19:52.5		2	0	100	-13.57
19:55		2	20	100	-15.40
19:57.5		2			-22.23
20:00		2	0	100	-24.89
20:12.5	1				
20:40	1	3	0	100	-16.3
20:45		3	70	100	-18.39
20:50		3	0	100	-22.42
21:00		3	0	100	-11.67
21:05		3			3.54
21:10	1	3			20.25
21:15		3	40	100	11.84
21:20		3			27.34
21:25		3			25.12
21:45	1		0	100	6.62

Table 7-8. Toxicity Analyses of Composite Samples

Sample	*C. dubia* lethality (% effect	*Ceriodaphnia* IQ (% effect)	Microtox (% effect)
comp #1	40	100	-1.67
comp #2	10	100	63.76
comp #3	10	100	14.35

These results indicate that compositing affects observed toxicity. The expected effect is a reduction in toxic response because samples with low concentrations of contaminants dilute the concentration of contaminants in the composite sample, producing a reduced toxic effect. This effect was observed in the composites from the February 26, 1996, storm event. There was a difference in the response of the three test systems. The *C. dubia* IQ test produced a similar effect in both individual and composite samples. The Microtox assay produced results that differed between individual and composite samples. In composites #1 and #3, the results reflect the dilution effect observed in the *C. dubia* results. In composite #2, the composite indicated high levels of toxicity while the individual samples showed stimulation.

The question of compositing in time-scale toxicity determinations should consider the study objective. If the objective is to use toxicity results to assess system response (e.g., first flush or concentration time analysis) or source identification, then time or flow sequenced sampling and analysis is preferred. If the objective of the study is a general assessment of toxicity to accompany an assessment of contaminant loading, then it is appropriate to perform toxicity tests on composited samples. It should be recognized that while compositing is appropriate for an assessment of contaminant loading, the compositing will tend to reduce toxicity by contaminant dilution and may lead to an underestimation of actual toxicity, particularly when short-term exposures may produce delayed effects.

7.6 Wet Weather Toxicity Questions

7.6.1 How Do I Characterize Intra-Event, Event, and/or Long-Term Toxicity? (Effect vs. Impact)

The tests used to characterize intra-event, event, and long-term toxicity must reflect the time scale of exposure likely to be experienced by receiving water organisms and the expected change in concentration in storm waters when closely spaced events result in relatively clean runoff for later events. For intra-event analysis, laboratory tests with exposure durations of minutes to a few hours are used, whereas for event analysis, laboratory tests with exposure durations ranging from intra-event time scales of a few hours to the 24–48 hour durations more typical of WET procedures may be used. For multiple events, single event results are integrated together to provide an overall picture (see Section 8.5). Samples for toxicity testing can be taken in-pipe and also in the receiving water to determine the effect of dilution on discharge toxicity. In situ deployments and in-stream assessments may also be used to verify the impact on the receiving water (see Chapter 8.0).

At the Kaufman Lake site an intensive monitoring program of the storm sewer discharge was carried out between 5/20/96 and 6/1/96. During this period, four storm events took place (5/23, 5/24, 5/26, and 1/6). Discharges from the storm sewer were monitored for the first and last of these events (Table 6-3), while receiving water was sampled throughout the period (see Table 6-4).

The first storm event showed high toxicity (87.4% light inhibition in Microtox and 80% fluorescence inhibition in the *C. dubia* IQ test). These toxic responses occurred in samples from the storm sewer taken within one hour of the start of the discharge (8:30 to 9:30), and a high level of light inhibition in the IQ test was evident at 9:30 in the downstream receiving water samples. Limited toxicity was measured in the storm sewer discharge for the last storm (14% light inhibition in the Microtox test and 0% fluorescence inhibition in the IQ test), and no toxicity was measured downstream.

In-stream monitoring showed that the number of invertebrate taxa at the upstream and downstream sites changed little before and after the intensive assessment period (Table 7-9). This indicates that long-term chronic effects might mask the effects of individual storms on the receiving water.

Table 7-9. Invertebrate Taxa at KLSS Upstream and Downstream Sites at Beginning and End of Intensive Campaign

Sampling date	No. of taxa at site	
	CSREF A site	DS MID site
5/21/96	4.7	3.0
6/4/96	5.7	3.7

7.6.2 How Many and What Type of Events Should I Sample to Characterize Toxicity?

At a given location, the number of samples must be sufficient to cover the potentially most toxic events and those likely to have an acute impact on the receiving water community. For instance, sampling should encompass times of highest runoff when contaminant delivery is greatest and at lowest receiving water flow when dilution is lowest. Transitional periods might require only limited or no sampling coverage. Event characteristics also vary by season. For example, storm events monitored in this study had different levels of total dissolved solids associated with the runoff of road deicing salts in the winter and late spring.

The number of storm events needed to identify wet weather effects depends on study objectives and the accuracy required by study design quality assurance. A general toxicity characterization can be achieved by applying standard sampling criteria (e.g., minimum of 72 hours after an earlier event and the event meeting runoff criteria) to one or two events. If seasonal variability is needed, then sampling is required for one or more events during each season. If source identification is an objective, multiple events can be sampled, or an extensive synoptic survey might be implemented for a single storm.

It is expected that storms of different size produce different levels of toxicity. In this research, storms were classified as small, medium, and large (see Section 2.3). This classification also related to expected frequency of return—small storms are more common. In selecting the number of storm events to sample, that number can be adjusted by storm size. A practical consideration in the study design is that it is easier to sample small storms, because they are more common, irrespective of the region (see Table 2-1).

The experience gained from this project indicates that an initial screening analysis is needed to identify toxic potential and that multiple storms should be sampled to confirm toxicity. This research also demonstrated that sampling closer to sources, even in-pipe sampling, provides a clearer picture of toxicity with fewer events needed to confirm expected toxicity. However, in-pipe toxicity does not necessarily equate to in-stream impact, which depends upon the dilution and dispersion available in the receiving water.

7.6.3 What Happens to Toxicity in Closely Spaced Events?

At a given location, the toxicity of events occurring soon after an initial event might not be pronounced if the majority of the available contaminants have been removed by the first event. At the Kaufman Lake site, an intensive monitoring program was carried out between 5/20/96 and 6/1/96 in which four storm events took place (5/23, 4/24, 5/26, and 1/6). The first and last of the storm-sewer discharges were monitored and while the first storm showed high toxicity, only minimal effects were measured in samples from the last storm (see Section 7.6.1).

7.6.4 Are There Some Events that Should Not Be Sampled?

Events occurring soon after an event that exhibited moderate or high toxicity might be inappropriate for sampling if the majority of the available contaminants was removed by the first event.

7.6.5 What is the Toxicity Associated with Rainwater?

Several studies have shown that rainwater an be toxic. This toxicity is not surprising, since rain droplets are known to remove particulates and water-soluble contaminants from the atmosphere.

In addition, natural rainwater is virtually free of dissolved solids producing a solution that has low hardness, and a low pH, which is associated with carbon dioxide dissolution. It has been well-described in toxicity testing that some contaminants, particularly heavy metals, are more toxic when hardness levels are low, or pH conditions favor the presence of biologically active forms of the contaminants. This project has documented the drop in conductivity in both runoff and stream flow associated with the runoff of rainwater. Extensive toxicity testing has not identified a consistent pattern that could be attributed to the inherent toxicity in the rainwater, but it is clear from fundamental chemistry and knowledge of rainfall characteristics that rainfall can affect conditions that affect toxic response.

When designing wet weather assessment studies, it is recommended that testing examine runoff from different portions of the event hydrograph using basic screening or advanced toxicity test systems. If toxicity is found in samples with low conductivity, testing should be considered to assess background rainwater toxicity.

7.7 Water Quality Questions

7.7.1 Where Do I Sample to Adequately Assess Water Quality?

Ideally, sampling points for water quality should be at, or in the vicinity of, the points at which samples are taken for toxicity testing.

7.7.2 Do I Need to Sample for Water Quality when the Objective of the Analysis is Toxicity Assessment?

Water quality analyses strengthen toxicity cause-effect relationships, if the test endpoint can be related to measured contaminant concentrations. As such, chemical analysis can be an important part of advanced screening or confirmatory testing. However, it should be recognized that this is not always feasible where complex mixtures of contaminants are involved and that the whole rationale for toxicity testing results from the limitations of using chemical analysis alone as a tool for monitoring stormwaters. Information on basic physicochemical parameters of samples, such as pH, dissolved oxygen, hardness and conductivity, are important for the interpretation of toxicity data, particularly when the causative agent or agents of toxicity are being evaluated.

7.7.3 Why is Continuous Monitoring of Some Parameters Essential?

It is essential to have continuous monitoring of certain parameters, such as stage height, conductivity and dissolved oxygen, to be able to interpret when storm events start and the nature of that event in relation to others over time at a site or between events at different sites.

7.7.4 What Water Quality Changes are Typical of Storm Events and How are These Related to Changes in Toxicity?

This research identified that conductivity was the most reliable indicator of changing water quality during storm events. At KLSS, storm events typically were associated with a decreasing then increasing conductivity, indicative of the passage of low conductivity rainwater dominating the runoff. In addition, spikes in conductivity were often observed during events indicating first flush effects, or the effects of concentration time in a system where increased dissolved solids passed the sampling point.

The water quality changes that were observed during this project were highly variable and dependent on receiving system type and characteristics, location in the watershed, season, antecedent conditions, and storm characteristics.

7.8 Sources Questions

7.8.1 Must I Do Anything Special to Sample or Analyze for CSO/SSO/Urban Runoff Effects?

Stormwaters have unique characteristics based upon source characteristics. Combined sewer overflow (CSO) and sanitary sewer overflow (SSO) sources originate from sewers carrying wastewater and can be expected to contain a full range of common wastewater pollutants. In addition, these "sewer" sources of stormwater have higher concentrations of certain pollutants, such as biochemical oxygen demand (BOD), chemical oxygen demand (COD), pathogenic bacteria, etc., that might be expected in general urban runoff or rural/agricultural nonpoint runoff.

Because of the higher oxygen demand expected in some CSO/SSO samples, it might be necessary to adjust toxicity testing procedures and possibly include aeration. At a minimum, special attention should be given to oxygen monitoring in screening and advanced testing with CSO/SSO samples. Urban runoff is affected by watershed land use, and the presence of certain land uses can direct analysis to specific parameters, or lead to the selection of test systems most suitable for expected, or known parameters.

The protocol for test system selection is designed to accommodate samples of different quality and characteristics. In general, no special sampling is required for basic screening analysis, although special sampling might be required as advanced testing is implemented to meet specific analysis objectives.

7.8.2 What Do I Need to Know About a Watershed to Identify Sources?

To identify sources of toxicity in a watershed it is important to know about the pattern of land use contributing to storm water runoff. Knowledge of general land use activities, such as agricultural, industrial, roads, or residential, in the watershed allow an assessment of the types of contaminants likely to be present. This information can also be useful where there are seasonal applications of substances in certain locations that might result in seasonal stormwater toxicity.

It is also useful to have specific information on industrial and other commercial activities to pinpoint likely inputs of known contaminants. This information can then be tied into the findings of toxicity testing to identify sources.

7.8.3 How Do I Identify the Source of an Observed Effect?

Toxicity tracing from an outfall back up the system might allow the source of the toxicity to be identified, while the use of TIE procedures can allow the causative agent(s) of toxicity to be investigated (see Section 7.9.8). Use of a storm sewer model, which predicts flow times through different areas of a watershed, in conjunction with time-sequenced sampling, helps identify possible sources of toxicity. Information on the use of storm sewer models to trace the sources of toxicity and the use of TIE with basic screening tests are described in Chapter 5.0 and Appendix B.

7.9 Interpretation and Analysis Questions

7.9.1 How Do I Interpret the Data from Basic Screening Tests?

Interpretation of the data from basic screening tests initially involves determining whether there have been storm-related effects, that is whether the test systems have responded to stormwater samples. If responses are detected, it is then necessary to determine whether these responses are considered to constitute toxicity and to classify the storm based on the extent of the responses and then to identify whether additional advanced or confirmatory testing is needed. Responses in basic screening tests can only be regarded as biologically meaningful if an impact on the receiving water biota is found to result from stormwater discharges.

7.9.2 How Do I Decide from Basic Screening Test Data If a Discharge is Toxic?

In basic screening tests, the responses of test organisms (as light output in the Microtox test, fluorescence in the IQ test, and lethality in mortality tests) in undiluted samples are initially measured. Stormwater samples from intra-event or event analysis are regarded as showing toxicity if responses in test systems exceed 20% (see Section 3.4.3). Note that toxicity shown in a wet weather discharge sample should not be used to define an impact source. Confirmation of the cause of an observed impact should consider receiving system dilution of the discharge receiving water testing to eliminate upstream, or other possible, causes of an identified impact.

7.9.3 How Do I Use Intra-Event Analysis to Identify Where Toxicity Occurs in a Storm?

For intra-event analysis of storm sample, datas should be used to identify where test responses exceeded 20% either as direct measurements for in-pipe samples or by comparison with pre-storm values where samples were taken in the receiving water near the discharge (see Section 3.4.3).

The measured responses in a test during the event can be compared statistically against the background pre-storm values using either parametric (for example, analysis of variance [ANOVA]) or non-parametric (for example Kruskal-Wallis) multiple comparison techniques depending upon whether the data are normally distributed and the variances of test groups are homogeneous. If a single composite sample is taken in the receiving water during a storm event, test organism response should be compared with those measured in a pre-storm sample using an appropriate parametric or non-parametric two-sample statistical analysis.

7.9.4 How Do I Classify Discharges on the Basis of Basic Screening Test Data?

In the protocol, the scheme for classifying storm events based on in-pipe sampling (see Table 3-1) involves considering:

- The extent of toxicity measured in samples;
- The consistency of response between tests;

- The percentage of samples showing toxicity; and
- The position of these in the hydrograph.

Toxicity during a wet weather event is variable, and, by taking account of frequency and consistency of response, the classification takes account of samples showing high toxicity, but reduces the influence of extreme values for individual samples on the toxicity classification. This achieves a balance between recognizing that events are variable and minimizing false positives. Section 5.2 reviews research that establishes post-exposure effects resulting from brief exposures. Furthermore, averaging low or no toxicity samples tends to underestimate toxic potential. That said, any extreme or atypical values might require further investigation, perhaps by re-testing with alternative tests or organism batches, to ascertain whether the results are genuine.

For event analysis, classification is based upon the extent of the toxicity measured in samples and the number of tests in the battery responding.

For each discharge, there is usually a series of storm classification measures, since data are available from a series of storm events. It is expected that discharges from a single pipe will show varying degrees of toxicity from one storm to another, depending on a wide range of factors, such as intensity of rainfall, antecedent dry period, recent pesticide application, sensitivity of test organisms, etc. Since the concern is with the toxic potential of the discharge, the actual classification should be based on the highest observed toxicity across storm rather than an average of the toxicity determinations for all storms. Again, any extreme values should be investigated to minimize the risk of false positives, because although variability in toxicity is to be expected, classification should not be based upon isolated and unverified responses. For example, if a discharge point consistently shows no toxicity then shows high toxicity for a single storm event, this might warrant investigation. The degree of confidence associated with any estimation of toxic potential depends on the nature of the results from multiple storms and on the results from multiple elements of the test battery, considering both frequency and consistency of response. Field observation on actual in-stream impacts is also important in validating conclusions drawn from such results.

An initial toxicity screen should be used to design a program that determines the toxicity category (moderate/high, specific/general, infrequent/intermediate frequency/frequent) and also determines whether advanced screening is needed.

Using this toxicity classification system, moderate levels of toxicity have generally been measured at KLSS, though the storm sewer would be classified as having the potential for high toxicity based on the 5/23/96 sample (see Table 7-10). The Cleveland sites and Pylon site at Fort Worth would be classified as of moderate toxicity, while the Cra site in Fort Worth would be classified as highly toxic. For sites where samples have been taken in-pipe, the available dilution/dispersion in the receiving water needs to be considered to determine whether there is likely to be an impact and whether advanced screening is needed. When toxicity was evident in the *C. dubia* IQ test, it was observed in most samples taken through the storm, whereas for the Microtox test, toxicity was usually only found in a limited number of samples.

Table 7-10. Microtox and *C. dubia* IQ Data for Intra-Event Analysis of Different Storms at Various Locations and Resulting Classifications

Location	Date	Maximum toxic response measured (%) Microtox (20 min.)	Maximum toxic response measured (%) *C. dubia* IQ (1 hr)	Classification of storm event
KLSS	7/4/95	0	90	Moderate/specific/frequent/first flush & peak
	7/23/95	55	90	Moderate/general/frequent/first flush and peak
	10/23/95	25	85	Moderate/specific/frequent/ first flush and peak
	2/26/96	57	40	Moderate/general/intermediate freq./first flush & peak
	3/24/96	24	50	Moderate/general/intermediate/peak
	5/23/96	87	80	High/general/intermediate/peak
	6/1/96	14	10	No toxicity
	7/14/96	70	80	High/general/intermediate frequency/first flush
	7/21/96	48	0	Moderate/specific/intermediate frequency/first flush
Cra (Ft Worth)	5/24/95	47	87	Moderate/general/frequent/first flush & peak
	5/27/95	0	90	Moderate/specific/intermediate frequency/peak
	7/9/96	76	22	Moderate/specific/frequent/first flush & peak
	8/9/96	81	100	High/general/frequent/first flush & peak
Cleveland				
SS-01	7/16/96	15	100	Moderate/specific/frequent/first flush & peak
SS-02	"	1	90	Moderate/specific/frequent/first flush & peak
SS-03	"	5	100	Moderate/specific/frequent/first flush & peak
SS-04	"	0	80	Moderate/specific/frequent/first flush & peak

7.9.5 What Course of Action Should Be Followed for Discharges Showing No Toxicity in Basic Screening Tests?

An absence of toxicity in storm events indicates that it is possible to eliminate this site from further toxicity testing. In fact, it suggests that scarce financial and personnel resources could better be applied to other locations or other aspects of a stormwater management program. As with toxicity screening following US EPA procedures, some continuing monitoring might be needed to confirm that no changes occur in toxicity potential.

7.9.6 What Course of Action Should Be Followed for Discharges Showing Moderate or High Toxicity in Basic Screening Tests?

The presence of moderate or high toxicity in samples taken in the receiving water is a clear indication that conditions associated with wet weather discharges are cause for environmental concern. A logical first step is to determine if known wet weather sources are the source of toxicity. A second critical need is to determine the environmental significance of known sources, which might require watershed assessment and advanced screening. Advanced or confirmatory testing should only be carried out on samples that show moderate or high toxicity to more than one test of the screening test battery. This approach ensures that resources will not be used inappropriately and effort directed unnecessarily to false positive samples.

If a discharge is judged to have the potential for moderate toxicity, then it is necessary to consider more advanced tier testing. This advanced tier testing can be designed for several purposes. The first would be to identify the toxic agent and, through that identification, the likely source of contamination. Another option would be to use the measured toxicity to direct longer term testing, such as in situ tests to assess more subtle effects and possible cumulative effects of multiple storms. When a laboratory program identifies stormwater samples as toxic, a critical adjunct step is to ascertain to what extent the receiving water biota are affected. It is clear that moderate levels of toxicity present the greatest difficulty to both testing/assessment activities and management.

If high levels of toxicity are observed in time-sequenced storm samples from a discharge, the need for advanced tier testing is greater. First, the advanced tier testing should involve some type of TIE procedure to clearly identify the cause of toxicity and, again, the possible source. Time-scale toxicity testing can also be used to develop duration values critical to the observed toxicity. Findings of high levels of toxicity present the least difficulty in defining advanced tier testing and management priority.

7.9.7 How Do I Use Advanced Screening Tests to Clarify the Extent of Toxicity Measured in Basic Screening Tests?
